Abstract

Primary cilia are microtubule-based sensory organelles whose assembly and function rely on the conserved bidirectional intraflagellar transport (IFT) system, which is powered by anterograde kinesin-2 and retrograde cytoplasmic dynein 2 motors. Nematodes additionally employ a male-specific kinesin-3 motor, KLP-6, which regulates ciliary content and function by promoting release of bioactive extracellular vesicles (EVs) from cilia. Here we show by live cell imaging that a KLP-6 homolog, KIF13B, undergoes bursts of bidirectional movement within primary cilia of cultured mammalian cells at 0.64 ± 0.07 μm/s in the anterograde direction and at 0.39 ± 0.06 μm/s in the retrograde direction, reminiscent of conventional IFT. In addition, we found that KIF13B undergoes EV-like release from the ciliary tip whereas a ciliary membrane marker, SMO-tRFP, remains stably associated with cilia during such EV release. Our results suggest that KIF13B, similar to KLP-6, regulates ciliary membrane content by promoting ciliary EV release, possibly in coordination with conventional IFT.

Introduction

Primary cilia are microtubule-based sensory organelles found on the surface of almost all animal cells and are pivotal for regulating diverse signaling pathways such as Sonic hedgehog (Shh) and polycystin-1/polycystin-2-mediated signaling [1]. Cilia are compartmentalized organelles whose assembly, maintenance and function depend on the conserved intraflagellar transport (IFT) machinery that via kinesin-2 and cytoplasmic dynein 2 motors, respectively, brings IFT-A and IFT-B complexes with associated ciliary cargoes into and out of the organelle [2, 3]. Ciliary composition and function are additionally regulated by the transition zone at the ciliary base [4], as well as by shedding and environmental release of extracellular vesicles (EVs) from cilia [5, 6]. Such EVs act as signal-carrying entities in *Caenorhabditis elegans* and *Chlamydomonas* [7-9] and may rid cilia of unwanted material in vertebrates [10, 11]. The precise mechanisms underlying the release of EVs from cilia are not clear, but the process is negatively regulated by the BBSome, a retrograde IFT membrane cargo adaptor [12], in both mammalian cells [10] and *C. elegans* [13]. In mammalian cells, release of EVs from cilia requires local polymerization of actin at the EV release site [10], whereas in *C. elegans* the kinesin-3 motor KLP-6 was shown to move anterogradely within male-specific sensory cilia [14], where it promotes ciliary targeting and release of polycystin-2-carrying EVs to control male mating behavior [7]. Several other factors regulating EV biogenesis, shedding and release from cilia in *C. elegans* have been identified, many of which affect tubulin post translational modification and hence KLP-6 motility within cilia [6]. It is unknown if vertebrate kinesin-3 motors similarly move within primary cilia and promote ciliary EV release, and to date KLP-6 is the only kinesin apart from IFT kinesin-2 motors with demonstrated intraciliary motility.

We previously showed that a KLP-6 homolog, KIF13B, localizes to primary cilia in mouse fibroblasts and immortalized human retinal pigment epithelial (hTERT-RPE1) cells, and that its depletion in these cells leads to ciliary accumulation of CAV1 and impaired Shh signaling [15]. However, the molecular basis for this phenotype was not clear and it is unknown if KIF13B actually moves within cilia. Interestingly, a proteomics analysis indicated that KIF13B accumulates within cilia of *Ift27* mutant mouse inner medullary collecting duct 3 (IMCD3) cells [16], which are deficient in retrograde IFT- and BBSome-mediated ciliary export of membrane proteins [17], suggesting that KIF13B could be transported out of cilia by IFT and the BBSome. Here, we show by live cell imaging that KIF13B undergoes bursts of IFT-like bidirectional movement within primary cilia of hTERT-RPE1 cells, and that it is occasionally released from the ciliary tip in EV-like particles.

Intraciliary movement and tip release required KIF13B's own motor domain, and a ciliary membrane marker, SMO-tRFP, was not co-released with KIF13B from cilia under these conditions. These results indicate that KIF13B, similar to KLP-6, may regulate ciliary membrane content by promoting ciliary EV release, possibly in coordination with conventional IFT.

Results and discussion

To investigate if KIF13B moves inside cilia we expressed previously validated eGFP-KIF13B fusion protein [15, 18] in hTERT-RPE1 cells stably expressing a red fluorescent ciliary membrane marker, SMO-tRFP [19], and subjected cells to serum deprivation to induce ciliogenesis prior to analysis by confocal live cell imaging (see Materials and methods for details). In all cells examined (n=59), eGFP-KIF13B was strongly concentrated at the ciliary base, and 17 of these additionally displayed rapid and transient accumulation of GFP-KIF13B within the cilium itself. Furthermore, in 5 of these 17 cells eGFP-KIF13B underwent EV-like release from the ciliary tip (Figure 1A-E; Movie 1). Notably, ciliary SMO-tRFP was not co-released with eGFP-KIF13B under these conditions (Figure 1A; Movie 1), indicating that the observed release of eGFP-KIF13B is not due to general disintegration of the ciliary tip. Kymograph analysis indicated that eGFP-KIF13B moves bidirectionally within cilia at 0.64 ± 0.07 μm/s in the anterograde direction (mean $\pm$ sem of n=37 measurements from 5 cells) and 0.39 ± 0.06 μm/s in the retrograde direction (mean $\pm$ sem of n=36 measurements from 5 cells). This is within the range of speeds reported for anterograde and retrograde IFT in mammalian cells [20], but slower than the reported anterograde speed for KIF13B moving on cytoplasmic microtubules in e.g. HeLa cells (2-3 μm/s; [18]). Kymographs indicated that eGFP-KIF13B moves progressively in both directions without slowing or acceleration and without prolonged pauses at the ciliary tip. From the cumulative histogram of velocities we find that anterograde movement is slightly faster than retrograde movement (Figure 1F and G). The cumulative histogram of velocities, v, was fitted by a Weibull distribution function of the form $y(v) = 1 - \exp\left[-(\alpha \cdot v)^{\beta}\right]$ with α=1.58 and β=2.11 for anterograde and α=2.76 and β=2.94 for retrograde transport, respectively, suggesting a rather broad distribution of velocities (Figure 1G). Image-based simulations of IFT indicate that movement of eGFP-KIF13B inside cilia with such velocities over the entire cilia length of < 5 μm would result in oscillation frequencies for bidirectional movement of about 30 sec (Figure 2). The observed periodicity of intensity oscillations of eGFP-KIF13B in cilia was much slower; typically,

between 200-500 sec (Fig. 1D and Movie 1). This dynamic behavior likely reflects the import and export kinetics of KIF13B in primary cilia combined with frequent switching of directions. It is comparable to the avalanche-like injection of IFT particles into cilia, observed previously [21], indicating that eGFP-KIF13B moves frequently up and down in cilia before eventually being exported/released from the cilia base or tip.

Quantitative live cell imaging analysis was additionally performed using motorless eGFP-KIF13B. This analysis demonstrated that motorless eGFP-KIF13B enters cilia in 7 out of 26 cells examined, but its fluorescence intensity was much lower in cilia than at the basal body, and bursts of intraciliary movement and tip release were not observed (Figure 1-figure supplement 1A, B). Hence intraciliary motility and tip release of KIF13B depend on its own motor domain. We could not detect eGFP-KIF13A in cilia of hTERT-RPE1 cells under similar conditions (Figure 1-figure supplement 1C), whereas kinesin-2 motor GFP-KIF17 was stably localized at the ciliary tip (Figure 1-figure supplement 1D), as expected [22].

A previous study indicated that KIF13B is not needed for EV release from cilia in IMCD3 cells [10]. Consistently, live imaging analysis of eGFP-KIF13B in ciliated IMCD3 cells stably expressing the ciliary membrane marker mCherry-Arl13b showed eGFP-KIF13B localization at the base of, but not within, cilia of these cells (Figure 1-figure supplement 1E). As cells lacking IFT27 contain increased ciliary levels of SMO [17] as well as KIF13B [16], we wondered if the stable presence of SMO-tRFP in cilia of the hTERT-RPE1 used for our imaging analyses lead to the observed intraciliary movement and tip release of eGFP-KIF13B. We therefore analysed if eGFP-KIF13B could enter cilia of IMCD3 cells, stably expressing mCherry-Arl13b, upon treatment with SMO agonist purmorphamine. However, purmorphamine did not induce ciliary entrance of eGFP-KIF13B in these cells (Figure 1-figure supplement 1F). This is in agreement with a recent cilia proteomics analysis that failed to detect KIF13B in cilia of Shh-stimulated IMCD3 cells [23], suggesting that ciliary entrance and movement of KIF13B is not triggered by the presence of SMO in cilia.

In summary, we found that KIF13B transiently enters cilia, moves bidirectionally within the organelle at speeds reminiscent of IFT, and occasionally undergoes EV-like release from the ciliary tip. Intraciliary movement and tip release require KIF13B's own motor domain and appears to be cell-type specific, as reported for KLP-6 in *C. elegans* [14]. Since KIF13B is a plus end-directed motor, its anterograde movement within cilia is likely powered by its own intrinsic motor activity, as supported by our observations with motorless eGFP-KIF13B. In contrast, KIF13B retrograde intraciliary movement must be mediated via its association with the dynein-2 driven retrograde IFT machinery. In support of this notion,

KIF13B seems to accumulate in cilia of *Ift27* mutant mouse IMCD3 cells [16], which are deficient in retrograde IFT- and BBSome-mediated ciliary protein export [17]. However, further work is required to determine how KIF13B intraciliary movement is coordinated with the IFT/BBSome machinery, and how KIF13B entrance into cilia is regulated. Interestingly, we observed that SMO-tRFP was not co-released with eGFP-KIF13B at the ciliary tip, suggesting that the released EV-like particles are generated from a subdomain of the ciliary membrane. The cholesterol-binding protein CAV1 was implicated in EV release in other contexts [24], and we speculate that EVs may be released from a subdomain of the ciliary membrane enriched in sterols and CAV1. If this indeed is the case, the ciliary accumulation of CAV1 observed in hTERT-RPE1 cells lacking KIF13B [15] could be a consequence of impaired EV release from cilia. We are currently investigating this possibility.

Materials and methods

Plasmids

The following previously described plasmids were used: eGFP-KIF13B [25], motorless eGFP-KIF13B [26], eGFP-KIF13A [15], GFP-KIF17 [27], and pcDNA3.1 (+) (Thermo Fisher Scientific). Plasmids were propagated in *Eschericia coli* DH10B cells using standard procedures and purified using NucleoBond Xtra Midi EF Kit (Macherey-Nagel).

Mammalian cell culture and transfection

hTERT-RPE1 cells stably expressing SMO-tRFP were generously provided by Christopher J. Westlake and have been described previously [19]. The cells were cultured in in Dulbecco's Modified Eagle Medium (DMEM; Thermo Fisher Scientific) supplemented with 10% heat inactivated fetal bovine serum (FBS; Thermo Fisher Scientific), 1% penicillin-streptomycin (Thermo Fisher Scientific), and 10 µg/mL Hygromycin B. Mouse IMCD3 cells stably expressing mCherry-ARL13B were a generous gift from Peter Gorilak and Vladimir Varga at Laboratory of Cell Motility, Institute of Molecular Genetics of the Czech Academy of Sciences, Prague, Czech Republic. These were cultured in DMEM/F12 medium (Thermo Fischer Scientific) containing 10% heat inactivated FBS and 1% penicillin-streptomycin. For the imaging experiments, cells were seeded on glass-bottom dishes 35/22 mm (HBSt-3522) from Willco Wells. Cells were transfected with with KIF-encoding plasmid and empty vector pcDNA3.1 (+) (1 µg total DNA) using 2 µl Lipofectamine 3000 Reagent and 2 µl P3000

(Thermo Fisher Scientific). hTERT-RPE1 cells stably expressing SMO-tRFP were transfected a day after seeding and IMCD3 cells expressing mCherry-Arl13b were reverse transfected at the time of seeding. To induce ciliogenesis, cells were cultured overnight (16 hr) in a medium free of FBS and antibiotics. For hTERT-RPE1 cells, serum starvation started 2 hr post transfection and for IMCD3 cells ca. 16 hr post transfection. To activate the Shh pathway and promote SMO ciliary entrance in IMCD3 cells, the cells were serum starved with DMEM/F12 medium containing 2 μM purmorphamine (Sigma, cat# SML0868).

Fluorescent live cell imaging

Live cell imaging was carried out on several confocal microscopes, all temperature (37ºC) and CO_2 (5%) regulated in a humidity chamber. These included a fully motorized Olympus IX83 inverted microscope equipped with a spinning disc (Yokogawa) and a Hamatsu ORCA-Flash 4.0 digital camera (C13440); a motorized inverted Nikon-Andor spinning disk microscope equipped with CSU-X1 spinning disk (Yokogawa), and/or laser launcher, Okolab microscope stage incubator, and a perfect focus system (PFS) (at DaMBIC, University of Southern Denmark). Both 60x and 100x Numerical Aperture (NA) 1.4 oil objectives (Olympus) were used. The 488 and 561 laser lines were used for imaging eGFP and tRFP, respectively. The time-lapse sequences were obtained with time intervals ranging from 5 to 10 sec. For laser scanning confocal microscopy at DaMBIC, University of Southern Denmark, a Nikon Ti-2, A1 LFO confocal microscope with a Plan Apo λ 100 x NA 1.4 oil objective with the following excitation/emission settings was used: 488/525 nm for eGFP and 561/595 nm for tRFP. The interval for the time-lapse sequences was 3 sec or 1.1 sec. All live cell imaging was carried out in DMEM or M1 medium containing 150 mM $NaCl_2$, 5 mM KCL, 1 mM $CaCl_2$, 1 mM $MgCl_2$, 5 mM glucose, and 20 mM HEPES.

Image analysis and simulations

All image analysis and simulations were was carried out in ImageJ (https://imagej.nih.gov/ij/), either using existing plugins, or implemented as self-developed Macro scripts (available from the authors upon request). Subsequent time series analysis was implemented as Jupyter notebooks in Python (https://jupyter.org/). First, cilia intensity of eGFP-tagged KIF13B (wilt-type or motorless mutant) was isolated based on the red fluorescent marker protein SMO-tRFP. For that, a rectangular region of interest (ROI) was defined around the red cilia marker, and an intensity threshold was applied to the SMO-tRFP

fluorescence in cilia weighted by the mean intensity of the red marker in the entire ROI. This procedure accounted for eventual photobleaching and secured a stable cilia area segmentation. A binary mask comprising the cilia area with intensities of either 0 or 1 was generated and multiplied with the corresponding green image series of the eGFP-tagged KIF13B. Integrated fluorescence intensity of eGFP-KIF13B was measured from videos with long acquisition time (i.e. 5-6 sec, acquired at a spinning disk confocal system) and normalized to the total green fluorescence in the rectangular ROI. To determine periodicities in cilia location dynamics of eGFP-KIF13B, the extracted intensity time series was transformed into frequency space using the Fast Fourier transform function of the scipy library in Python. Time-lapse sequences with shorter acquisition time (i.e. 1.1.sec intervals) were treated identically, but in addition to calculating integrated intensities, a Kymograph analysis was carried out. For that, the segmented cilia were first spatially aligned using a rigid body registration procedure. A 3-pixel wide line (straight or segmented) was used and the kymograph calculated using the Multikymograph plugin to Image J developed by Drs. A.Seitz and J. Rietdorf. Straight lines were identified and velocities of eGFP-KIF13B were calculated using the accompanying Macro script based on the known pixel size and interval time. Cumulative histograms of velocities measured in the anterograde and retrograde direction were calculated and fitted to a Weibull function as described in the Results and discussion section.

Image simulations of cilia movement were implemented as ImageJ Macro with a fixed cilia length of 5 μm, a simulated pixel size of either 0.05 or 0.1 μm and a frame rate of 1 frame per sec (1 Hz). A variable number of consecutive motors was translated towards the cilia tip with a constant speed. A stochastic velocity component was added from a uniform distribution, comprising about 0-10% of the total velocity to account for the stochastic nature of motor movement. Simulated images were convoluted with a Gaussian filter of width equal to 0.15 or 0.25 μm and Gaussian noise was added to account for the blurring by the microscope optics and the camera read out noise, respectively.

Figure legends

Figure 1. Transient bidirectional movement and EV-like tip release of eGFP-KIF13B in primary cilia of hTERT-RPE1 cells. (A) eGFP-KIF13B (green) is transiently moving into cilia, marked with SMO-tRFP (red). In less than one minute, eGFP-KIF13B accumulates in cilia and some is released from the cilia tip (arrows) between 360-400 sec of the video sequence. (B) Measurement of eGFP-KIF13B fluorescence intensity in cilia over time showing entry into cilia in repeated bursts. The video sequence in (A) is part of a longer recording, and the time window is indicated with a blue box. (C) Kymograph of the first part of sequence in (A) demonstrating that eGFP-KIF13B accumulation within cilia with this time resolution looks like two waves. (D) Fourier transformation (power spectrum) of the data in (B) with main periodicities indicated. (E) Example of similar analysis as in (B) with only one burst of eGFP-KIF13B observed (under the graph are example snapshots aligned with the curve). (F) Kymograph of high-time resolution sequences showing lines for anterograde (straight lines) and retrograde (dashed lines) eGFP-KIF13B intraciliary movement. (G) Weibull distribution function of the form $y(v) = 1 - \exp\left[-(\alpha \cdot v)^{\beta}\right]$ with α=1.58 and β=2.11 for anterograde and α=2.76 and β=2.94 for retrograde transport, respectively, suggests a rather broad distribution of eGFP-KIF13B velocities in hTERT-RPE1 SMO-tRFP cells.

Figure 2. Image simulations of cilia movement. (A) Left panel shows five simulated motors as consecutive single pixels and right panel shows the appearance of those motors through the microscope. (B) Kymographs calculated for images of one or 3 motors were used

for validation of the analysis procedure for a nominal velocity of 0.25 µm/sec. The true velocity can be recovered with >95% accuracy. (C) Integrated intensity was quantified for a portion of the simulated cilia to emulate time-resolved measurements of eGFP-KIF13B in cilia (compare with Figure 1B and E). There were two periodic intensity peaks, since the quantification of cilia intensity allowed for partial exit of the simulated motors at the cilia base. (D) Fourier transform of the intensity profile reveals this 2-fold periodicity, the higher frequency corresponds to one-way transport and the lower frequency (given the periodicity of 30 sec) corresponds to the full bidirectional movement of the particles.

Movie 1. Live cell imaging movie showing transient, burst-like intraciliary movement and tip release of eGFP-KIF13B in RPE1 SMO-tRFP cells.

Figure 1-figure supplement. Control experiments for eGFP-KIF13B live cell imaging analyses. (A) Example snapshots of movie showing motorless eGFP-KIF13B in SMO-tRFP cells, which is mainly accumulating around the ciliary base with a fraction localizing stably to cilia over time (25 cells imaged in total). (B) Measurement of motorless eGFP-KIF13B fluorescence intensity in cilia over time, based on movies as in (A). (C, D) Frames of representative movies from live cell imaging analysis of eGFP-KIF13A (C) and GFP-KIF17 (D) in hTERT-RPE1 SMO-tRFP cells. A total of 4 and 3 transfected cells were imaged for eGFP-KIF13A and GFP-KIF17, respectively. (E, F) Frames of movies from live cell imaging of eGFP-KIF13B in IMCD3 cells stably expressing mCherry-Arl13b cells with no Hedgehog stimulation. (E, F) Representative time frame snap shots of eGFP-KIF13B in IMCD3 cells stably expressing mCherry-Arl13b in the absence (E) or presence (F) of 2 µM purmorphamine. In these cells eGFP-KIF13B is localized at the two centroiles at the base of the cilia. A total of 10 and 16 cells were imaged for conditions in (E) and (F), respectively.
