ABSTRACT

Traumatic brain injury (TBI) is one of the leading causes of death and disability worldwide. Cerebral edema following TBI is known to play a critical role in injury severity and prognosis. In the current study we used multimodal magnetic resonance imaging (MRI) to assess cerebral edema 24 hours after unilateral contusive TBI in male and female rats. We then directly quantified brain water content in the same subjects *ex vivo.* We found that in male rats, the injured cortex had higher brain water content and lower apparent diffusion coefficient (ADC) values compared with the contralateral side. Females did not show hemispheric differences for these measures. However, both males and females had similarly elevated T_2 values in the injured cortex compared with the contralateral side. A strong correlation was observed between brain water content and T_2 values in the injured cortex in male rats, but not in females. These observations raise questions about the interpretation of radiological findings pertinent to edema in female TBI patients. A better mechanistic understanding of sex differences and similarities in the pathophysiology of post-traumatic edema is needed to help improve patient management and the development of effective treatment strategies for TBI in men and women.

INTRODUCTION

Traumatic brain injury (TBI) is a leading cause of death and disability in the United States[1, 2]. Post-traumatic edema is a critical element of TBI pathophysiology and is strongly related to poor patient outcomes[3-6]. Cerebral edema and subsequent increases in intracranial pressure post-TBI are well-established prognostic factors for morbidity and mortality[3, 6].

Although women incur a significant number of TBIs, much is still unknown regarding differences in pathophysiology between men and women[7, 8]. Historically, men have outnumbered women in clinical trials and most studies in animal models have been limited to male animals[7, 8]. In TBI patients, the severity, type, and duration of symptoms appear to differ between men and women, although prospective and retrospective studies have not supported a significant association between sex and mortality after TBI[9-13]. In rodent TBI models, sex differences in brain damage and neurobehavioral recovery have long been established[14]. Steroid hormones such as estrogen and progesterone are thought to play a protective role against brain edema development and may help explain significant sex differences[15-17].

In animal research, water content in the brain can be directly quantified via the "wet-dry" method, where freshly dissected tissue is weighed, desiccated, and weighed again to calculate the percent tissue water. Previous studies have used this approach to characterize cerebral edema in diffuse and focal TBI models[18-21], but translation of findings requires alternative non-invasive methods. Magnetic resonance imaging (MRI) is routinely used for clinical management in stable TBI patients[22-24]. MRI is also increasingly being used in animal models to investigate TBI mechanisms, including cerebral edema. However, MRI methods have not been used to examine possible sex differences in edema after TBI. The goal of this study was to assess cerebral edema in male and female rats after moderate contusive TBI using multimodal MRI followed by direct quantification of brain water content.

MATERIALS AND METHODS

Animals

Fifteen male and 15 female rats (F344; Charles River, Wilmington, MA, USA) were used in the study. Rats were 67-83 days old and weighed 157-229 g (male) and 112-152 g (female) at the time of surgery. Animals were housed in same-sex pairs on a 12-hour light-dark cycle with free access to food and water. All protocols were approved by the University of Kansas Medical Center Animal Care and Use Committee consistent with the standards of animal care in the United States Public Health Service Policy on the Humane Care and Use of Laboratory Animals. Each surgery cohort contained an equal number of male and female rats.

Controlled Cortical Impact (CCI)

CCI surgeries were carried out as we have previously described[25-27]. In brief, animals were anesthetized with isoflurane (4% induction, 2% maintenance in 2:1 Medical air:Oxygen). Body temperature was maintained with a heating pad. The head was immobilized in a stereotaxic frame, and the skin shaved and scrubbed with iodine and ethanol. Bupivacaine (0.25%) was administered subcutaneously at the surgical site. Utilizing aseptic technique, a midline incision was made and the skull exposed. The circular craniectomy was formed by a 6mm Michele trephine over the right sensorimotor cortex, lateral to bregma and centered between bregma and the temporal ridge. Moderate CCI was delivered with an impactor mounted to a stereotaxic manipulator (Leica; Saint Louis, MO; impactor tip diameter = 5mm; velocity = 5 m/s; depth = 2mm; contact time = 300 ms; angle = 5° from vertical). The incision was sutured closed and animals were transferred to a heated recovery cage. After recovery of locomotion, animals were returned to their home cages.

Magnetic Resonance Imaging (MRI)

MRI scans were performed approximately 24 hours after TBI (average 23.4 ± 2.8 hours) on a 9.4 Tesla system with a Varian INOVA console (Agilent Technologies, Santa Clara, CA). The system is

equipped with a 12 cm gradient coil (40 G/cm, 250 µs; Magnex Scientific, Abingdon, UK). A custom-made quadrature surface radiofrequency coil, consisting of two geometrically decoupled 18mm loops, was placed on the animal's head to transmit and receive at 400 MHz.

During imaging, anesthesia was delivered via nosecone (1.5 - 3% isoflurane in 2:1 Medical Air:Oxygen) to maintain a respiration rate of 40 - 80 cycles/minute. Respiration was monitored with a pressure pad (SA Instruments, Stony Brook, NY, USA). Animals were placed on a heating pad and body temperature was maintained at 37 ± 1 °C via feedback control (Cole Parmer, Veron Hills, IL, USA). Transverse and sagittal GEMS localization images were acquired to check the animal's positioning in the magnet (FOV_{ax} = 2.56 x 2.56 cm^2, FOV_{sag} = 5.12 x 2.56 cm^2, matrix = 128 x 128, TR/TE = 90 ms/2.8 ms, slices = 9, thickness = 1 mm). High-resolution T_2-weighted images were acquired using a RARE sequence (FOV = 2.56 × 2.56 cm^2, matrix = 256 × 256, TR/TE = 4000/72 ms, averages = 2, thickness = 1 mm, echo train length = 8, echo spacing = 18 ms, total acquisition time ~4 minutes).

Diffusion weighted imaging (DWI) was performed using a standard mono-polar diffusion weighted spin echo sequence (FOV = 2.56 × 2.56 cm^2, matrix = 128 × 128, TR/TE = 1500/26 ms, gradients applied along readout direction, b = 50, 500, 1000 s/mm^2, averages = 1, slices = 9, thickness = 0.8 mm with a 0.2 mm gap, total acquisition time 9 minutes 40 seconds). Apparent diffusion coefficient (ADC) values were calculated for each voxel in MATLAB (Mathworks Inc., Natick, MA, USA) from a 2-parameter exponential fit of the b values.

For mapping T_2 weighted images, a series of multi-slice spin echo acquisitions were performed (FOV = 2.56 × 2.56 cm^2, matrix = 128 × 128, TR = 3 s, TE = 20, 30, 50, 75, 100, 150 ms, averages = 2, slices = 9, thickness = 0.8 mm with a 0.2 mm gap, acquisition time = 6 minutes 25 seconds for each TE). T_2 values were calculated for each voxel in MATLAB from a 2-parameter exponential fit of the TE values. The DWI and T_2 maps were acquired with identical slice positions, FOV, and spatial resolution.

Brain water content

Immediately following MRI, rats received an overdose of isoflurane and were euthanized via decapitation. Brain tissue was rapidly extracted from the skull, placed in a coronal slicing matrix, and a 10 mm block was cut beginning ~1 mm rostral to the cortical injury extending caudally (**Fig. 1A**). The block was removed, cut in half horizontally to separate dorsal from ventral structures, then cut in half vertically at the midline (**Fig. 1B**). The dorsal brain samples from the left (contralateral to TBI) and right (ipsilateral to TBI) hemispheres were used for wet-dry analyses. Each sample was immediately weighed (Mettler Toledo AE100 Scale, Columbus, OH, USA) and values were recorded as the wet weight. The samples were then placed in a laboratory oven (Grieve Laboratory Oven Model L R-271C, Round Lake, IL, USA) at 100 °C. Dry weights were recorded after 24, 48 and 72 hours and the lowest dry weight was used in water content calculation; for most subjects this was at 72 hours. Water content was calculated using the formula: [wet weight (g) - dry weight (g)] / [wet weight (g)] x 100.

MRI analysis

Regions of interest (ROIs) were drawn over the ipsilateral and contralateral cortex for each subject using MIPAV software. ROIs were drawn on three sequential diffusion weighted images (b = 50 s/mm^2) encompassing the center of the injury (centered at bregma). First a vertical line was drawn at the midline, and from a point marked at the base of the brain a second line was drawn at a 45-degree angle. The ROI was completed by connecting the points where these lines crossed the cortex, following the dorsal surface of the brain and the corpus callosum. After the ROI was drawn for the ipsilateral cortex, it was flipped 180 degrees across the vertical midline and manually adjusted to fit the contralateral hemisphere. The same ROIs, generated by a single experimenter, were used for analysis of DWI and T$_2$ images.

Statistical analysis

Descriptive data are reported as mean ± standard error. We used mixed-effects ANOVA with sex as the between-subjects factor and hemisphere as the within-subjects factor, followed by paired t-tests to compare hemispheres within each sex. Bonferroni adjustment was applied for each outcome measure to control for multiple comparisons. Correlations between MRI parameters and brain water content were analyzed using the Spearman test. All tests were two-sided and performed with R software[28]. Statistical significance was defined as $p < 0.05$.

Subject exclusions and MRI quality screening

One female rat died during imaging and was excluded from the study. Tissue water measurements were excluded from 4 rats (1 male, 3 female) due to data collection error. Quality assessments of MRI data were performed by a blinded screener. For DWI, screening led to exclusion of 2 males and 2 females due to motion artifact. For the T_2 images, 2 males and 1 female were excluded due to data corruption. Subjects with partial data (e.g. successful T_2 but not DWI) were included in the analysis.

RESULTS

Brain water content

Brain water measurements showed a main effect of hemisphere and a significant interaction between hemisphere and sex (F(1,23)=7.575, p=0.011) indicating that the effect of TBI was different between males and females. Follow-up testing showed significantly higher brain water in the ipsilateral hemisphere compared to contralateral in males (83.43 ± 1.05 ipsi vs. 82.92 ± 1.04 contra; p = 0.0016) but no difference in females (83.82 ± 1.03 ipsi vs. 83.86 ± 1.07 contra; **Fig. 2**).

Diffusion weighted imaging

ADC measurements from an ROI centered on the injured cortex and a control ROI on the contralateral side (**Fig. 3A**) showed no main effect of hemisphere or sex, and a trend toward interaction between hemisphere and sex that did not reach significance ($F(1,18) = 3.338$, $p = 0.084$). Although there were no main effects, since previous studies generally restricted to males have found reduced ADC acutely after TBI[29-32], we separately explored effects of injury on ADC within each group. Paired t-tests found male rats had lower ADC in the injured cortex than on the contralateral side (6.2E-04 ± 8.63E-06 ipsi vs. 6.60E-04 ± 1.25E-05 contra, $p = 0.019$; **Fig. 3B**) while female rats showed no difference between ipsilateral and contralateral ADC (6.36E-04 ± 1.98E-05 ipsi vs. 6.13E-04 ± 2.15E-05 contra; **Fig. 3B**).

T_2 -weighted image mapping

T_2 values in the injured cortex showed a main effect of hemisphere ($F(1,18)=54.014$, $p<0.0001$). There was no main effect of sex and no interaction between sex and hemisphere. Follow-up testing showed significantly higher T_2 in the ipsilateral ROI compared to the contralateral side in males (41.85 ± 0.68 ipsi vs. 38.38 ± 0.16 contra, $p = 0.0001$) and in females (41.56 ± 0.47 ipsi vs. 38.36 ± 0.31 contra, $p < 0.0001$).

Correlation between brain water content and imaging measures

In the injured hemisphere of male rats, brain water content trended toward a negative correlation with ADC values, but this did not reach significance ($r = - 0.44$, $p = 0.15$; **Fig. 3**). In males after TBI there was a strong positive correlation between brain water and T_2 values ($r = 0.73$, $p = 0.007$). By contrast, in female rats the brain water content in the injured hemisphere was not correlated with either ADC values ($r = 0.30$, $p = 0.43$) or with T_2 values ($r = 0.01$, $p = 0.96$).

DISCUSSION

Sex differences in TBI damage and subsequent functional recovery have long been observed. However, the mechanisms underlying this observation have not been well characterized. This study used multimodal MRI and brain water measurements to assess cerebral edema 24 hours after contusive TBI in male and female rats. At this acute time point, we found consistent evidence of post-traumatic edema in males but more mixed results in females. In male rats, the hemisphere that received a direct cortical contusion had significantly higher brain water content, lower ADC, and higher T_2 values than the contralateral side, while in females the injured hemisphere showed only elevated T_2.

Classically, cerebral edema has been categorized as either vasogenic or cytotoxic in origin. More recently it has been recognized that this distinction may be somewhat arbitrary since the molecular mechanisms of both processes are highly inter-related[33]. Vasogenic edema arises from direct disruption of the blood brain barrier and leaking of solute-laden fluid from the blood into the brain interstitial space. Cytotoxic edema results from disruptions to cell membrane ion channels causing ion-driven movement of water into cells and a relative shrinkage of the extracellular compartment. Quantitative DWI and T_2 mapping have each been used as imaging biomarkers of cerebral edema[30, 34-37]. The ADC calculated from DWI is a measure of water diffusion within the target tissue, which is influenced by the relative balance of water in the intracellular versus the extracellular compartment. Thus, elevated intracellular water (i.e. cytotoxic edema) tends to lower the ADC, while elevated extracellular water (vasogenic edema) tends to increase ADC[31, 37-40]. By contrast, T_2 mapping measures the transverse relaxation time of protons and is sensitive to the total water content in the tissue regardless of cellular compartment.

In male rats we found lower ADC and higher T_2 values in the injured cortex, confirming a predominantly intracellular edema as previously reported[29, 31, 37]. In female rats, we found no difference in ADC values between hemispheres, but elevated T_2 in the injured cortex. One interpretation is that T_2

mapping is a more sensitive measure of cerebral edema than diffusion weighted imaging. If this is the case, it remains unclear why female rats showed elevated T_2 in the injured cortex but not elevated brain water content. This difference could result from the slightly different regions sampled or from differing sensitivities of the two methods. Alternatively, the lack of hemispheric difference in ADC in female rats could reflect a more heterogeneous manifestation of edema; indeed individual female rats showed a wide range of ADC responses to TBI including decrease (reflecting primarily intracellular edema), increase (primarily extracellular edema), and no change from the contralateral side (reflecting either no edema, or potentially a balanced mix of intracellular and extracellular edema). The reason for this variability in females remains to be determined, but certainly hormonal cycle stage is a strong candidate for investigation.

In this initial study we did not control for hormonal status in female rats, since in the real-world women may sustain TBI at any time in their cycle. A growing body of research indicates that estrogen and progesterone may attenuate several aspects of TBI pathophysiology, including edema[16, 17, 41-45]. It is possible that differing sex hormone levels associated with cycle stage contributed to the greater variability of ADC and T_2 values we observed in female rats compared with males. However, the variability of brain water measurements was similar in males and female groups. This underscores the growing recognition that hormonal effects on TBI outcomes are complex and may depend on the particular outcome measure used, the time point, and characteristics of the injury[7, 8, 16, 46-49].

We measured cerebral edema 24 hours post injury, a time point that corresponds to maximal edema after CCI in adult male rats[20, 21, 29, 50]. Since the development of edema after brain trauma is a dynamic process, the timing of which is likely to be affected by the severity and type of injury, results from single time point studies should be interpreted with caution. A possible interpretation of our results is that females develop less severe edema than males after identical TBI procedures; an alternative explanation might be that the time course of edema development differs in males versus

females. Indeed, in a time course study of diffuse TBI, O'Connor et al. reported that female rats had more severe edema than males at 24h, *and also* had less edema than males at earlier and later timepoints[51]. To date, sex differences in the time course of edema have not been investigated after focal TBI, and longitudinal studies that include both sexes remain an important area for future research.

The surgeries and imaging procedures in this study were performed under isoflurane anesthesia, with the dose of isoflurane in each animal adjusted during the course of each procedure based on physiological parameters. In order to determine whether different anesthesia doses might have contributed to the sex differences we observed, we reviewed our study records to calculate the anesthesia duration and the cumulative anesthesia dose (percent isoflurane x time) for each animal. We found no difference between males and females in either metric (**Supplemental Table S1**). Previous studies have reported that isoflurane can worsen post-traumatic edema, but these were conducted exclusively in male animals[52-54]. The effect of isoflurane on cerebral edema in females is unknown, but if it is similar to males then we would speculate that in our study the same average dose administered to males and females would affect both groups equally. The requirement for anesthesia is an inherent limitation of invasive studies in animal models, but future studies can help address this by intentionally matching the isoflurane dose and duration between experimental and control groups, tracking isoflurane dose for use as a covariate, and/or considering alternative inhaled or injectable anesthetic agents[29, 50, 51, 55].

Translational neuroimaging studies in animals allow for direct comparison between non-invasive MRI measures and invasive assays to confirm pathophysiological mechanisms. We found that ADC and T_2 values—imaging measures that have traditionally been used to make inferences about cerebral edema—were associated with measured brain water content as predicted in male rats, but not in females. The reason for this is not currently clear, but the observation raises important questions about clinical interpretation of radiological findings in female TBI patients. Due to a historic focus on males in

TBI research, much remains unknown about sex differences in TBI pathophysiology. The lack of data currently available on the time course and molecular mechanisms of cerebral edema in females needs to be addressed. A better understanding of the differences and similarities between sexes will help improve patient management and the development of effective treatment strategies.

Legends

Figure 1. Brain injury location and regions dissected for brain water content analysis. A) dorsal view of the rat brain. The circle depicts the site of craniectomy and cortical impact. Using a coronal slicing matrix, a 10mm thick section of brain was dissected beginning ~1 mm anterior to the cortical injury and extending caudally. (B) The 10 mm section was further dissected with a horizontal slice aligned with the bottom of the corpus callosum as shown, and a vertical slice at the midline to separate the left (contralateral to TBI) and right (ipsilateral to TBI) sides. The dorsal brain samples from each side were used for analysis of brain water content.

Figure 2. Brain water content after TBI in male and female rats. Plot shows the calculated percent tissue water with lines connecting the contralateral and ipsilateral measures in each subject. In male rats, a paired t-test showed higher brain water in the ipsilateral hemisphere compared to contralateral (p = 0.0016). In female rats, there was no significant difference in brain water between hemispheres.

Figure 3. Magnetic resonance imaging measures of cerebral edema after TBI in male and female rats. **(A)** Regions of interest (ROI) for analysis are shown on three sequential diffusion weighted images encompassing the center of the injury in a male rat 24 hours after controlled cortical impact. Contralateral ROI = grey outline, ipsilateral ROI = black outline. **(B)** Plots show mean ROI values, with lines connecting the contralateral and ipsilateral measures in each subject. In male rats, a paired t-test showed lower apparent diffusion coefficient (ADC) values ipsilateral to injury compared with the contralateral side (p = 0.019). In female rats, there was no significant difference between ipsilateral and contralateral ADC. By contrast, T_2 values were higher in the ipsilateral ROI compared with the contralateral side in both males (p = 0.0001) and females (p < 0.0001).

Figure 4. Relationship between brain water content and MRI measures of cerebral edema in male and female rats. In the injured hemisphere of male rats 24 hours after TBI, there was a trend toward negative association between brain water content and ADC values that did not reach significance (r = -0.44, p = 0.15). Brain water content in males was strongly correlated with T_2 values in the cortex ipsilateral to injury (r = 0.73, p = 0.007). By contrast, water content in the injured hemisphere of female rats was not correlated with ADC (r = 0.30) or with T_2 values (r = 0.01). Note that animals with partial data were included in the study (e.g. successful T_2 but not DWI scan, see details in "Subject exclusions and MRI quality screening").
