KEY POINTS

- Recent observations of oculomotor plant response properties and neural activity across the oculomotor system have called into question classical formulations of both the oculomotor plant and the oculomotor integrator.

- Here we use measurements from new and published experiments in the larval zebrafish together with modelling to reconcile recent oculomotor plant observations with oculomotor integrator function.

- We developed computational techniques to characterize oculomotor plant responses over several seconds in awake animals, demonstrating that long timescale responses seen in anesthetized animals extend to the awake state.

- Analysis of firing patterns of oculomotor integrator neurons demonstrates the sufficiency of this activity for stabilizing gaze given an oculomotor plant with multiple, distributed response timescales.

- Our results support a formulation of gaze stabilization by the oculomotor system in which commands for stabilizing gaze are generated through integration on multiple, distributed timescales.

ABSTRACT

A fundamental principle of biological motor control is that the neural commands driving movement must conform to the response properties of the motor plants they control. In the oculomotor system, characterizations of oculomotor plant dynamics traditionally supported models in which the plant responds to neural drive to extraocular muscles on exclusively short, subsecond timescales. These models predict that the stabilization of gaze during fixations between saccades requires neural drive that approximates eye position on longer timescales and is generated through the temporal integration of brief eye velocity-encoding signals that cause saccades. However, recent measurements of oculomotor plant behaviour have revealed responses on longer timescales, and measurements of firing patterns in the oculomotor integrator have revealed a more complex encoding of eye movement dynamics. Here we use measurements from new and published experiments in the larval zebrafish to link dynamics in the oculomotor plant to dynamics in the neural integrator. The oculomotor plant in both anaesthetized and awake larval zebrafish was characterized by a broad distribution of response timescales, including those much longer than one second. Analysis of the firing patterns of oculomotor integrator neurons, which exhibited a broadly distributed range of decay time constants, demonstrates the sufficiency of this activity for stabilizing gaze given an oculomotor plant with distributed response timescales. This work suggests that leaky integration on multiple, distributed timescales by the oculomotor integrator reflects an inverse model for generating oculomotor commands, and that multi-timescale dynamics may be a general feature of motor circuitry.

INTRODUCTION

Motor plants transform commands from motor neurons into action. Because motor plant responses to neural drive can be complex and history-dependent, commands needed to elicit a particular movement differ from the desired patterns of muscle activation. Standard models of motor control assume that premotor circuitry generates appropriate motor commands by filtering intended muscle activation through an inverse model of the plant being controlled (Kawato 1999; Lisberger 2009). This filtering is then cancelled by the plant's response to the command, resulting in the intended movement. In this manner, the filtering via the inverse model compensates for the response properties of the plant.

This inverse model framework has proven useful in understanding motor command generation in the oculomotor system (Figure 1A; Green et al. 2007; Robinson 1989; Van Opstal et al. 1985). In the classical view, based on the work of Robinson (1964), passive oculomotor plant behaviour in the horizontal plane is modelled by a pair of one-dimensional viscoelastic (Voigt) elements in series, each characterized by a time constant that dictates the exponential time course of the element's length change following a step change in applied force. These time constants have been estimated to be relatively short: 10-60 ms and 250-660 ms (Goldstein 1984; Optican and Miles 1985; Robinson 1964; Sklavos et al. 2006; Stahl and Simpson 1995; Stahl et al. 2015). The motor command required for step changes in eye position (saccades), determined by inverting this two-element plant model, is composed of three components, each of which compensates for a different aspect of the plant model's response properties (Goldstein 1984; Optican and Miles 1985; Robinson 1964). The first component is a brief eye velocity-encoding burst of firing (termed the "pulse") that overcomes plant viscosity to quickly pull the eye to a new position. The second is an eye position-encoding "step" that counters the plant's elasticity to maintain the eye at a fixed position during fixation. The final component is an exponential decay (termed the "slide") with a time constant intermediate between the viscoelastic element time constants (see Mathematical Appendix), which reflects the attenuating force needed to stabilize gaze as the viscoelastic elements equilibrate following the saccade.

Each component appears to be reflected in the firing patterns of ocular motor neurons during horizontal eye movements (Robinson 1981). The pulse arises from saccadic burst

neurons that project to the ocular motor nuclei. The step (Cohen and Komatsuzaki 1972;
Robinson 1989; Scudder et al. 2002; Skavenski and Robinson 1973) and slide (Aksay et al.
2000; McFarland and Fuchs 1992) components have been observed in the firing of premotor
neurons constituting the velocity-to-position neural integrator for horizontal eye movements
(hVPNI), which receives eye velocity burst signals and appears to compute their temporal
integral, producing the step (Figure 1); the origins of the slide are less clear. Since gaze
stability in the dark, when the oculomotor system cannot rely on visual feedback to generate
motor commands, far exceeds that which could be attributed to the oculomotor plant alone,
premotor circuits appear to use an inverse plant model that enables substantial gaze stability
without visual feedback.

More recent work has exposed deficiencies in the classical view of eye movement
command generation. Sklavos et al. (2006; 2005) found evidence of additional time constants
on the order of 1 and 10 s following long steps of force externally applied to the eye. Quaia
et al. (2009) analysed the response of primate extraocular muscle to elongation steps,
demonstrating muscle tension relaxation on a wide range of timescales, with time constants
ranging up to at least 40 s. Davis-Lopez de Carrizosa et al. (2011) measured lateral rectus
muscle tension in cats, finding that it decays on timescales of 1 to 10 s during fixations
between saccades while eye position is approximately stable. Additionally, firing rates of
abducens motor neurons in primates during different types of eye movement are not
consistent with a common two-element plant model (Sylvestre and Cullen 1999). These
results support an expanded model of the oculomotor plant having several viscoelastic
elements with time constants distributed across several orders of magnitude, from 100 ms to
10 s (Sklavos et al. 2005, 2006). The long timescale responses of such plant models imply
that additional drive components that decay on long timescales are necessary to produce
stable fixations (Figure 1B,C; Sklavos et al. 2005).

However, questions remain about the relevance of long response timescales in the
awake, behaving (active) state. Previous measurements of oculomotor plant dynamics in alert
animals have been limited to short time intervals (< 400 ms in monkey, Anderson et al. 2009;
< 2 s in mouse, Stahl et al. 2015), precluding observation of long timescale responses. These
studies also used brief eye position steps < 1 s, which would not appreciably deform

viscoelastic elements with long time constants (Anderson et al. 2009; Sklavos et al. 2006). Furthermore, previous fitting of oculomotor plant models has depended on the assumption that viscoelastic elements were at equilibrium (Sklavos et al., 2005) and was therefore not suitable for fitting model parameters in awake animals.

Other recent observations have revealed that neural activity in the hVPNI and ocular motor neurons does not simply encode eye position and a single fast slide, as predicted by classical models. We have reported that during fixations, firing rates in hVPNI neurons decay on long timescales that vary across an order of magnitude within individual larval zebrafish (Miri et al. 2011a). Such heterogeneity in firing rate decay timescales has also been measured during fixation in adult goldfish hVPNI (Miri et al. 2011a) and in monkey oculomotor integrator neurons (Joshua et al. 2013). In cats, abducens firing after saccades decays on varying timescales generally greater than 1 s, with such decays believed to arise from the oculomotor integrator (Davis-Lopez de Carrizosa et al. 2011). However, it remains to be seen whether firing in the hVPNI could constitute a signal sufficient to stabilize a plant with distributed response timescales.

Here we used measurements of oculomotor plant dynamics and analysis of previously obtained neural recordings in the larval zebrafish to assess whether the hVPNI could be implementing an approximate inverse model that accommodates long timescale behaviour of the oculomotor plant to promote gaze stability. We performed very long mechanical displacements in both anaesthetized and awake, behaving animals in order to deform long timescale response elements. We developed analytical methods for measuring the eye's return from long displacements in awake, behaving animals. Our measurements demonstrate the existence of both short (< 1 s time constant) and long (> 1 s) response timescales in the larval zebrafish oculomotor plant in both anaesthetized and awake animals. We used these measurements to fit oculomotor plant models for each animal, employing a new method that does not require an equilibrium assumption. We then compared the predictions of the neural drive during active state fixations with measurements of activity in the larval zebrafish hVPNI. Analysis of the distribution of decay times seen in hVPNI neuron firing rates suggests that this distribution is sufficient to enable stabilization of an oculomotor plant with the distributed response timescales we observed, including those longer than 1 s. Our results

support a view of integration in the oculomotor system in which hVPNI firing, rather than

purely or primarily encoding eye position, compensates for plant viscoelasticity by

generating firing rate decay on multiple, distributed timescales (Figure 1).

METHODS

Ethical approval

All experiments were performed in compliance with protocols approved by the Princeton

University Institutional Animal Care and Use Committee (protocols #1726 and 1863), and in

accordance with the policies of the *Journal of Physiology*. Following these guidelines

ensured that animal distress was minimized in the course of our study.

Framework for modelling oculomotor plant

We modelled the oculomotor plant as a combination of viscoelastic Voigt elements in series

that respond over n effective timescales. This was represented as a linear filter whose impulse

response function consists of a sum of exponentially decaying components (Robinson 1964;

Sklavos et al. 2005),

$$p(t) = \sum_{i=1}^{n} c_i e^{-t/\tau_i}, \tag{1}$$

182 where c_i is the coefficient of the component with time constant τ_i. The time constants can be

183 identified by finding the step response of the system. If a force $f(t)$ is applied to the system

184 at time $t = 0$, the measured eye position $y(t)$ will be a convolution of the force profile and

185 the impulse response,

$$y(t) = (f * p)(t) = \int_0^t \mathrm{d}u \; f(u) p(t-u). \tag{2}$$

187 If the applied force is stopped at time $t = t_0$, then the measured eye position at later times

188 will be

$$\begin{aligned} y(t > t_0) &= \int_0^{t_0} \mathrm{d}u \; f(u) \sum_{i=1}^{n} c_i e^{-(t-u)/\tau_i} \\ &= \sum_{i=1}^{n} \left(c_i \int_0^{t_0} \mathrm{d}u \; f(u) e^{-(t_0-u)/\tau_i} \right) e^{-(t-t_0)/\tau_i} \\ &= \sum_{i=1}^{n} a_i e^{-(t-t_0)/\tau_i}, \end{aligned} \tag{3}$$

190 that is, the response after release will be a sum of exponentials with the same time constants

191 as the plant.

192   Based on the above, in order to model the oculomotor plant, we took the following

193 steps, detailed in the sections below:

1. Apply a transient external force ("displacement") resulting in a step change in eye
   position, and measure the eye position after release from displacement ("step
   response").
2. Fit a multiexponential model to the step response and extract the plant time constants
   $\{\tau_i\}$.
3. Find the plant coefficients $\{c_i\}$ by fitting a model of the form in equation (2) to the
   eye position during and after displacement.

Step response measurement

mitfa$^{-/-}$ (nacre) mutant zebrafish (*Danio rerio*) larvae (Lister et al. 1999) ages 5-8 days post-fertilization were used for all experiments. We obtained the nacre strain from Zebrafish International Resource Center. Embryos were reared in egg water (Westerfield, 2007) in petri dishes in an incubator at 28°C on a 12 h light/12 h dark cycle. Larvae at this age feed from their yolk and additional food was not provided.

      To enable eye tracking, larvae were immobilised by embedding in a thin layer of 1.7% low melting point agarose (SeaPlaque, Lonza) immediately prior to data collection, and the agarose was removed from around the eyes to allow free eye movement. A rectangular agarose block containing the larva was excised and mounted on a Sylgard platform in a water-filled chamber. Individual larvae were embedded for no more than 3 hours. Following data collection, larvae were removed from agarose and immediately euthanized by submerging in ice water for > 5 minutes, to which bleach was added to a concentration of 1% by volume.

      We used one of two methods to anaesthetize larvae. Ethyl 3-aminobenzoate methanesulfonate (MS-222, Sigma; $n = 10$ larvae) was gradually added to the chamber water to achieve a concentration at which spontaneous eye movements stopped. Final concentrations were between 0.005 and 0.015% (weight/volume). For ketamine experiments ($n = 6$ larvae), embedded larvae were incubated for 15 minutes in 0.5% (weight/volume)

ketamine prior to mounting in the chamber; no ketamine was added to the chamber water.

This ketamine concentration was found to be sufficient to abolish spontaneous eye movement

in most larvae. Data were not collected from larvae that performed eye movements under

anaesthesia. Separate sets of larvae were used for each of the experimental groups: MS-222

anesthetized, ketamine anesthetized, and awake.

The left eye's response to step displacement was measured in the dark. In order to

displace the eye, a blunt probe (hemispherical tip ~30 µm in diameter) controlled by a

hydraulic micromanipulator (Siskiyou) was brought toward a point ~50 µm temporal of the

centre of the left eye at an oblique angle relative to the eye's minor axis (considering the eye

as an ellipsoid; Figure 2A). After gently contacting the eye, the probe was advanced to rotate

the eye temporally in the horizontal plane. Probe advancement was performed quickly, taking

less than a second. For active state measurements ($n = 6$ larvae), this displacement was

performed 5-7 s following a saccade in which the eye moved nasally. This allowed the

expected position of the eye in the absence of the displacement to be estimated by

extrapolating a fit to the eye position between the saccade and the displacement (see below).

The eye was released by quickly retracting the probe. Eye position was tracked at ~70 Hz for

> 60 seconds following release using methods previously described (Beck et al. 2004; Miri

et al. 2011b). Briefly, a 945-nm LED illuminated the chamber from below while a mirror,

long-pass filter, and charge-coupled device (CCD) camera above the chamber collected video

images that were processed in real-time to extract eye position measurements using software

custom written in LabView (National Instruments). In this software, two regions of interest

(ROIs) that included either the eyes or a fixed segment of the body were drawn on a reference

CCD image. During data collection, the ROIs were thresholded, the two largest objects

within the eye ROI were defined as the eyes, the largest object within the body field was

defined as the body segment, and the edges of these three objects were smoothed. The body

axis was defined as the line connecting the centre of the body segment and the midpoint

between the centroids of the eyes. Horizontal eye positions were measured as the angle

formed by the major axis of the eye and the body axis. Eye position measurements were

digitized by a Digidata 1440A (Molecular Devices) and recorded at 5000 Hz in Clampex

(v.10, Molecular Devices). Visual inspection of eye tracking images indicated that eye shape

was at most minimally disturbed by contact with the probe and any disturbance was confined

to the site of probe contact. There was no visible deformation of the eye from contact with

the probe that extended appreciably into the displacement response.

In each anaesthetized larva, two displacements of differing duration were performed:

10 and 60 s in MS-222 experiments, 15 and 90 s in ketamine experiments. Displacements

ranged from 14.8 to 22.2° under MS-222, and 8.5 to 20.9° under ketamine. Pairs of

displacements performed on individual larvae were nearly equal, differing on average by

only 1.5°. In awake larvae, up to five displacements were performed on each larva, each

between 6.5 and 8.5 s in duration, and 11.6 and 26.0° in size. Active state trials in which

spontaneous eye movements occurred during the applied displacement or within 8 s

following the release were discarded. As a result, at most two responses from each larva were

analysed. Spontaneous eye movements during displacement could be identified by motion of

the undisplaced eye. At least 10 minutes elapsed between displacements.

Step response fitting

Eye position during the displacement prior to release was measured from an image captured

while the eye was displaced. The time of release was defined as the time of the last sample

during which the probe was contiguous with the eye in the video image. For MS-222 and

ketamine experiments, baseline eye position was measured as the mean eye position during

a 50 second epoch preceding the displacement and was subtracted from the eye position time

series.

For active state responses, the centre of gaze was estimated from a plot of eye velocity

versus eye position (a "PV plot"; Becker and Klein 1973; Goldman et al. 2002) assembled as

follows from at least three minutes of eye position data collected during spontaneous eye

movement prior to the displacement. First, data from 100 ms prior to each saccade until 500

ms after each saccade were discarded. The remaining time series data were divided into non-

overlapping 0.3 s segments. Next, the mean eye position and the slope of a least-squares fit

line to eye position over each segment were calculated to define the two coordinates of points

comprising the PV plot. Finally, a linear function was least-squares fit to these points. The

intercept of this function with the eye position axis was defined as the centre of gaze and
subtracted from all measurements in the eye position time series.

Since data were initially acquired at ~70 Hz and digitized at 5000 Hz, we
downsampled eye position time series before performing any data analysis. We therefore
subsampled traces every 72 time points, resulting in new traces at 69.44 Hz that we then
analysed. Subsequent analysis of the power spectra of eye position traces showed
anomalously large peaks at ~30 Hz, which are likely artefacts. These were removed, while
preserving the phase in each frequency bin, by scaling the amplitudes of the Fourier transform
in the peaks so that the amplitude was equal to that of the mean amplitude of the 6 frequency
bins surrounding the peak (3 closest on each side of the peak). All analyses were performed
in Python 3.7, using the Scientific Python stack (SciPy and NumPy).

Anaesthetized step responses Eye position step responses (Figure 2B) in anaesthetized larvae
were fit with a multiexponential model,

$$y(t) = \sum_{i=1}^{n} a_i e^{-k_i t} + \varepsilon(t), \tag{4}$$

where ε is independent Gaussian noise with mean 0 and variance σ^2, $k_i = 1/\tau_i$ are inverse
time constants, and the number of components n ranged between 1 and 6. Each coefficient
was constrained to be nonnegative, $a_i \geq 0$, and the sum of the coefficients was constrained
to equal 1. Visual inspection of these time series near the release time found
ringing/oscillation present during the initial 50-200 ms following release in some cases,
perhaps resulting from the manual control of the hydraulic manipulator. We therefore
analysed responses beginning 230 ms and ending 60 s after release time

For each larva, we simultaneously fit the short and long step response with models of
the form in equation (4) for each value of n between 1 and 6. For each value of n, we defined
the best n-component model to be the one which maximized the sum $\mathcal{L}$ of log-likelihoods $\mathcal{L}_j$
for each response j,

$$\mathcal{L} = \sum_{j} \mathcal{L}_j. \tag{5}$$

306   Here,

307
$$\mathcal{L}_j = -\frac{T}{2}\log\frac{2\pi}{\psi_j} - \frac{\psi_j}{2}\sum_{k=1}^{T}(y(t_k) - \hat{y}(t_k))^2,$$
(6)

where T is the total number of time points $\{t_k\}$ recorded in the response, y_j is the recorded

eye position, $\hat{y}_j$ is a model in the form of equation (4), and, for numerical stability, we defined

$\psi_j = 1/\sigma_j^2$ where σ_j is the standard deviation of the noise. We allowed the fits to each of the

two response durations to have different sets of coefficients $\{a_i\}$, but we required a single set

of inverse time constants $\{k_i\}$, with time constants constrained to be greater than 43.2 ms, or

3 samples. Separate standard deviations of the noise σ_j were fit for each response. To find

sets of parameters that maximized $\mathcal{L}$, we used the nonlinear solver Truncated Newton

Conjugate-Gradient (TNC; implemented in the "optimize" library of SciPy), which we

provided with an analytical formula for the gradient of $\mathcal{L}$ that was derived by hand. We used

100 initial sets of parameter values by choosing coefficients uniformly at random between 0

and 1 and then dividing each coefficient by the sum of all coefficients. Initial time constants

were chosen by taking random powers of 10, generated by first taking n evenly spaced

powers between -1 and 2, and adding Gaussian noise with mean 0 and standard deviation 0.1

to each. By examining the mean squared error curves of fits as n increased, we saw clear

"elbows" after which fit quality stopped visibly improving. Separately for each larva, we

called the value of n at which this elbow occurred n^*. For the sake of parsimony, we picked

the best overall model for each larva to be the best n^*-component model.

To examine the sensitivity of the parameter estimates, we used a parametric bootstrap

procedure as follows. For each larva, we used the best step response fit (coefficients, time

constants, and measurement noise variances) to generate 100 new eye position traces

according to the model in equation (4), and re-ran our fitting procedure on each of these, then

calculated the standard deviations of the resulting bootstrap parameters, which we used as an

estimate of the standard deviations of the true parameter distributions.

331   In order to determine the necessity of including long time constant components, we

332 next repeated the above procedure to find the best fits for each larva when time constants

333 were constrained to be less than 10 s.

335 *Active state step responses* Because the eye moves spontaneously in the active state and is

336 not at the centre of gaze prior to the imposed displacement, we did not model the active state

337 step response as a decay toward the centre of gaze. Rather, we modelled it as returning to

338 where the eye would have been had the displacement not occurred (Figure 2C). Let $y_{\mathrm{target}}(t)$

339 be the position of the eye if no displacement had occurred. Then, we modelled the active state

340 step response as

$$y_{\mathrm{sr}}(t - t_{\mathrm{release}}) = y(t) - y_{\mathrm{target}}(t), \tag{7}$$

342 where, as before, $y(t)$ is the measured eye position.

343   We determined $y_{\mathrm{target}}(t)$ by extrapolating the changing position of the eye, based on

344 the 4-6 s of post-saccadic eye relaxation immediately preceding displacement (Figure 2C).

345 We found that this relaxation could also be modelled well by equation (4), which we fit by

346 maximum likelihood estimation to the eye position from 500 ms after the previous saccade

347 to displacement onset, using the method described above for anaesthetized step responses.

348 For all active state responses we picked a 2-component model for the best extrapolation, as

349 there was negligible improvement in fit quality for >2 components.

350   To test the quality of this extrapolation technique, we identified long nasal fixations

351 lasting at least 14.75 s in eye position recordings prior to each active step response. We then

352 performed the same fitting procedure used to find $y_{\mathrm{target}}(t)$ above, here fitting eye position

353 from 500 ms to 6 s post-saccade (Figure 2D). We then calculated how much the resulting fit

354 function deviated from the true eye position in a ~230 ms window of time centred at 14.64 s

355 post-saccade by calculating the error relative to the extrapolation at each data point in this

356 interval,

$$\text{relative error at time } t = \frac{y(t) - y_{\mathrm{target}}(t)}{y_{\mathrm{target}}(t)}. \tag{8}$$

For each fixation, we then calculated the average relative error over the 16 data points in this
window (Figure 2D, inset; black point indicates the centre point of this window at time
$t_{\text{extrap}} = 14.64$ s). A negative relative error meant that the extrapolation decayed more slowly
than the true fixation. We found that the average relative error was positive, so that fits were
likely to decay more quickly than the true fixation, but with relatively large variance (Figure
2D, right; mean $\pm$ standard deviation [sd] = 0.14 ± 0.32; $n = 9$). 3 out of the 9 fixations
resulted in a negative average relative error, where the extrapolated eye position decayed
more slowly than true eye position. Thus, a step response estimated from these extrapolations
would also decay more slowly than the "true" step response and would be more likely to have
long time constants. In order to make our fitting procedure more robust to such an artefact,
which could lead to spurious identification of long time constant decays, we sought to also
fit a more quickly decaying, "conservative" extrapolation of eye position for each active state
step response.

We fit the conservative extrapolations by finding fit functions which fit the first 4-6
s of eye position well, but also decayed faster than the best extrapolation. We did this by
including a penalty term in our optimization that incentivized fit functions to pass through a
virtual point at time t_{extrap} that was closer to the null eye position than the best extrapolation
would be. First, we defined Δ to be the most negative relative error, averaged over the
window described above (Figure 2D, right, bottom blue point). Then, starting with the best
extrapolation (Figure 2C,D, red curve), we fit a higher order model, i.e., $n + 1$ components
if the best extrapolation needed n components, by maximum likelihood estimation, but where
we augmented the model (4) by fitting an additional point $y(t_{\text{extrap}}) = (1 + \Delta)y_{\text{target}}(t_{\text{extrap}})$.
All of the fixations before displacement were less than 7 s long, so this additional point did
not overwrite any actual data points. We let the noise at this additional point, $\varepsilon(t_{\text{extrap}})$, be
normally distributed with mean 0 and variance σ^2/λ. Increasing λ increasingly penalizes fits
that do not pass through $y(t_{\text{extrap}})$. By bisection search on λ, we allowed the procedure to
choose a fit whose sum of squared errors over the real data deviated from that of the best
extrapolation by ~10% as follows (Figure 2C,D, black curve). For each value of λ, we
performed maximum likelihood estimation from 100 starting points and picked the most

parsimonious model, as described above (Anaesthetized step responses), to perform this
comparison. The bisection search terminated when the deviation of the sum of squared errors
fell between 9.9 and 10.1%. The eye position predicted by the maximum likelihood model
for the value of λ for which the bisection search terminates was defined to be the conservative
extrapolation.

For both the best extrapolation and conservative extrapolation, we calculated the
corresponding step response time series $y_{\mathrm{sr}}(t)$. For each displacement in each larva, we fit
multiexponential models to both of these resulting active step response time series from 230
ms to between 8 and 14 s after release from displacement, with the fits performed as above
for anaesthetized responses. After discarding responses due to spontaneous eye movements,
a single response was fit for 3 of 6 larvae and a pair of responses was fit for the remaining 3.
We again ran the parametric bootstrap procedure, as in the anaesthetized case above, here
using the best three-component fits in order to evaluate the sensitivity of parameter estimates.
In order to evaluate the necessity of long time constant components, we also fit responses
while constraining the time constants to be less than 5 s. This was again done assuming the
best and conservative extrapolations.

For comparison of anaesthetized and active state results, we also fit three-component
models as above to just the first 15 s of eye position following the 10 s displacement in larvae
anaesthetized with MS-222.

Oculomotor plant model estimation

To estimate an oculomotor plant model for each larva, we used measured step responses to
calculate parameters of the linear filter given by equation (2) above. We assumed that each
step response was the result of an applied force convolved with a linear filter representing
the oculomotor plant. As described above, a linear filter model implies that the eye position
after release from displacement will have the same number of components and the same time
constants as the plant (see equation (3)). However, the coefficients of the plant $\{c_i\}$ must still
be determined. Because the profile of the applied force is unknown, finding the coefficients
of the plant requires simultaneously finding the appropriate applied force profile. This is a
"blind deconvolution" problem and is generally under-constrained. Here, however, we have

two important constraints that facilitate finding a solution: first, we partially know the applied

force profile, i.e., that it is zero after the time of release; and second, the plant is assumed to

be a sum of exponentials with known time constants.

For each larva, we assembled eye position time series y_j starting from the onset of

displacement for each response j until 8 to 14 s after release. All of the anaesthetized larvae

had 2 responses each, 3 of 6 awake larvae had two responses, and the remaining three had a

single response. Eye position was considered to be constant during displacement (see Step

response fitting). For awake larva time series, we used estimated step responses $y_{sr}(t)$

resulting from both best and conservative extrapolations, as described above. Similarly to

fitting step responses, we removed the first 230 ms of data after release from displacement

due to ringing/oscillation shortly after release. Data points in this epoch were replaced with

the prediction of the best fit exponential model to the step response.

For linear filter estimation, we then defined the following loss function,

430
$$E(f_1,\ldots,f_m,c_1,\ldots,c_n) = \frac{1}{2}\sum_{j=1}^{m}\sum_{k=1}^{T_j} w_{jk}[(f_j * p(c_1,\ldots,c_n))(t_k) - y_j(t_k)]^2. \qquad (9)$$

431   Here, m is the number of responses for the larva, $f_j(t)$ is the time-varying force applied for

432   response j, $p(t;c_1,\ldots,c_n)$ represents the plant model parameterized by variable coefficients

433    $\{c_i\}$ and fixed time constants $\{\tau_i\}$, time is discretized as $t_k = k\Delta t$ where $1/\Delta t$ is the sampling

434   rate, and T_j is the number of time points in the response y_j. Each data point in the loss function

435   is weighted by a factor

436
$$w_{jk} = \begin{cases} 1/T_{release,j} & \text{during displacement, } k \leq T_{release,j} \\ 1/(T_j - T_{release,j}) & \text{after release} \end{cases},$$

437   where $T_{release,j}$ is the number of data points in the displacement period. This weighting causes

438   the loss function to be a sum of the mean squared fit error during displacement and the mean

439   squared fit error during the step response, with errors in these periods weighted equally even

440   though the period lengths are heterogeneous. We approximated convolution of continuous

441   signals with a discrete convolution, since Δt is small,

$$442 \qquad (f * p)(t_k) = \Delta t \sum_{k'=0}^{k} f(t_{k'}) p(t_{k-k'}). \qquad (10)$$

The blind deconvolution can then be computed by finding the forces $\{f_j\}$ and plant

coefficients $\{c_i\}$ such that the loss E is minimized. First, we used the nonlinear solver TNC

from 100 starting points that consisted of $\{c_{i,\text{initial}}\}$ chosen uniformly at random on $(0, 1)$ and

normalized to sum to 1. These preliminary results were used as the initial point, $\{c_i^{(0)}\}$ for an

alternating least squares procedure, as follows:

1. *Applied force estimation step.* On iteration $l + 1$, given estimates for the plant

coefficients $\{c_i^{(l)}\}$, solve the optimization problem

$$450 \qquad \begin{aligned} f_1^{(l+1)'},\dots,f_m^{(l+1)'} &= \text{argmin}_{f_1,\dots f_m} E(f_1,\dots,f_m,\{c_i^{(l)}\}) \\ &\text{subject to } f_j(t > t_{\text{release}}) = 0 \text{ for } j \in \{1,\dots,m\}. \end{aligned}$$

451   2. *Plant estimation step.* Given these estimates of the applied forces, update the estimate

452   of the plant coefficients,

$$453 \qquad \begin{aligned} c_1^{(l+1)'},\dots,c_n^{(l+1)'} &= \text{argmin}_{c_1,\dots,c_n} E(\{f_j^{(l+1)'}\},c_1,\dots,c_n) \\ &\text{subject to } c_i \geq 0 \text{ for all } i. \end{aligned}$$

454   Note that the solutions obtained by this procedure are not unique: for example, if all

455   the plant coefficients are divided by a constant K, then as long as the resulting applied

456   forces are also multiplied by K, the new scaled coefficients still solve the problem.

457   We resolve this degeneracy by imposing the condition that the final plant coefficient

458   estimates sum to 1:

$$459 \qquad c_i^{(l+1)} = \frac{c_i^{(l+1)'}}{K} \text{ and } f_j^{(l+1)} = K f_j^{(l+1)'}, \text{ where } K = \sum_{i=1}^{n} c_i^{(l+1)'}.$$

These two steps are then repeated until the decrease in error is smaller than a

threshold, $E^{(l+1)} - E^{(l)} \leq 10^{-8}$. Note that the error cannot increase on any step, because in

the worst case the same solution as the previous iteration can be chosen. Because the discrete

convolution given by equation (10) is linear, we can write it as a matrix-vector product, and

each of the two steps above can be solved efficiently and accurately by a linear least squares

solver (lsq_linear in SciPy's "optimize" library). The plant model for each larva was chosen

to be the one of the 100 solutions that had the smallest final value for E.

We repeated this procedure using time constants and eye positions resulting from the

conservative extrapolations in awake larvae. In order to evaluate the necessity of long time

constants, we also repeated the procedure using only the fast (< 1 s) time constants resulting

from the step response fit, both for anaesthetized and awake larvae.

For each plant model, we calculated the fractional contribution of each exponential

component to the total area under the curve by integrating over the range $t = 0$ to $t = 60$ s

for anaesthetized plants, and to $t = 20$ s for the active state plant models.

Neural drive estimation

Using the active state plant models, we estimated the force needed to produce the eye position

profile observed during fixation. We assumed this force was proportional to the neural drive

output by motor neurons. We computed neural drive estimates by deconvolving active state

eye position during the period of fixation preceding displacement with the corresponding

plant model for each larva. In order to reduce noise, we used $y_{\text{target}}(t)$ as a smoothed

representation of eye position before displacement (see Fitting step responses), and

performed the deconvolution by solving a linear least squares problem with non-negative

least squares, as described above (Oculomotor plant model estimation). We measured the

persistence of both the estimated neural drive and the corresponding eye position by summing

the time series during fixation starting from and normalized to the value at 0.25 s post-

saccade, and dividing this sum by the number of elements in the time series (Lee et al. 2015).

With this measure, a perfectly stable time series would have a persistence value of 1.

We also directly calculated the time constants of the slide components of the neural

drive for each plant by calculating the poles of the Laplace transform of the neural drive. This

was equivalent to finding the roots of the polynomial

491
$$N(s) = \sum_{i=1}^{n} c_i \prod_{j \neq i} (s + k_j), \qquad (11)$$

where c_i and k_i are the amplitude and inverse time constant of the ith plant component, as in

equations (1) and (4) (see Mathematical Appendix, Analytical calculation of neural drive for

a multiexponential plant, for derivation). This was done numerically using the function

"roots" in NumPy.

Comparison of estimated neural drive to hVPNI activity

Optical recordings   To compare the required neural drive to the activities of cells in the

hVPNI, we used previous optical recordings of somatic calcium-sensitive fluorescence in a

separate set of 6 larvae to estimate neuronal firing rates during fixations (Miri et al. 2011b).

Calcium-sensitive dye loading and optical recording methods are described in the original

reference. Data were collected using Oregon Green BAPTA-1 AM (Invitrogen) on a custom-

built laser-scanning two-photon microscope that allowed synchronous eye tracking and

fluorescence image time series collection from sagittal planes within the hindbrain.

Fluorescence data acquisition and microscope control were performed using Cfnt v.1.529

(Michael Mueller, MPI, Heidelberg). Images were 256 x 256 pixels spanning 100 µm x 100

µm regions and acquired at 2 ms per line (~2 Hz) in time series of 750 frames. For each larva,

five or six fluorescence image time series were collected from image windows lying in

parasagittal planes at fixed dorsoventral and rostrocaudal coordinates in the ventral ~2/3 of

the caudal hindbrain (rhombomere 7/8). All data analysed here were collected in the dark to

eliminate visual feedback.

hVPNI firing rate estimation   For each cell, we determined baseline fluorescence to be the

smaller of two quantities: the mean of the saccade-triggered average fluorescence from 2 s

to 1 s before ipsiversive saccades, and the mean of the saccade-triggered average

fluorescence from 4 s to 5 s after contraversive saccades. We fit a calcium impulse response

function (CIRF), modelled by a single exponential decay, to baseline-subtracted

contraversive saccade-triggered average fluorescence time series, as in previous studies

(Daie et al. 2015; Miri et al. 2011b) and calculated the coefficient of determination, R^2, for

each fit. As in previous studies (Miri et al. 2011a , Miri et al. 2011b), cells for which CIRF

fits had $R^2 \geq 0.5$, and the Pearson correlation between saccade-triggered average fluorescence

and CIRF-convolved eye position after a contraversive saccade was > 0.5, were used (167 of

195 cells).

For each cell j satisfying these criteria, we modelled baseline-subtracted ipsiversive

saccade-triggered average fluorescence x_j as a convolution between the CIRF and the sum

of two components: a delta function modelling the saccadic burst and a multiexponential

function representing the saccade-triggered average firing rate,

528
$$x_j(t) = e^{-k_{\mathrm{CIRF},j}t} * \left(a_0 \delta(t) + \sum_{i=1}^{n} a_i e^{-k_i t} \right) + \varepsilon_j(t), \tag{12}$$

where $k_{\mathrm{CIRF},j}$ is the cell-specific inverse CIRF time constant, k_i are inverse time constants of

the saccade-triggered average firing rate, with coefficients $a_i \geq 0$ for all components i, and

ε_j is Gaussian noise with mean 0 and variance σ_j^2. For each number of exponential

components n between 1 and 3, we solved for the coefficients $\{a_i\}$ and inverse time constants

$\{k_i\}$ that minimized the mean squared error of the model fit to data, using the nonlinear solver

TNC from 100 initial sets of parameters. For each number of components n, we picked the

best n-component model fit to be the one with the smallest mean squared error. Separately

for each cell, we called n^* the value of n after which adding another component decreased

the mean squared error by less than 1%. Then, we defined the best overall firing rate model

fit for each cell to be the best n^*-component model fit. We analysed responses from cells

where the ratio of the sum of squared errors of the best firing rate model fit to the sum of

squares of the data (sum of squares ratio, SSr) was less than 0.007 (151 of 167 cells)—cells

with SSr greater than this value had fits that were notably worse upon visual inspection. For

each cell, we calculated firing rate persistence values in the same manner described above

for neural drive and eye position persistence (Neural drive estimation).

Summary plant and neural drive estimation   For the 9 active state step responses from 6

larvae, we simultaneously fit a single set of time constants, using the same procedure as above

(Step response fitting). Then, using these time constants, we performed the blind

deconvolution procedure (Oculomotor plant model estimation) to find the best fit plant model

for all 9 responses simultaneously ("summary plant"). We then computed the saccade-
triggered average eye position using smoothed versions of fixations from each of 6 separate
larvae in which optical recording was performed. Smoothing was performed by fitting
multiexponential functions to the saccade-triggered average eye position from each animal,
as described above (Step response fitting). A neural drive estimate was then generated for
each larva by deconvolving the saccade-triggered average eye position with the summary
plant.

We then performed a regularized linear regression of the saccade-triggered average
firing rates of all hVPNI neurons onto the neural drive estimate for each larva, with regression
weights constrained to be nonnegative, using a linear least squares solver (lsq_linear). We
used a regularization term equal to the sum of squares (L_2 norm) of the regression weights of
each time series, multiplied by a regularization parameter. We chose this parameter
separately for each larva by bisection search so that approximately 50% of the weights were
nonzero, broadly in agreement with the fraction of putative hVPNI neurons that synapse onto
motor neurons in electron microscopy data (Lee et al. 2015, Vishwanathan et al. 2017).

To show the importance of intermediate timescales in the neural drive (Mathematical
Appendix), for each larva we generated 100 synthetic populations of 150 mock cells whose
firing rates were each described by an exponential decay. For each population, 75 of the cells'
firing rates had time constants randomly drawn uniformly between 0 and 1 s, and 75 had time
constants generated by taking 10 to the power of a uniform random number between 1.3 and
2, resulting in random time constants between 20 s and 100 s. We then performed a
regularized linear regression of the mock cells' firing rates onto the estimated neural drive
exactly as for the real cells.

RESULTS

Measurement of zebrafish oculomotor plant response under anaesthesia

All experiments described here were performed in the dark to prevent the influence of visual feedback. In order to determine whether the larval zebrafish oculomotor plant, like that of the anaesthetized primate, shows both short and long response timescales (Sklavos et al. 2006; Sklavos et al. 2005), we first measured the response of the eye to horizontal step displacements (referred to below as "step responses") of two different durations in larvae anaesthetized with MS-222. Because MS-222 inhibits action potential firing and thus input to neuromuscular junctions, active muscle tone is likely diminished or absent in this state so that the observed responses primarily reflect the passive properties of the plant. Similar amplitude abducting step displacements lasting 10 and 60 s were applied to one eye of anaesthetized larvae (n = 10) and the return trajectory of the eye was tracked following release (Figure 2A,B). The use of two different step durations helps expose both short and long response timescales; if the plant responded on exclusively short timescales, it would effectively reach steady state within 10 s, so that the responses to 10 and 60 s displacements would be similar.

However, the responses to 10 and 60 s step displacements were strikingly different (Figure 3). To quantify response timescales present in these trajectories, for each larva we simultaneously fit with multiexponential functions the first 60 s following release of responses to both displacements. These functions had from 1 to 6 exponential decay components and were constrained at the time of release to equal the eye position prior to release. For each function with a given number of components, fits assumed a single set of time constants but distinct sets of corresponding amplitudes for the responses to the 10 and 60 s displacements. Oscillatory artefacts sometimes present in responses during the first 200 ms following release, perhaps resulting from the manual control of the hydraulic manipulator, led us to omit the first 230 ms of responses when fitting. Thus, our model fits cannot be expected to well capture response timescales faster than ~100 ms. Single exponential functions failed to capture much response structure, while models with 4 components provided a better fit (Figure 3A,B). Improvements in fit quality as the number of model components increased were similar to those observed previously for plant responses

measured in anaesthetized monkeys (Sklavos et al. 2005) and awake mice (Figure 3B; Stahl
et al. 2015).

In order to determine the minimum number of discernible timescales in step
responses, we examined the change in mean squared error of fits as the number of exponential
decay components used in the fits was increased. For each larva, there was an "elbow" at 4
components, after which the reduction in mean squared error by adding more components
was extremely small (Figure 3B). The median values of the time constants of the four-
component fits were 0.092, 1.34, 7.95 and 91.6 s (Figure 3C). Bootstrapped variance
estimates for time constant values were small relative to the gaps between values for
successive components (median sd of estimates ranged between 2.1 and 6.6% as a fraction
of the time constant values). Time constants greater than 10 s were necessary to well fit
responses; multiexponential models constrained to have time constants less than 10 s failed
to fit step responses as well as unconstrained models having equivalent numbers of
components (Figure 3A; 39- to 172-fold increase in MSE for four-component models).

We next measured step responses under another anaesthetic, the NMDA receptor
antagonist ketamine. These experiments were performed for three reasons: (a) to demonstrate
that aspects of the results obtained with MS-222 are not dependent on the choice of
anaesthetic, (b) to better compare our results in the larval zebrafish with those of Sklavos et
al. (2005) in the primate, and (c) because there is some indication in mammals that at
ketamine doses near the threshold above which the animal becomes unresponsive to eye
manipulation, some active muscle tone is preserved, making ketamine anaesthesia potentially
closer to the active state (Blanks et al. 1977; King et al. 1978; Sklavos et al. 2005). We did
not attempt to verify the presence of active muscle tone under ketamine. After anaesthetizing
larvae ($n = 6$) with ketamine, we applied similarly sized abducting step displacements of 15
and 90 s to one eye and tracked its return trajectory following release (Figure 3D).

We simultaneously fit the responses following 15 and 90 s displacements using
multiexponential functions as described above. The choice of slightly different step durations
here was arbitrary and should not obscure the general agreement this similarity demonstrates.
Fit results were similar to those obtained under MS-222 (Figure 3D-F). The median values
of the time constants of four-component fits were 0.131, 2.01, 10.7, and 110.2 s, similar to

those obtained under MS-222 (Figure 3F). Bootstrap confidence interval estimates for time

constant values were small relative to the gaps between values for successive components

(median sd of estimates ranged between 4.7 and 8.4% as a fraction of the time constant

values). Models constrained to have time constants less than 10 s again failed to fit step

responses well (Figure 3D, 8- to 58-fold increase in MSE for four-component models).

Collectively, the data from anaesthetized larvae suggest that the larval zebrafish

oculomotor plant, like that of the primate, demonstrates both short (< 1 s) and long (> 1 s)

response timescales. Moreover, our observation of time constants spread over several orders

of magnitude under both types of anaesthesia matches results from comparable primate

experiments (Sklavos et al. 2006; Sklavos et al. 2005).

Measurement of oculomotor plant responses in the active state

Because active tone in extraocular muscles could influence the response properties of the

oculomotor plant, we examined whether long response timescales were discernible in awake,

behaving larvae. Previous observations of active state plant responses have been limited to

relatively brief time windows (< 400 ms in monkey, Anderson et al. 2009; < 2 s in mouse,

Stahl et al. 2015), potentially obscuring the presence of long response timescales. Here we

succeeded in measuring active state plant responses of longer duration thanks to the relatively

low saccade frequency of larval zebrafish. Five to seven seconds after an adducting saccade

in the dark, we applied abducting step displacements lasting 6.5 to 8.5 s. On 9 occasions

across 6 larvae, we were able to record responses lasting > 8 s without any interrupting

saccades. To our knowledge, active state measurements of comparable duration have not

been previously reported.

In order to properly fit these responses, we needed to estimate what the eye position

would have been during the responses had the imposed displacements not occurred (Figure

2C). Because eye position decays toward the centre of gaze appreciably during fixations in

larval zebrafish, we could not use the eye position immediately prior to displacement as an

estimate of the expected eye position in the absence of displacement. Instead, we estimated

the expected eye position by fitting multiexponential models to eye position between the

previous adducting saccade and the displacement, and then extrapolated the model fits

forward in time to estimate eye position in the absence of displacement. Models having

between 1 and 6 components were initially fit, and the number of components used for

subsequent analysis was chosen using the reduction in mean squared error from each added

component as described above. In addition to this "best" extrapolated eye position fit, we

also performed a second "conservative" fit with faster eye position decay (see Methods,

Figure 2D) that conservatively accounts for possible over-estimates in the duration of the

step response resulting from extrapolation. We extrapolated both the "best" and

"conservative" fit functions through the step and subsequent response epochs to predict eye

position had the displacement not been applied. We defined the step response as the

difference between the eye position following release and these extrapolated fit functions

(Figure 2C, grey arrows).

To quantify response timescales in the active state, we fit multiexponential functions

to responses from 230 ms to 8 - 21 s following release for each larva. For 3 larvae, a single

response was fit. For 3 other larvae, responses to two separate displacements were

simultaneously fit with a common set of time constants, but distinct component amplitudes

for each displacement were permitted. Results assuming the best and conservative

extrapolations were generally in agreement. Single exponential functions failed to well-

capture response structure (Figure 4A,B). For 5 of 6 larvae, responses were best fit by a three-

component model (Figure 4C), while responses from the remaining larva was best fit by a

four-component model. Fit improvements upon inclusion of additional components beyond

4 were again generally very small (Figure 4D). Time constants were broadly distributed for

all larvae, assuming both the best and conservative eye position extrapolations (Figure 4E,F).

Assuming the best extrapolation, the median values of the time constants of three-component

fits for all 6 larvae were 0.166, 2.17, and 36.3 s. Bootstrapped variance estimates for time

constant values were again small relative to the gaps between values for successive

components (median sd of estimates was around 5% as a fraction of the inverse time constant

values). Here again, very long time constants were necessary for an adequate fit;

multiexponential models constrained to have time constants no greater than 5 s produced

much worse fits to step responses than unconstrained models having equivalent numbers of

components (Figure 4A,B, 3- to 459-fold increase in MSE for three-component models using

the best extrapolation and 1.3- to 356-fold increase using the conservative extrapolation).

Collectively, these results demonstrate that, even when accounting for possible errors in

extrapolation, active state step responses also display both short and long response

timescales.

696   Comparing the active state results to those obtained with anaesthesia reveals strong

similarities. The mean time constants across larvae from active state fits are qualitatively

similar to those found under both MS-222 and ketamine (Figure 3C,F), again ranging over

several orders of magnitude. Quantitatively, the time constants for the active state fits tended

to be a few times smaller than for the anaesthetized preparations. However, this may be an

artefact of the limited measurement time in the active state; the mean time constants we found

when we fit only the first 15 s of post-release eye position in anaesthetized larvae differed

from those of the best 3 component fits to active state larvae by just 10-20%.

Implications for neural drive

We next addressed the implications of our above plant response observations for the nature

of the neural drive extraocular muscles would require in order to stabilize gaze during

fixation. To estimate this neural drive from eye position measurements, we used a simplified

model that captures salient plant response properties. Our model assumes that eye position

can be approximated by a convolution of neural drive with the plant's response dynamics.

We used the active state step responses to calculate the parameters of a linear filter

representing the impulse response function of the oculomotor plant for each larva. To

compute these plant models, we calculated filters that would best map a force applied to the

eye during displacement onto the response observed after release (see Methods, Figure 5A).

The response after release for a multiexponential plant model is a multiexponential decay

with time constants equal to those of the plant model. Thus, we defined "distributed" plant

models as multiexponential filters constrained to have the same number of components and

time constant values as the fits to active state step responses.

719   We observed three pertinent features of the resulting plant models. First, we found

that models derived from both the best and conservative extrapolations of eye position could

accurately reproduce the active state step responses (best extrapolation: mean $R^2 \pm sd = 0.965$

± 0.032, conservative extrapolation: mean $R^2 \pm$ sd = 0.948 ± 0.054; Figure 5B-D). Second,

the functions inferred for force during displacement appeared to be composed of pulse, step,

and some number of exponential slide components, as expected under a multiexponential

plant model (Figure 5C, red; Mathematical Appendix). Lastly, plant model amplitudes were

largest for the fastest components (Figure 5D,E). With component amplitudes summing to

one, the median amplitude for the fastest component was 0.922 or 0.917 assuming the best

or conservative extrapolations, respectively.

Given the small relative amplitudes of the long timescale components, we asked what

impact these components would make on gaze stabilization during fixation. Despite their

small amplitudes, these components contribute a comparatively large fraction of the area

under the curve of the plant model response functions up to 20 s post-impulse (Figure 5F),

suggesting an important role in governing plant responses. To verify this, we repeated the

plant model estimation using multiexponential filters in which the components with time

constants greater than 1 s were removed, leaving the one or two fastest components ("fast

plant" models). The remaining time constants align well with those of previous models of

the mammalian oculomotor plant (Goldstein 1984; Optican and Miles 1985; Robinson 1964;

Sklavos et al. 2006; Stahl and Simpson 1995; Stahl et al. 2015). However, using filters

lacking long timescale components resulted in much poorer step response estimates (best

extrapolation: mean $R^2 \pm$ sd = -0.136 ± 0.068, conservative extrapolation: mean $R^2 \pm$ sd = -

0.191 ± 0.090; Figure 5B). Results were similar using step response fits where time constants

were constrained to be less than 1 s. Thus, long timescale components with even the small

relative amplitudes we observed appear to play a critical role in dictating plant responses.

The above observations rely on our measurements of active state step responses,

which themselves involved the extrapolation of eye position expected in the absence of

displacement. Therefore, we checked to see if substantially similar plant models are

consistent with step responses measured under anaesthesia, which involved no extrapolation

of eye position (Figure 6A). We again found that our models could reproduce measured step

responses (Figure 6B,C), that inferred force functions were composed of pulse, step, and

exponential slide components (data not shown), and that the fastest components had the

largest amplitudes (Figure 6D). Importantly, the distributions of component time constants,

amplitudes, and fractional area under the curve for the inferred plant models (Figure 6D,E)

were similar to the distributions observed for active state plant models (Figure 5E,F). Thus,

the pertinent features of recovered plant models do not appear to be artefacts of our use of

extrapolation in active state response measurements.

Based on the estimated active state plant models, we next estimated the neural drive

required to stabilize gaze during fixation (Figure 7A-D). We focus here on the neural drive

needed long after the saccade has ended (> 0.25 s after initiation) to distinguish this drive

from the large transient drive needed to quickly move the eye during a saccade. In the case

of fast plant models that lack long timescale components, the neural drive needed to fully

stabilize eye position is essentially constant over this epoch (Figure 7B, blue dashed line).

This reflects the step component (Goldstein and Robinson 1986; Optican and Miles 1985;

Robinson 1964) that has long been thought to be necessary for gaze stability during fixation,

representing the temporal integral of eye velocity commands. The time course of this estimate

is not dependent on the precise values of filter parameters – essentially constant drive will be

necessary to stabilize eye position whenever filter time constants are exclusively fast

(Mathematical Appendix).

The addition of multiple long timescale components to the plant model markedly

changes the character of the neural drive required to fully stabilize gaze (Figure 7B, red

trace). First, the drive is no longer dominated by a step component, as substantial decay in

drive provided by slide components is seen seconds into the fixation. This makes intuitive

sense, as the step component is filtered by the plant's long timescale components, so the step

amplitude required is smaller. In fact, the step component amplitude can be shown to be

inversely proportional to the area under the plant filter (Mathematical Appendix). Second,

slow decay in the neural drive, generated by the slide components, is necessary to compensate

for the slow equilibration of the viscoelastic elements to their steady states. We directly

calculated the slide component time constants, finding that exactly one fell between each pair

of consecutive plant model time constants and at least one slide time constant was always $>$

1 s (Figure 7D). To test whether slide time constants fall between consecutive plant model

time constants more generally, we directly calculated slide time constants for simulated three-

or four-component plants and found that the observation held over the broad range of

parameters tested (Mathematical Appendix). Thus, the presence of long timescale plant

responses appears to imply the presence of slowly decaying neural drive components.

Actual measurements of larval zebrafish eye position show prolonged but imperfect

fixations (Figure 7C, grey trace). Nevertheless, neural drive estimates obtained using

distributed plant models, unlike those obtained using fast plant models, again decay more

quickly than eye position (Figure 7C, red vs. blue trace). Furthermore, the neural drive

contains long timescale slide components identical to those required to maintain perfect

fixation (Figure 7D). We show in the Mathematical Appendix that, under the inverse model

formulation, neural drive yielding imperfect fixations more generally has slide components

identical to those that generate stable fixations, in addition to components resembling

recorded eye position that are analogous to the step component for stable fixations.

How much do neural drive estimates for distributed plant models differ from those

for fast plant models, given actual eye position measurements? We used "persistence values"

to quantify the difference in time course persistence expected between neural drive and eye

position, assuming either distributed or fast plant models (9 fixations from 6 larvae; Lee et

al. 2015). We defined the persistence value for a neural drive or eye position time series as

its integral starting from 0.25 s post-saccade, normalized so that a stable time series yields a

persistence value of 1. Hence larger persistence values correspond to increasingly persistent

time courses. Distributed plant models lead to neural drive persistence that is substantially

less than eye persistence, whereas fast plant models imply similar drive and eye persistence

(Figure 7E). The median ratios between the persistence values of estimated neural drive and

eye position were 0.72 and 1.04 for the distributed and fast plant models, respectively. Thus,

distributed plant models predict neural drive will substantially diverge from eye position.

The relationship between measured hVPNI activity and eye position

We next assessed whether the activity of neurons in the hVPNI, which has traditionally been

assumed to generate a constant step component, is consistent with a role in stabilizing gaze

given the long response timescales in the plant and their implications for neural drive outlined

above. We first compared the difference in time course persistence expected between the

neural drive and eye position during fixation for individual larvae (Figure 7E) with that seen

between measurements of hVPNI firing and eye position recorded in a previous study (Miri et al., 2011a,b). Time course persistence was computed for hVPNI neurons whose saccade-triggered average firing rates were estimated from calcium-sensitive cellular fluorescence measured during saccadic eye movement. We modelled saccade-triggered average fluorescence as a multiexponential firing rate function convolved with a calcium impulse response function describing the fluorescence response following an action potential (see Methods, Figure 8A,B; Miri et al. 2011a,b; Daie et al. 2015). Out of an initial dataset of 195 neurons across 6 larvae, we excluded neurons that were not putative integrator neurons (28/195 neurons excluded) such as those exhibiting bursting activity in response to a saccade, and those for which fluorescence was not well fit by the saccade-triggered average fluorescence model (16/195 neurons excluded), leaving 151 neurons for subsequent analysis. Consistent with previous results, we observed a broad range of persistence values across this population (Figure 8C).

We then compared persistence values for hVPNI neurons with those of the saccade-triggered average eye position calculated from simultaneously recorded eye position (Figure 8D). We found that firing rate and eye persistence measurements were statistically unlikely to be drawn from the same distribution (p = 0.0106, two-sided Wilcoxon rank-sum). Firing rate persistence was lower than that for the corresponding eye position for 122/151 neurons (81%). The median ratio between the persistence values for firing rate and eye position across all neurons was 0.69, very close to the corresponding value for neural drive estimates (0.71, red line in Figure 8D). Overall, the distribution shown in Figure 8D is more consistent with what would be expected given the distributed plant models than given the fast plant models.

We next addressed whether the firing rates of the population of hVPNI neurons could be used to construct a neural drive that stabilizes gaze given long response timescales in the plant. For this analysis, we generated a three-component summary plant model computed as for the individual larvae but using a simultaneous fit to the active state responses from all six larvae (Figure 9A-C). This summary model had component amplitudes and time constants similar to the medians of the corresponding distributions from models for individual larvae (Figure 9B). We then deconvolved the saccade-triggered average eye position for each larva with this summary plant model to generate a neural drive estimate. Assuming that hVPNI

output could effectively be fed forward by motor neurons, we asked whether weighted sums

of saccade-triggered average firing rates for recorded hVPNI neurons could well-

approximate these neural drive estimates (see Methods, Figure 9D-F). Weights were

constrained so that 50% were positive, and the rest zero, in agreement with anatomical

estimates of the proportion of integrator cells that synapse onto motor neurons (Lee et al.

2015, Vishwanathan et al. 2017). We found that a weighted sum of hVPNI firing could well-

approximate the neural drive estimate for all 6 larvae ($R^2 = 0.989$-1.000). This indicates that

hVPNI firing is sufficient to constitute the neural drive needed to stabilize an oculomotor

plant characterized by long response timescales.

That such good fits can be achieved is perhaps not surprising given the range of

persistence timescales present in hVPNI activity (Figure 8C). However, we note that

intermediate timescales are critical to fit neural drive estimates well. Weighted sums of

simulated cell populations containing only a distribution of short (<1 s) and very long (>20

s) timescales could not reconstruct neural drive estimates (Figure 9E, cyan traces; 10- to 183-

fold increase in MSE). Thus, the intermediate persistence timescales not present in classical

models of the oculomotor neural integrator are a necessary component of this drive.

DISCUSSION

We report here two significant findings regarding the oculomotor plant and the motor circuits that control it. First, we extend the demonstration of both short and long response timescales in the plant (Quaia et al. 2009; Sklavos et al. 2006; Sklavos et al. 2005) to the active, unanaesthetized state, and to a new vertebrate model organism. Recent reports of long timescale responses in the primate plant have been conducted under anaesthesia. The relevance of these responses to the active state has been argued only indirectly using models (Sklavos et al. 2005). Second, our results establish that, despite such long timescales, the firing seen among hVPNI neurons (Daie et al. 2015; Miri et al. 2011a) can still be interpreted in terms of an inverse model-based compensation of plant viscoelasticity. While previous work has focused on the encoding of eye position in neuronal populations necessary for gaze stability during fixation (Aksay et al. 2000; Escudero et al. 1992; McFarland and Fuchs 1992; Pastor et al. 1994), a deviation from simply representing eye position appears crucial to the hVPNI's function. As predicted for an inverse plant model that achieves substantially stable gaze, firing among larval zebrafish hVPNI neurons shows both less persistence on average than eye position itself, and a heterogeneity of persistence timescales.

Previous models of the oculomotor plant that included only fast response timescales implied that during fixation, neural drive to the plant would decrease over the first tens or hundreds of milliseconds and thereafter would stably approximate eye position (Goldstein 1984; Optican and Miles 1985; Robinson 1964). This decrease in drive that follows the saccade-inducing burst, attributed to an exponentially decaying slide component, reflects the attenuating force needed to stabilize gaze as the viscoelastic elements equilibrate. The presence of distributed response timescales in the plant that range up to tens of seconds implies a reduced need for the constant, step component of neural drive; instead, distributed timescales of decaying drive extend long into fixations to compensate for the distributed timescales of force dissipation. Indeed, measurements of abducens motor neuron firing during approximately stable fixations in cats show evidence of firing rate decay on timescales greater than 1 s (Davis-Lopez de Carrizosa et al. 2011). Hysteresis observed between abducens motor neuron firing and eye position greater than 2.5 s into fixations (Goldstein and Robinson 1986) is also consistent with the presence of neural drive components on the

many seconds timescale, as is the hysteresis seen across timescales between hVPNI neuron

firing and eye position (Aksay et al. 2003).

The requirement for neural drive that decays across short and long timescales

complicates descriptions of drive to the plant. The notion that the drive is composed of an

eye velocity-encoding component, an eye-position component, and an exponentially

decaying slide component can be extended to include multiple decaying slide components

distributed across a range of timescales (see Mathematical Appendix). However, long

response timescales in the plant imply that the drive required for stable gaze will have a step

component with small relative amplitude. Furthermore, because sums of exponential

components differing in component number, time constants, and amplitudes can well-

approximate the same function (Istratov and Vyvenko 1999), the presence of at least several

response timescales implies that discerning precise values for these parameters may not be

possible. However, parameters from the multiexponential fits we used to characterize plant

responses do meaningfully reflect the distribution of response timescales.

Despite this ambiguity regarding the neural drive needed to stabilize gaze, the need

for multiple slide timescales does entail a coherent view of the transformation performed by

the hVPNI in stabilizing gaze. Each slide timescale can be computed as a "leaky" integral of

a brief eye velocity-encoding burst – an imperfect integral that "leaks" away over time with

a particular time constant. The hVPNI can then be viewed as computing a sum of multiple

leaky integrals of eye velocity (Figure 1A). Individual hVPNI neurons may reflect distinct

combinations of these integrals in their firing, as would the ocular motor neurons they target.

Since leaky integration can also be expressed as a convolution with an exponentially

decaying filter, the hVPNI can be seen as convolving eye velocity with a multiexponential

filter. One practical manifestation of this leaky integration of eye velocity is that hVPNI firing

will decay faster than eye position (the pure integral of eye velocity), consistent with our

observations of hVPNI firing in the aggregate. While pure integration remains a useful

approximation of the transformation performed by the hVPNI, the distributed nature of its

integration timescales may have important consequences for the underlying biological

mechanisms (Daie et al. 2015; Miri et al. 2011a; Seung 1996; Seung et al. 2000). In previous

work, we have identified an array of neural circuit architectures capable of generating leaky

integrals on multiple, distributed timescales (Miri et al. 2011a).

This view of the hVPNI as decaying on multiple timescales is conceptually similar to

previous work suggesting power law decay of neural firing rates in the oculomotor integrator,

since power law decays can be approximated by weighted sums of exponential decay terms.

Previous work has proposed that the transformation of eye velocity signals by the hVPNI is

not pure temporal integration, but fractional-order integration (Anastasio 1994). What is

commonly referred to in calculus as integration (integration "of order 1") can be generalized

to integrations of arbitrary real (hence "fractional") order (Podlubny 1999). Integration of an

order between 0 and 1 is equivalent to convolution with a power function filter of the form

t^{α}, where α is equal to the integration order minus one. Finding evidence for integration of

order between 0 and 1 in oculomotor circuits, Anastasio (1994) posited that the neural drive

to the oculomotor plant may constitute a fractional integral of eye velocity. He further

proposed that this fractional integral relation might serve to compensate fractional integration

of neural drive by the plant. That is, the motor circuitry and the plant itself may each be

contributing a fraction of the integration necessary to transform eye velocity signals into a

position signal.

Our results here show that the range of persistence timescales present in hVPNI firing

is broad enough to constitute a signal matching estimates of the neural drive needed to dictate

eye position during fixation. Although contemporary multiexponential plant models imply

that this drive should differ from previous descriptions of hVPNI output emphasizing the

encoding of eye position, we show here that linear sums of larval zebrafish hVPNI neuron

firing, relayed by motor neurons, could stabilize gaze assuming the plant models we

computed. Observations of distributed persistence timescales in the hVPNI of adult goldfish

(Major et al. 2004; Miri et al. 2011a) and cat (Davis-Lopez de Carrizosa et al. 2011) suggest

that hVPNI output and oculomotor plant dynamics could be similarly reconciled for adult

vertebrates.

Despite the sufficiency of hVPNI firing for comprising a drive that can compensate

for distributed response timescales in the oculomotor plant, the variation in persistence across

neurons may still seem curious. If the plant is well modelled by a single filter, then there will

exist a single fixed mapping between eye velocity-encoding commands and the drive needed

to produce observed eye position, reflecting a single inverse model of the plant. This single

inverse model could be instantiated by the hVPNI such that all hVPNI neurons fired

identically, counter to our observations. One possible explanation is that the variation in

hVPNI persistence reflects the circuit architecture that gives rise to distributed persistence

timescales, or an architecture that additionally enables context-dependence in the distribution

of these timescales across neurons, as has recently been observed (Daie et al. 2015). Another

possibility is that variation in neuronal persistence timescales provides a means for conferring

robustness to gaze control. Changes in plant dynamics could be counterbalanced simply by

reweighting inputs to motor neurons or the extraocular muscles, effecting a reweighting of

different timescales in the neural drive. Lastly, it is also possible that our measurements belie

a greater complexity in the plant. It could be that the plant comprises separate dynamic

components that are independently compensated by drive to extraocular muscles (Dietrich et

al. 2017; Hernandez et al. 2019). This would imply a need for premotor circuitry to instantiate

not one but multiple inverse models, and to generate distinct drive components that would

not always be in similar proportion. Variation in the firing persistence of hVPNI neurons

would then be inevitable.

Our results reported here indicate that long response timescales are not unique to the

primate oculomotor plant. This adds to the demonstration by Davis-Lopez de Carrizosa et al.

(2011) that abducens motor neuron firing decays faster than abducens muscle tension during

fixation in cats, which suggests the presence of long response timescales in the plant as well.

Thus, the implications of these timescales for compensation by motor circuits may be further

addressed in a range of model organisms including the larval zebrafish, which is particularly

amenable to circuit-level analysis (Ahrens et al. 2012; Arrenberg and Driever 2013; Friedrich

et al. 2013; Orger et al. 2008) and has achieved prominence in the study of visuomotor

behaviour (Bianco et al. 2011; Gahtan et al. 2005; Helmbrecht et al. 2018; Okamoto et al.

2008; Portugues and Engert 2009; Sylvester et al. 2017). For example, how the cerebellum

contributes to oculomotor integration by tuning brainstem circuits could also be fruitfully

addressed using the larval zebrafish model (Miki et al. 2020; Aizenberg and Schuman 2011).

While gaze stability appears to require something beyond pure temporal integration,
the underlying circuitry remains a valuable model for circuit-level short-term memory (Major
and Tank 2004). In particular, the multiple timescales of firing persistence seen in the hVPNI
appear to be analogous to those seen in cortical short-term memory circuits (Bernacchia et
al. 2011; Machens et al. 2010), suggesting that multi-timescale responses may represent a
core feature of short-term memory systems throughout the brain. Moreover, models of neural
integration proposed in previous work on the larval zebrafish hVPNI (Miri et al. 2011a) have
been extended to interpret response diversity among oculomotor integrator neurons in
monkeys (Joshua et al. 2013). We note that leaky integration of velocity signals on distributed
timescales in the hVPNI still requires the generation of firing that persists much longer than
typical membrane and synaptic time constants. Cellular and/or circuit mechanisms must exist
that generate this persistence. Thus, elucidating these mechanisms in the larval zebrafish
should contribute to our understanding of short-term memory in other circuits.

FIGURES

Figure 1 Models of gaze stabilization. (A) Schematic illustration of the conversion of eye

velocity commands into the neural drive $f(t)$ necessary to maintain stable fixation. This

neural drive is conveyed by the ocular motor neurons to determine eye position $y(t)$. The

oculomotor plant is modelled as a linear filter $p(t)$ operating on this drive. Premotor circuitry

generates components of $f(t)$ from signals encoding eye velocity. The classical view, which

predates recent results, held that the plant can be characterized by components that relaxed

on 10's and 100's of ms timescales. Gaze stability on longer timescales then would require

the generation of a neural drive that approximates the temporal integral of eye velocity. Here

we argue that evidence for a broad distribution of response timescales in the plant redefines

the role of premotor circuitry as involving a summation of leaky integrations on distributed

timescales. hVPNI: horizontal velocity-to-position neural integrator. (B) Decomposition of

the neural drive needed to stabilize gaze under classical and contemporary models of the

oculomotor plant. (C) Neural drive required to maintain stable fixation, from 500 ms to 10 s

after saccade termination, for a classical plant model (black) and ones with longer response

timescales (cyan, red).

1007

Figure 2 Methodological approach. (A) Schematic illustration of the method used to
measure the oculomotor plant step response. A blunt probe controlled by a hydraulic
micromanipulator was used to transiently displace the eye. (B) In anaesthetized larvae, the
step response was the eye position measured after release from an imposed step displacement.
(C) In awake larvae, the eye after displacement was assumed to return to the position it would
have occupied had no displacement occurred. Thus, the step response was estimated to be
the measured eye position after release from the step displacement (grey), minus the
extrapolation of pre-displacement eye position (red). A faster decaying conservative
extrapolation (black) was also calculated. (D) Left: to validate the extrapolations, fits to the
initial portion (darker grey) of long unperturbed fixations were extrapolated (red), and the
fractional error of the extrapolation relative to the true eye position was averaged over a ~230
ms window centred at 14.64 s (inset: cyan, data; dashed black, mean of these data). Right:
the average relative error across the 230 ms window for each measured fixation (red arrow
corresponds to the fixation shown on the left).

Figure 3 The eye's return from step displacements in anaesthetized zebrafish larvae reveals

short and long response timescales in the oculomotor plant. (A) Example responses of the

eye (grey) following step displacements lasting 10 s (left) or 60 s (right), normalized by eye

position prior to release, in larvae anaesthetized with MS-222. Coloured traces: simultaneous

fits to both displacements with multiexponential models having one (cyan), two (black), or

four components with time constants unconstrained (red) or constrained to be less than 10 s

(purple). (B) Mean squared error (MSE) of fits with different numbers of components (black)

and percent change in MSE compared to the fit with one fewer component (red) in larvae

anaesthetized with MS-222. Boxes span the 25th to 75th percentile range; whiskers show

maximum and minimum values ($n = 10$ larvae). (C) Coefficient amplitudes and time

constants for four-component fits in larvae anaesthetized with MS-222. (D-F) Same as A-C

but for larvae anaesthetized with ketamine ($n = 6$), for which step displacements lasted 15

or 90 s.

1037

Figure 4 The eye's return from step displacements in awake zebrafish larvae exhibits short
and long response timescales. (A,B) Example active state step response calculated using the
best (A) and conservative (B) extrapolation of eye position in the absence of displacement.
Fits of multiexponential models having one (cyan), two (black) or three components with
time constants unconstrained (red) or constrained to be less than 5 s (purple) are overlaid.
(C,D) Mean squared error (MSE) (C) and percent change in MSE (D) for step response fits
compared to models with one fewer component, calculated using the best (red) or
conservative (black) eye position extrapolations for each larva. Boxes span the 25th to 75th
percentile range; whiskers show maximum and minimum values ($n = 6$ larvae). (E,F)
Distributions of amplitudes and time constants for fits to step responses calculated using the
best (E) and conservative (F) eye position extrapolations. Dots and lines show parameter
combinations for larvae for which the best fit was a three-component model (red; best

1050　　extrapolation: $n = 5$, conservative extrapolation: $n = 4$) or a four-component model (black;

1051　　best: $n = 1$, conservative: $n = 2$).

1052

Figure 5 Oculomotor plant models can be recovered from step responses in awake zebrafish

larvae. (A) Schematic outlining the method used to estimate linear filters that capture plant

response properties. The measured eye position is assumed to derive from the sum of two

inputs to the plant: external force applied by the probe, which leads to the active state step

response $y(t)$, and internally generated neural drive, which would lead to the (extrapolated)

unperturbed eye position. We estimated the plant filter and applied force that best fit the

active state step responses. Active state step responses were estimated from the "best"

extrapolation procedure of Figure 2C and normalized to be 1 at the time of release. (B)

Example active state step response (grey), and predicted step responses from the best

recovered three-component plant model (red) or a plant model refit using only the fastest two

time constants from the three-component plant model (cyan). (C) Time course of recovered

applied force, normalized to be 1 immediately after pulse offset, assuming the best three-

component (red) or fast two-component (cyan) plant. (D) Time course of the impulse

response of the best three-component (red) and fast two-component (cyan) plant models. (E)

Distribution of amplitudes and time constants for each component of the best recovered plant

models. Dots and lines show parameter combinations for larvae for which a three-component

model was best (red, $n = 5$) or for which a four-component model was best (black, $n = 1$).

(F) Fraction of the total area under the curve (AUC), calculated over 20 s, contributed by

each plant component for the best recovered three- (red, $n = 5$) or four-component (black,

$n = 1$) plant models.

Figure 6 Oculomotor plant model estimates for anaesthetized larvae are consistent with active state estimates. (A) Schematic outlining the method used to estimate linear filters that describe plant response properties. We estimated the plant filter and applied force that best fit the measured anaesthetized step responses. (B) Example responses of the eye (grey) following step displacements lasting 10 s (left) or 60 s (right), normalized by the eye position prior to release, in larvae anaesthetized with MS-222. Coloured traces: predicted step response from the best recovered four-component model (red) and a plant model refit using

only the fastest two time constants from the four-component plant model (cyan). (C) Same

as B, but for larvae anaesthetized with ketamine, for which step displacements lasted 15 s or

90 s. (D) Coefficient amplitudes and time constants for each component of the best four-

component plant models for larvae anaesthetized with MS-222 (red, $n = 10$) or ketamine

(black, $n = 6$). (E) Fraction of the total area under the curve (AUC) contributed by each

component for the best four-component plant models for larvae anaesthetized with MS-222

(red) or ketamine (black). Boxes span the 25th to 75th percentile range; whiskers show

maximum and minimum values (MS-222, $n = 10$; ketamine, $n = 6$).

Figure 7 Estimating the neural drive to the oculomotor plant during fixation. (A) Eye
position was deconvolved with the filter from a given larva's plant model to estimate the
neural drive needed to generate that eye position. (B) Perfectly stable eye position (grey) and
neural drive estimates calculated from the best three-component (red) and fast two-
component (cyan) plant model for an example awake larva. Time courses were normalized
to be 1 at 250 ms after saccade termination. (C) Same as B, but for a measured fixation. (D)
Time constants of the distributed plant (black) and of the slide components of the neural drive
(red circles). (E) Persistence of estimated neural drive assuming the best three- or four-
component (red) or the fast two-component (cyan) plant model plotted against eye position
persistence. Each point represents a fixation recorded from an awake larva. Dotted line
indicates a one-to-one ratio of drive persistence to eye persistence.

1102

1103

Figure 8 The relationship between the persistence of eye position and of neuronal firing in
hVPNI neurons is consistent with the neural drive required for a plant with long timescale
responses. (A) Illustration of the method used to recover firing rates of hVPNI neurons. First,
the calcium impulse response function (CIRF) was fit to baseline subtracted saccade-
triggered average (STA) Ca^{2+}-sensitive fluorescence during a contralateral saccade (top).
Only cells to which the CIRF fit was relatively good ($R^2 > 0.5$), and for which fluorescence
was correlated to eye position when convolved with the CIRF (corr > 0.5) were included in
further analysis (167/195 cells). For these cells, STA fluorescence during an ipsilateral
saccade was fit with a multiexponential model of post-saccadic firing convolved with the
CIRF (bottom; Methods, hVPNI firing rate estimation). If the ratio of the sum of squared
errors of fits to the sum of squares of ipsilateral STA fluorescence (sum of squares ratio, SSr)
was greater than 0.007, the cell was excluded (16/167 cells excluded). (B) Examples of the
worst, median and best quality fits to ipsilateral STA fluorescence of included cells (top) and
corresponding inferred firing rate functions, normalized to equal 1 at 0.25 s after saccade
time (bottom). (C) Distribution of firing rate persistence (sum of red shaded areas in B) across
all included neurons. (D) Histogram of the ratio of firing rate persistence to eye position
persistence. Grey line indicates the median ratio. Coloured lines indicate the median ratio of

neural drive persistence to eye persistence across larvae assuming a distributed (red) or fast

(cyan) plant model for each larva.

1123

1124

Figure 9 The distribution of hVPNI firing patterns is sufficient to stabilize gaze when the

plant has long timescale responses. (A,B) Time course (A) and component amplitudes and

time constants (B) of a single summary plant model fit to the active state step responses from

all awake larvae. (C) Predicted step response given the summary plant model (red) compared

to the predicted response given the best plant model for each individual larva (black).

Examples are the worst (top), median (middle) and best (bottom) of the 9 reconstructed step

responses, sorted by mean squared error. (D) Schematic of steps used to estimate the neural

drive during fixation as a linear combination of hVPNI firing rates. Saccade-triggered

average eye positions during fixation from the 6 larvae from which Ca^{2+}-sensitive

fluorescence was recorded were deconvolved with the summary plant model to estimate the

required neural drive. For each larva we calculated a regularized linear regression of

estimated neural drive onto the firing rates of all recorded hVPNI cells ($n = 151$ cells). (E)

Grey: estimated neural drive calculated for the fish with the least (left) and most (right)

persistent average eye position during fixation using the summary plant model. Red: best

linear fit of hVPNI firing rates to the estimated neural drive. Cyan: band containing the best

95% of linear fits to the estimated neural drive from 100 synthetic populations of mock cells

whose firing rates were exponential decays with random time constants <1 s or >20 s. (F)

Regression weight for each hVPNI cell, averaged across fits to all 6 average eye positions,

with cells sorted by increasing firing rate persistence.

DATA AVAILABILITY

MATHEMATICAL APPENDIX

Analytical calculation of neural drive for a multiexponential plant

Here, we derive analytical expressions for the neural drive expected in the case of a linear

multi-exponential plant under the inverse model formulation, extending the work of Sklavos

et al. (2005). First, we provide a general formula, then specific formulae for the one- and

two-exponential cases, and finally discuss simulation results for three- and four-exponential

plants.

Suppose that the measured eye position during normal fixations can be described by

sums of n_{pos} exponential decays with time constants $\tau_{\text{pos},i} = 1/k_{\text{pos},i}$ and amplitudes $c_{\text{pos},i}$,

$$1329 \qquad y(t) = \sum_{i=1}^{n_{\text{pos}}} c_{\text{pos},i} e^{-t/\tau_{\text{pos},i}} = \sum_{i=1}^{n_{\text{pos}}} c_{\text{pos},i} e^{-k_{\text{pos},i} t}, \tag{A.1}$$

1330 with perfectly stable eye position represented by a single exponential decay with $k_{\text{pos}} = 0$.

1331 We assume that the eye position is generated by linear filtering of the neural drive by a plant

1332 with a multiexponential impulse response function, as in equations (1) and (2). Taking the

1333 Laplace transform of equations (1), (2) and (A.1), equation (2) becomes

$$1334 \qquad \sum_{i=1}^{n_{\text{pos}}} \frac{c_{\text{pos},i}}{s + k_{\text{pos},i}} = Y(s) = F(s)P(s) = \left(\sum_{i=1}^{n} \frac{c_i}{s + k_i} \right) F(s),$$

1335 where $k_i = 1/\tau_i$ are the inverse time constants, as before, and Laplace transformed variables

1336 are represented with capital letters. Examining only $P(s)$, the Laplace transform of $p(t)$, we

1337 can turn the sum of fractions into a single fraction,

$$1338 \qquad P(s) = \frac{\sum_{i=1}^{n} c_i \prod_{j \neq i} (s + k_j)}{\prod_{i=1}^{n} (s + k_i)} = \frac{\prod_{i=1}^{n-1} (s + \lambda_i)}{\prod_{i=1}^{n} (s + k_i)}, \tag{A.2}$$

1339 where the numerator is an $n-1$ degree polynomial with roots $-\lambda_i$, and where we have used

1340 that the sum of the amplitudes c_i is 1. We can similarly write the Laplace transform of the

1341 eye position, $Y(s)$, as a single fraction that is the ratio of two polynomials. Then, the Laplace

1342 transform of the neural drive is

1343
$$F(s) = \frac{Y(s)}{P(s)} = \frac{\prod_{i=1}^{n_{\text{pos}}-1}(s+\lambda_{\text{pos},i})\prod_{i=1}^{n}(s+k_i)}{\prod_{i=1}^{n_{\text{pos}}}(s+k_{\text{pos},i})\prod_{i=1}^{n-1}(s+\lambda_i)}. \tag{A.3}$$

1344 Assume that $\lambda_{\text{pos},i}$, k_i, $k_{\text{pos},i}$ and λ_i are all unique. Then, by partial fraction decomposition,

1345 equation (A.3) becomes

1346
$$F(s) = 1 + \sum_{i=1}^{n_{\text{pos}}}\frac{a_{\text{pos},i}}{s+k_{\text{pos},i}} + \sum_{i=1}^{n-1}\frac{a_{\text{slide},i}}{s+\lambda_i}, \tag{A.4}$$

1347 and taking the inverse transform, the neural drive in the time domain is

1348
$$f(t) = \delta(t) + \sum_{i=1}^{n_{\text{pos}}}a_{\text{pos},i}e^{-t/\tau_{\text{pos},i}} + \sum_{i=1}^{n-1}a_{\text{slide},i}e^{-\lambda_i t}, \tag{A.5}$$

which consists of a pulse, a set of components that decay as eye position, and $n-1$

exponentially decaying slides with time constants $1/\lambda_i$ that may be complicated

combinations of the plant coefficients and time constants, but which do not depend on the

desired eye position. Note that if the desired eye position had had a component with time

constant given by the plant (such that $k_{\text{pos},i} = k_j$ for some i and j), then a component with

this time constant would not be required in the drive.

From the residue theorem, the amplitude of any eye position component can be

calculated by evaluating $(s + k_{\text{pos},i})F(s)$ at $s = -k_{\text{pos},i}$,

1357
$$a_{\text{pos},i} = [(s+k_{\text{pos},i})F(s)]_{s=-k_{\text{pos},i}} = \frac{1}{P(-k_{\text{pos},i})}. \tag{A.6}$$

1358 For the special case of perfectly stable eye position, a single component with inverse time

1359 constant $k_{pos} = 0$, this component is a step with amplitude

$$1360 \qquad a_{\text{pos}} = \frac{1}{\sum\limits_{i=1}^{n} \dfrac{c_i}{k_i}} = \frac{1}{\sum\limits_{i=1}^{n} c_i \tau_i}. \qquad\qquad (A.7)$$

1361   That is, since the area contributed by each plant component i is $c_i \tau_i$, the amplitude of the step

1362   component is equal to the inverse of the total area of the plant filter. To provide additional

1363   intuition about the effect of long time constants on the neural drive, we below consider the

1364   simple examples of plants with either a single exponential decay or a sum of two exponential

1365   decays and for simplicity, eye position that can be described by a single exponential decay.

1366

1367   **A single exponential plant**

1368   Consider the case of a single exponential plant model,

$$1369 \qquad\qquad p(t) = e^{-kt}.$$

1370   Then, the Laplace transform of the neural drive is

$$1371 \qquad\qquad F(s) = \frac{s+k}{s+k_{\text{pos}}} = 1 + \frac{k - k_{\text{pos}}}{s + k_{\text{pos}}},$$

1372   and in the time domain,

$$1373 \qquad\qquad f(t) = \delta(t) + (k - k_{\text{pos}})e^{-t/\tau_{\text{pos}}},$$

where $k > k_{\text{pos}}$. Thus, in this simplest case, the neural drive consists of a pulse and a

decaying component that follows eye position. In the case of stable fixation ($k_{\text{pos}} = 0, \tau_{\text{pos}} \rightarrow$

∞), this component is a step whose amplitude increases in proportion to the decay rate k of

the plant. To interpret this result, note that convolution with an exponential filter can be

thought of conceptually as a leaky integral. To generate stable eye position, an eye velocity

command must be supplemented with an eye position command to compensate for the effect

of the plant's leaky filter. As the time constant increases, i.e., as k decreases, the plant's

integration becomes less leaky, and the step-like position command becomes less necessary.

1382

A double exponential plant

1383

1384 Next, consider a plant with two exponential components,

1385
$$p(t) = c_1 e^{-k_1 t} + c_2 e^{-k_2 t},$$

1386 with $c_1 + c_2 = 1$ and $k_1 > k_2$, which implies $\tau_1 < \tau_2$. This has Laplace transform

1387
$$P(s) = \frac{c_1}{s+k_1} + \frac{c_2}{s+k_2} = \frac{c_1(s+k_2) + c_2(s+k_1)}{(s+k_1)(s+k_2)} = \frac{s+c_1 k_2 + c_2 k_1}{(s+k_1)(s+k_2)}.$$

1388 The required neural drive is

1389
$$F(s) = \frac{(s+k_1)(s+k_2)}{(s+k_{\mathrm{pos}})(s+c_1 k_2 + c_2 k_1)} = 1 + \frac{a_{\mathrm{pos}}}{s+k_{\mathrm{pos}}} + \frac{a_{\mathrm{slide}}}{s+c_1 k_2 + c_2 k_1},$$

1390 which in the time domain is

1391
$$f(t) = \delta(t) + a_{\mathrm{pos}} e^{-t/\tau_{\mathrm{pos}}} + a_{\mathrm{slide}} e^{-t/\tau_{\mathrm{slide}}},$$

1392 a combination of a pulse, a position-like, and an exponentially decaying slide component,

1393 where a_{pos} and a_{slide} are defined below. The decay rate of the slide is a linear combination

1394 of the decay rates of the two plant components,

1395
$$\frac{1}{\tau_{\mathrm{slide}}} = k_{\mathrm{slide}} = c_1 k_2 + c_2 k_1,$$

1396 or in terms of time constants,

1397
$$\tau_{\mathrm{slide}} = \frac{1}{c_1 k_2 + c_2 k_1} = \frac{\tau_1 \tau_2}{c_1 \tau_1 + c_2 \tau_2}.$$

Since $c_2 = 1 - c_1$, the slide time constant is bounded by the two plant time constants. The

slide time constant is longest in the limit where the amplitude of the faster plant component

is large ($c_1 \to 1, c_2 \to 0$), in which case it approaches τ_2, the time constant of the slower

plant component. It is shortest in the limit in which the amplitude of the faster plant

component is very small ($c_1 \to 0, c_2 \to 1$), in which case it approaches τ_1.

The purpose of the slide can be seen clearly in the case of perfectly stable desired eye

position, $k_{pos} = 0$. Applying neural drive with only a pulse and position (step) component to

the plant, the eye position due to each plant component i is

1406

$$c_i e^{-k_i t} * (\delta(t) + a_{pos} u(t)) = a_{pos} \frac{c_i}{k_i} + c_i \left(1 - \frac{a_{pos}}{k_i} \right) e^{-k_i t},$$

where $u(t)$ is the Heaviside or unit step function. We can find a step amplitude a_{pos} such

that the exponential decay term in the above expression is cancelled for each plant component

individually, but we will be unable to simultaneously cancel the corresponding exponential

decay resulting from the other plant component (a pulse/step mismatch). This is corrected by

adding the additional slide component to the drive.

The amplitudes of the position and slide components of the drive are respectively

given by

1414

$$a_{pos} = \frac{(k_1 - k_{pos})(k_2 - k_{pos})}{k_{slide} - k_{pos}},$$

1415

$$a_{slide} = \frac{(k_1 - k_{slide})(k_{slide} - k_2)}{k_{slide} - k_{pos}}$$

$$= \frac{c_1 c_2 (k_1 - k_2)^2}{k_{slide} - k_{pos}}.$$

1416   For simplicity, let us consider perfectly stable fixations, $k_{pos} = 0$, so that again the

1417   eye position component is a step. Then, the ratio of the amplitude of the slide to the amplitude

1418   of the step is given by

1419

$$\frac{a_{slide}}{a_{pos}} = \frac{c_1 c_2 (k_1 - k_2)^2}{k_1 k_2}.$$

For a fixed choice of time constants, the ratio is proportional to the product $c_1 c_2 = c_1(1 -

c_1)$. If either c_1 or c_2 is sufficiently close to 1, then the amplitude of the slide will be extremely

small compared to the step. The ratio is maximized for $c_1 = c_2 = 1/2$.

In this study, we encountered the situation in which plant components contributed

similar areas to the plant, an important parameter setting we will now consider. In the case

of two equal area components, with $c_1/k_1 = c_2/k_2$, the coefficients of the plant components

become

$$c_1 = \frac{k_1}{k_1 + k_2}$$

1427

$$c_2 = \frac{k_2}{k_1 + k_2}.$$

1428   Then, the time constant of the slide is the average of the two plant time constants,

1429

$$\tau_{\text{slide}} = \frac{1}{2}(\tau_1 + \tau_2),$$

1430   and the amplitudes of the step and the slide are

$$a_{\text{pos}} = \frac{1}{2}(k_1 + k_2)$$

1431

$$a_{\text{slide}} = \frac{1}{2}\frac{(k_1 - k_2)^2}{k_1 + k_2}.$$

In this case, the contribution of the slide is appreciable only if the inverse time constants of

the two plant components are far apart. For the equal areas case, we also can understand

easily the effect of a long time constant on the required neural drive. For a fixed choice of

time constant τ_1 and amplitude c_1 for the faster component, as the time constant of the slower

component becomes longer, the slide time constant increases, the amplitude of the step

decreases, and the amplitude of the slide increases.

Three- and four-component plants

Using numerical simulations, we extended this analysis to three- and four-component plants. In each case, we generated 1 million plants with coefficients and inverse time constants chosen uniformly at random between 0 and 1, with coefficients then normalized so that they sum to 1. We calculated the time constants of the slide components by solving for the zeros $-\lambda_i$ of the Laplace transform of each plant (equation (A.2)). We found that, in all cases, there was exactly one slide time constant between each pair of neighbouring plant time constants.
