## **Abstract**

36  Precise quantitative information about the molecular architecture of synapses is essential to

37  understanding the functional specificity and downstream signaling processes at specific

38  populations of synapses. Glycine receptors (GlyRs) are the primary fast inhibitory

39  neurotransmitter receptors in the spinal cord and brain stem. These inhibitory glycinergic

40  networks crucially regulate motor and sensory processes. Thus far the nanoscale organization

41  of GlyRs underlying the different network specificities has not been defined. Here, we have

42  quantitatively characterized the molecular arrangement and ultra-structure of glycinergic

43  synapses in native spinal cord tissue using quantitative super-resolution correlative light and

44  electron microscopy (SR-CLEM). We show that GlyRs exhibit equal receptor-scaffold

45  occupancy and constant absolute packing densities of about 2000 GlyRs $\mu m^{-2}$ at synapses

46  across the spinal cord and throughout adulthood, even though ventral horn synapses have

47  twice the total copy numbers, larger postsynaptic domains and more convoluted morphologies

48  than dorsal horn synapses. We demonstrate that this stereotypic molecular arrangement is

49  maintained at glycinergic synapses in the *oscillator* mouse model of the neuromotor disease

50  hyperekplexia despite a decrease in synapse size, indicating that the molecular organization of

51  GlyRs is preserved in this hypomorph. We thus conclude that the morphology and size of

52  inhibitory PSDs rather than differences in GlyR packing determine the postsynaptic strength

53  of glycinergic neurotransmission in motor and sensory spinal cord networks.

54

## **Introduction**

56  Synaptic transmission relies on the integration of neurotransmitter-induced signals by

57  membrane receptors in the postsynaptic density (PSD). The molecular arrangement of

58  postsynaptic receptors and scaffold proteins is therefore key to the synaptic function, however

59  the heterogeneity and complexity of the PSD has made it difficult to resolve its internal

60  organization, to ascertain whether distinct compositional states exist, and to determine how

61  the organization is affected in disease.

62

63  Glycine receptors (GlyRs) are the main inhibitory neurotransmitter receptors in the adult

64  spinal cord and brainstem. Glycinergic neurons arise from different embryonic origins, with

65  specific types of neurons residing in characteristic layers of the spinal cord (Lu et al., 2015).

66  Depending on their location, glycinergic neurons mediate sensory and motor information in

67  the dorsal and ventral spinal cord, respectively, which requires high reliability and fidelity of

68    transmission (Alvarez, 2017). Consequently, deficits in glycinergic transmission are involved

69    in pain mechanisms (Harvey et al., 2004) and motor-related neurological diseases (Schaefer et

70    al., 2018). The electrophysiological properties of glycinergic currents indicate that only a

71    limited number of receptors are activated by the release of a single synaptic vesicle

72    (Oleskevich et al., 1999; Singer and Berger, 1999), suggesting that the nanoscale organization

73    of the receptors determines signal amplitude.

74

75    It has been shown that neurotransmitter receptors at excitatory and inhibitory GABAergic

76    synapses are organized within sub-synaptic domains (SSDs) that are aligned with presynaptic

77    elements of the active zone (AZ) (Crosby et al., 2019; MacGillavry et al., 2013; Pennacchietti

78    et al., 2017; Tang et al., 2016). These so-called trans-synaptic nanocolumns are thought to

79    increase the efficacy of synaptic transmission (Haas et al., 2018). At mixed inhibitory

80    synapses, both glycine and $GABA_A$ receptors are immobilized opposite to presynaptic release

81    sites through direct interactions with their common scaffold protein gephyrin (Maric et al.,

82    2011; Specht et al., 2013). However, absolute quantification of receptor numbers and their

83    precise arrangement within the native PSD is lacking. Further, the question is raised as to

84    whether the structure of glycinergic synapses varies in functionally diverse circuits of the

85    dorsal and ventral spinal cord, if it changes over time such as aging, and if it is disturbed in

86    GlyR pathologies such as the neuromotor disease hyperekplexia in humans. In these patients,

87    mutations within the receptor subunit genes *GLRA1* and *GLRB* lead to decreased receptor

88    availability and disturbances in glycinergic transmission, causing exaggerated startle reflexes,

89    muscle hypertonia and stiffness in infancy (Chung et al., 2013; Chung et al., 2010; Schaefer et

90    al., 2013).

91

92    To investigate whether the molecular arrangement of GlyRs may account for differences in

93    the functional specificity of sensory and motor circuits we have quantitatively analyzed the

94    ultra-structural organization of inhibitory synapses in native tissue. We have combined

95    molecule counting of endogenous GlyRs using single molecule localization microscopy

96    (SMLM) with correlative light and electron microscopic analysis (CLEM) to obtain absolute

97    receptor numbers as well as detailed spatial information of the synapse at the nanometer scale.

98    We have further examined to what extent the molecular organization is maintained throughout

99    adult development and during GlyRα1-deficiency. We show that GlyRs are packed at a

100   constant density of about 2000 receptor complexes per $\mu m^2$ at mature synapses, suggesting

101   that they are assembled in a stereotypic fashion. This GlyR molecular organization is

3

102  maintained in the hyperekplexia model *oscillator* despite a decrease in ventral synapse size,

103  indicating that GlyRα1-deficiency does not affect the integrity of the synaptic arrangement as

104  such. Collectively, these results provide the structural basis for understanding the mechanisms

105  underlying receptor availability and integration of neurotransmitter-induced signals.

106

107  **Results**

108  **Generation of a KI model expressing endogenous levels of mEos4b-GlyRβ**

109  In order to quantify GlyR numbers and their precise distribution at native synapses we

110  generated a knock-in (KI) mouse model expressing endogenous mEos4b-tagged GlyRβ

111  subunits (Fig. S1). The β-subunit drives the synaptic localization of the receptor through

112  direct interactions with the synaptic scaffold protein gephyrin at inhibitory synapses (Kim et

113  al., 2006; Meyer et al., 1995). To date, labeling the β-subunit has proven difficult and has thus

114  limited the study of the receptor. The coding sequence of mEos4b was inserted in exon 2 of

115  the *Glrb* gene by homologous recombination supported by a guide RNA (CRISPR-Cas9) to

116  increase recombination efficiency (ICS, Illkirch, France). The correct insertion was confirmed

117  by amplification and sequencing of genomic DNA. Semi-quantitative RT-PCR revealed that

118  equal concentrations of $Glrb^{Eos}$ and the wild-type transcript ($Glrb^{WT}$) are expressed in

119  heterozygous animals. When bred to homozygosity, KI animals reach adulthood and display

120  no overt phenotype, suggesting that the presence of the N-terminal fluorophore does not affect

121  receptor expression and function.

122

123  **Quantitative confocal imaging of endogenous mEos4b-GlyRβ and mRFP-gephyrin at**

124  **native spinal cord synapses**

125  To verify the expression and synaptic targeting of the mEos4b-GlyRβ protein we carried out

126  quantitative confocal imaging in 40 μm vibratome tissue sections. $Glrb^{Eos}$ animals were

127  crossed with a KI mouse line expressing mRFP-tagged gephyrin to visualize inhibitory

128  postsynaptic densities (PSDs) (Specht et al., 2013). Since the synaptic localization of the

129  GlyR is strictly dependent on its interaction with gephyrin (Patrizio et al., 2017), we expected

130  a high degree of co-localization of the two proteins in the brainstem and spinal cord

131  (Zeilhofer et al., 2005). Indeed, mEos4b-GlyRβ was widely expressed at inhibitory synapses

132  in the thalamus, midbrain, pons and medulla (Fig. S1). Very little fluorescence was detected

133  in the forebrain, despite the high reported expression of the *Glrb* transcript (Fujita et al., 1991;

134  Malosio et al., 1991; Weltzien et al., 2012).

4

135

136    In the spinal cord, we observed bright punctate mEos4b-GlyRβ signals throughout the gray

137    matter, with the exception of the superficial laminae of the dorsal horn, where the intensity of

138    the green fluorescence was markedly lower (Fig. 1A). The expression of mEos4b-GlyRβ and

139    mRFP-gephyrin in homozygous and heterozygous animals was quantified in confocal images

140    of thoracic and lumbar spinal cord slices at 2 months (Fig. 1B) and 10 months of age (Fig. S2).

141    The integrated mEos4b intensity at gephyrin-positive ventral horn synapses was exactly two

142    times higher in $Glrb^{Eos/Eos}$ mice than in $Glrb^{Eos/WT}$, demonstrating that both alleles are

143    expressed with the same efficiency, and that the mEos4b fluorophore does not affect the

144    synaptic localization of the receptor complexes. To confirm that the confocal image

145    acquisition was in the linear dynamic range we bleached the mEos4b fluorophores by

146    repeatedly scanning the same tissue area at constant laser power (Fig. 1A, white square),

147    which resulted in a linear decay of pixel intensities over a range of more than 20 fold (Fig.

148    1C).

149

150    Across the spinal cord slices, the intensity of synaptic mEos4b-GlyRβ puncta increased from

151    dorsal to ventral both in homozygous (Fig. 1D-E) and in heterozygous animals (Fig. S2).

152    Similarly, mRFP-gephyrin fluorescence was higher and more variable in the ventral horn,

153    suggesting that synapses were on average about twice as big as those in the dorsal horn,

154    despite being fewer in number (Fig. 1F, S2). The mEos4/mRFP ratio was relatively equal

155    across the spinal cord with the exception of the superficial layers of the dorsal horn, where

156    gephyrin levels largely exceeded the GlyRs (Fig. 1A and D). The lower GlyR-scaffold

157    occupancy of synapses in laminae I-III can be explained by the predominant expression of

158    $GABA_A$Rs that compete for receptor binding sites at these mixed inhibitory synapses

159    (Alvarez et al., 1996; Lorenzo et al., 2014; Todd et al., 1996).

160

161    **Dual-color super-resolution imaging of glycinergic spinal cord synapses**

162    To quantify the observed structural differences at super-resolution, we combined radial

163    fluctuation (SRRF) analysis of mRFP-gephyrin and photo-activated localization microscopy

164    (PALM, a form of SMLM) of mEos4b-GlyRβ in spinal cord tissue from double KI animals.

165    Sucrose impregnated cryosections of 2 μm thickness were prepared from dorsal and ventral

166    tissue and placed on gridded coverslips (Fig. 2A). SRRF and PALM images were acquired

167    sequentially. First, mRFP signals were recorded with high intensity 561 nm laser illumination

168   until all mRFP fluorophores were bleached (10,000 frames). mEos4b was then

169   photoconverted with increasing 405 nm laser intensity and imaged at 561 nm for 25,000

170   frames until all available fluorophores were exhausted. By acquiring both fluorophores in the

171   same emission band (607/36 nm), any chromatic misalignment between the two super-

172   resolved images was eliminated. SRRF reconstruction was carried out on the raw mRFP

173   image sequence and PALM images were generated from individual mEos4b detections using

174   Gaussian peak fitting (Fig. 2B).

175

176   The majority of synaptic clusters were small and spherical or elongated. Larger clusters

177   displaying a variety of morphologies including elongated shapes seen in side-view (Fig. 2B)

178   as well as convoluted structures which were more frequently seen in the ventral horn (Fig. S3).

179   As expected of two directly interacting synaptic components the degree of co-localization of

180   mEos4b-GlyRβ and mRFP-gephyrin was very high, with mean intensity correlation quotients

181   (ICQ) around 0.3 (Fig. 2C and S3). Minor mismatches between the super-resolution images

182   are explained by the fact that the majority of synapses are seen in cross-section and that the

183   two fluorophores are located on opposite sides of the postsynaptic membrane (~30 nm

184   distance, (Specht et al., 2013)). There were no obvious differences between the ICQ values of

185   dorsal versus ventral synapses (0.28-0.3), indicating equivalent GlyRβ-gephyrin binding in

186   the two regions. It should be noted that the ICQ reflects relative fluctuations between images

187   and is not sensitive to absolute differences in signal intensities, resulting in similar ICQ values

188   in animals that are heterozygous or homozygous for mRFP-gephyrin (Fig. 2C). Quantitative

189   comparison of mEos4b-GlyRβ and mRFP-gephyrin intensities confirmed that the amounts of

190   receptor and scaffold proteins are closely correlated, and that the occupancy of receptor

191   binding sites is the same in the dorsal and ventral horn, independent of synapse size (Fig. 2D

192   and S3). To estimate the sizes of the synapses we applied a density threshold to the PALM

193   pointillist images and calculated the areas of the mEos4b-GlyRβ clusters (Fig. 2E). The mean

194   synapse area in the ventral horn was larger and more variable than in the dorsal region, both

195   in animals of 2 and 10 months of age (Fig. 2F). We also remarked that the overall number of

196   synapses in ventral horn tissue was lower compared to the dorsal horn, significantly so by 10

197   months (Fig. 2G, see also Fig. 1F and S2). The inverse relationship between synapse number

198   and size is likely due to the presence of different cell types in the two regions, specifically

199   Renshaw cells and large motor neurons in the ventral horn that require strong inhibitory

200   control (e.g. (Bhumbra et al., 2014)).

6

201

**Absolute quantification of GlyR numbers and densities at native spinal cord synapses**

203      Given that mEos4b-GlyRβ subunits are expressed at endogenous levels in $Glrb^{Eos/Eos}$ animals

204      and that all the fluorophores were exhausted during the PALM recordings, we were able to

205      count the absolute number of GlyR complexes at native spinal cord synapses. The total

206      number of mEos4b-GlyRβ detections at synapses (Fig. S4) was converted into molecule

207      numbers, taking into account the blinking properties of the fluorophore and the $\alpha_3$:$\beta_2$

208      stoichiometry of the pentameric GlyR complex (Durisic et al., 2014; Patrizio et al., 2017). To

209      this aim, the average number of detections per fluorophore (detections/burst) and the fraction

210      of functional fluorophores (probability of detection, $P_{det}$; Fig. S5) were determined in each set

211      of experiments using extrasynaptic receptor complexes (Fig. 2E, red arrowheads). We

212      calculated a median copy number of 114 pentameric GlyR complexes at dorsal horn synapses

213      and twice that number at ventral horn synapses in 2 month old animals (Fig. 2H). Copy

214      numbers were almost identical at 10 months (Fig. S6), indicating that the glycinergic network

215      was mature at both time points. These numbers exceed estimates derived from

216      electrophysiological recordings in new-born, juvenile and adult rat spinal cord neurons that

217      suggest an activation ranging from 7 up to about 110 GlyRs during an average miniature

218      inhibitory postsynaptic current (mIPSC) (Chery and de Koninck, 1999; Oleskevich et al.,

219      1999; Singer and Berger, 1999; Takahashi, 1992). The high absolute numbers of GlyRs

220      measured by fluorophore counting therefore imply that the available receptors are not

221      saturated by quantal release, which is likely to increase the dynamic range of postsynaptic

222      inhibition (Alvarez, 2017).

223

224      Our quantitative PALM data further demonstrate that differences in receptor numbers result

225      from differences in synapse size (Fig. 2F). By combining the two parameters, we derived

226      mean GlyR densities of ~2000 $\mu m^{-2}$ (Fig. 2I, S6). Similar receptor densities of 1250 $\mu m^{-2}$ and

227      ~2000 $\mu m^{-2}$ have been measured at GABAergic synapses in cerebellar stellate cells and in

228      cultured hippocampal neurons, respectively (Liu et al., 2020; Nusser et al., 1997). We saw no

229      differences in the GlyR packing density at dorsal and ventral horn synapses, nor did we find a

230      clear size dependence, as determined by linear regression of all synapses (Fig. 2I) and the

231      evolution of the coefficient of variation of GlyR density with respect to synapse area (Fig. S6).

232      These findings are significant because they indicate that GlyR density is constant and largely

233      independent of neuron type, embryonic origin or physiological function. Assuming that

234  gephyrin molecules are clustered at densities of up to 9000 $\mu m^{-2}$ (Specht et al., 2013), our data

235  also suggest that close to 50% of the receptor binding sites are occupied by GlyRs at native

236  spinal cord synapses, in line with earlier observations of GlyR subunits that were

237  overexpressed in cultured neurons (Patrizio et al., 2017).

238

239  **Quantitative SR-CLEM of GlyRβ molecular organization**

240  To integrate the results of molecule counting with three-dimensional ultra-structural

241  information and the exact synapse size, we further analyzed dorsal and ventral horn synapses

242  by SR-CLEM. Previously imaged cryosections of $Glrb^{Eos/Eos}$ tissue from 10 month old

243  animals were embedded in epoxy resin, and ultra-thin (70 nm) serial sections were collected

244  on EM slot grids with an ultramicrotome (Fig. 3A). After osmium tetroxide enhancement,

245  electron micrographs of identified synapses were acquired in all serial sections and registered

246  manually, using the coverslip grids and cellular structures as reference (Fig. 3B-C). All of the

247  synapses that were both, imaged by PALM and reconstructed with EM were functionally

248  mature, as judged by the apposition of a single presynaptic terminal containing synaptic

249  vesicles. In line with our PALM data we found that glycinergic synapses in the ventral horn

250  were substantially larger and more variable in size than those in the dorsal horn (Fig. 3C-D).

251  There was good correspondence between the calculated synapse areas in the EM and PALM

252  image reconstructions, even though PALM underestimated the sizes of some large ventral

253  horn synapses (Fig. S7). This is probably due to the fact that a majority of synapses are tilted,

254  and that the axial component of the area is not captured in the SMLM projections. Whereas

255  most synapses in the dorsal horn were macular, ventral synapses were frequently composed of

256  sub-domains (Fig. 3E-G). In agreement with earlier studies (Alvarez et al., 1997; Lushnikova

257  et al., 2011; Santuy et al., 2018), the degree of complexity scales with the size of the PSD

258  (Fig. 3F), and was taken into account for the calculation of the combined area in the EM serial

259  sections.

260

261  The ratio of GlyR copy numbers and the area of the inhibitory PSDs obtained by EM resulted

262  in average receptors densities of approximately 2000 $\mu m^{-2}$ (Fig. 3H). Consistent with our

263  PALM estimates we did not observe significant differences between synapses in the dorsal

264  and the ventral horn (Fig. 2I, S6). Furthermore, the GlyR packing density was not dependent

265  on synapse size (Fig. 3I), supporting an earlier proposal (Lim et al., 1999). This suggests that

266  GlyRs are assembled in a systematic manner, where receptor numbers increase linearly with

267  synapse size. Since the morphological complexity of synapses increases with size, it can also

268    be concluded that GlyR occupancy at individual sub-domains of the PSD is uniform. GlyR

269    densities were indeed not significantly different within sub-clusters of reconstructed synapses

270    (Fig. 3G and I, black data points). Together, these findings point to a tight regulation of the

271    architecture of glycinergic synapses across different molecular length scales, where GlyRs are

272    arranged in sub-synaptic signaling units.

273

274    **Integrity of GlyR molecular arrangement is unaltered in the hyperekplexia mouse**

275    **model *oscillator***

276    Having identified that GlyRs have a stereotypic molecular organization that is maintained

277    throughout adulthood and across synapses in different neuronal circuits, we questioned

278    whether this arrangement is altered in a mouse model of hyperekplexia, a motor-related

279    neurological disease that significantly impacts motor processing in the ventral horn of the

280    spinal cord. The mouse mutation *oscillator (Glra1*$^{\text{spd-ot/spd-ot}}$*)* is recessively inherited and

281    causes a microdeletion and frameshift in the TM3-4 intracellular loop of the GlyR$\alpha$1 subunit

282    leading to subunit truncation and subsequent loss of functional GlyRs at synapses (Kling et

283    al., 1997). Homozygous *oscillator* mice do not live past 3 weeks of age (Buckwalter et al.,

284    1994). In contrast, heterozygous animals have a normal lifespan and exhibit a more subtle

285    phenotype. *Glra1*$^{\text{spd-ot/WT}}$ mice display an increased startle reflex and lower GlyR$\alpha$1 levels

286    (Kling et al., 1997), making them a suitable model for human hyperekplexia. We generated

287    mutant mice that were homozygous for mEos4b-GlyR$\beta$ (as described above) and

288    heterozygous for *oscillator* (*Glrb*$^{\text{Eos/Eos}}$ / *Glra1*$^{\text{spd-ot/WT}}$) as well as wild-type littermates

289    (*Glrb*$^{\text{Eos/Eos}}$ / *Glra1*$^{\text{WT/WT}}$). In these experiments, inhibitory synapses were detected by

290    immunolabeling of endogenous gephyrin using mAb7a antibody.

291

292    Quantitative confocal imaging in 40 µm vibratome tissue sections showed bright punctate

293    mEos4b-GlyR$\beta$ signals localized to synapses (Fig.4A). Across the spinal cord slices, the

294    intensity of synaptic mEos4b-GlyR$\beta$ puncta increased from dorsal to ventral in homozygous

295    WT animals (Fig. 4B), replicating the intensity profile observed previously (Fig. 1D). The

296    intensity of synaptic mEos4b-GlyR$\beta$ puncta in *oscillator* animals were substantially lower

297    than those of WT littermates, which explains the reductions in membrane levels of GlyR and

298    gephyrin previously observed by Western blotting (Kling et al., 1997). The mEos4/gephyrin-

299    7a ratio was relatively equal across the spinal cord with greater variation seen in *oscillator*.

300    No ectopic GlyR$\beta$ clusters were detected, meaning that GlyRs and gephyrin always

301  colocalized (Fig. S8). The number of gephyrin-positive synapses across the spinal cord

302  remained unchanged between WT and *oscillator*.

303

304  Using our quantitative PALM approach, we determined the number and size of glycinergic

305  synapses in tissue slices of dorsal and ventral spinal cord, as well as the mEos4b detection

306  density, in order to understand the alterations in glycinergic synapse architecture in this

307  mutant mouse model. In WT animals we observed small and spherical dorsal synapses and

308  larger, elongated ventral synapses, while *oscillator* synapses appeared small in both dorsal

309  and ventral tissue. (Fig. 5A). This was confirmed by quantitative analysis. The mean synapse

310  area in the ventral horn was significantly larger than in the dorsal region in WT animals (Fig.

311  5B), in agreement with our earlier data (Fig. 2F). However, this difference was lost in

312  *Glra1*$^{\text{spd-ot/WT}}$ littermates. The overall number of synapses was lower in ventral horn tissue

313  compared to the dorsal horn in both WT and *oscillator* animals (Fig. 5C). These data suggest

314  that the decrease in functional receptors in heterozygous *oscillator* mice manifests itself as a

315  reduction in the size of ventral synapses.

316

317  We further quantified the total number of mEos4b-GlyRβ detections at synapses (Fig.5D) and

318  found that the number and distribution of WT mice detections matched that of 2 and 10 month

319  old WT animals analyzed previously (Fig. S4). We found similar numbers of detections in

320  *oscillator* dorsal synapses compared to WT littermates, however in ventral tissue we found a

321  shift towards lower detection numbers per synapse, indicative of smaller synapses. By

322  combining the measurements of synapse area with the number of detections per synapse we

323  could derive the receptor density. Consistent with our previous PALM data, we found a

324  constant density independent of synapse size in WT mice, as determined by the shallow slope

325  of the linear regression (Fig.5E). We found a similar and constant GlyR packing density in

326  synapses of *oscillator* mice. This suggests that despite a decrease in the total numbers of

327  functional GlyRs in the heterozygous *oscillator* mouse model the molecular organization

328  underlying receptor clustering within the synapse is maintained, in line with the lack of an

329  overt neuromotor phenotype in these animals. In other words, the receptors are assembled

330  stereotypically in the disease model, as in WT, with synapse size consistently scaling with

331  receptor number. Together, our findings describe a highly regulated architecture of

332  glycinergic synapses in both WT animals as well as in a model of synaptic pathology,

333  providing a structural basis of glycinergic signaling.

334

10

335  **Discussion**

336  Combining single molecule PALM imaging, molecular counting and 3D electron microscopy

337  we have shown that glycinergic synapses in different regions of the spinal cord follow the

338  same structural principle, insofar as their receptor-scaffold occupancy and packing densities

339  are the same. This uniformity extends to the sub-synaptic level. The presence of so-called

340  sub-synaptic domains (SSDs) at inhibitory synapses has been shown by super-resolution

341  microscopy (Crosby et al., 2019; Dzyubenko et al., 2016; Pennacchietti et al., 2017; Specht et

342  al., 2013). However, it remains controversial whether the identified patterns represent the

343  overall structure of the PSD itself or whether they reflect intra-synaptic variations in molecule

344  clustering. Our quantitative SR-CLEM data lend support to the first model, whereby

345  inhibitory PSDs in the spinal cord are composed of sub-domains that shape the distribution of

346  the GlyRs. This organization is achieved through direct interactions between GlyRs and

347  gephyrin, as shown by the close correspondence between the receptors and scaffold proteins.

348  As such, the GlyR sub-clusters at spinal cord synapses do not constitute SSDs within the PSD

349  in the strict sense, since they exhibit uniform binding to the synaptic scaffold (discussed in

350  (Yang and Specht, 2019)). The stereotypic GlyR density within SSDs observed in our study

351  supports the idea that these structures can instead be equated with the convolutions of the

352  synaptic junction observed by EM (Alvarez et al., 1997; Lushnikova et al., 2011; Peters and

353  Palay, 1996; Santuy et al., 2018). The formation of these convolutions is probably a

354  consequence of gephyrin oligomerization that appears to introduce an asymmetry in the

355  synaptic scaffold. The situation may be different at GABAergic synapses, where the co-

356  existence of gephyrin-dependent and gephyrin-independent clustering mechanisms could lead

357  to the formation of spatially more restricted SSDs containing different $GABA_AR$ subtypes

358  (Pennacchietti et al., 2017; Specht, 2020).

359

360  The nanoscale organization of inhibitory PSDs is the same in glycinergic neurons in the

361  dorsal and the ventral spinal cord, despite their different embryonic origins. Ventral horn

362  synapses are generally larger, more complex and contain more GlyRs, suggesting that the size

363  of the synapse is differentially regulated in a regional and cell type specific manner to adjust

364  the level of glycinergic inhibition. As such, these synapses may be particularly well adapted

365  to motor circuits, assuring strong and reliable inhibition of the postsynaptic neuron (Alvarez,

366  2017). At the same time, the long and tortuous perimeter of the PSD is likely to accelerate the

367  dynamic exchange of GlyRs and other synaptic components (Chow et al., 2017; Santuy et al.,

368  2018), thereby promoting the molecular plasticity at complex inhibitory synapses (Specht,

11

369    2020). It can further be argued that large and morphologically complex synapses may be

370    particularly well adapted to integrate fast temporal, or indeed multi-vesicular release arising

371    from one or more presynaptic sites, thus providing a strong and reliable inhibition of the

372    postsynaptic neuron while maintaining fast neurotransmitter clearance (discussed in (Alvarez,

373    2017; Rudolph et al., 2015)).

374

375    In addition, our data show that GlyR density and occupancy do not change between 2 and 10

376    months of age, indicating that receptor clustering is fully mature by the earlier time point.

377    Studies of normal aging of spinal cord synapses are scarce, and its effect on receptor

378    organization has not been studied. Broadhead and colleagues (Broadhead et al., 2020) report

379    no difference between the number of excitatory synapses in the ventral horn and only a slight

380    increase in dorsal synapses between 2 to 9 month old mice. Broadly in line with these

381    findings, we found no difference in the number of synapses, synapse area, and GlyR packing

382    density in dorsal and ventral tissue between 2 and 10 months. Thus, glycinergic PSDs show

383    considerable control over their molecular composition throughout adulthood, further

384    emphasizing the functional significance of their synaptic architecture in both sensory and

385    motor signaling. Our data therefore suggest that a constant GlyR density potentially provides

386    the most efficient organization of the glycinergic PSD, while enabling the refinement of the

387    size and complexity of the synapse due to ongoing neural activity.

388

389    The neuromotor disease hyperekplexia results from defects in glycinergic inhibition in

390    humans. Several mouse models with analogous mutations in the *Glra1* gene recapitulate the

391    phenotype of exaggerated startle reflexes and muscle stiffness (Schaefer et al., 2018). In

392    general, the mutations in the various mouse models are less well tolerated than in humans,

393    often with lethal phenotypes in homozygotes. Hyperekplexia can be recessively or dominantly

394    inherited in humans, but neither has been shown to cause lethality. The *oscillator* model,

395    whilst lethal as a homozygous, displays a relatively mild phenotype in heterozygous animals,

396    with a measurable startle reflex and normal lifespan (Kling et al., 1997). Heterozygous

397    *oscillator* therefore represents a relevant model for the subtler phenotype in humans and the

398    long-term stability of glycinergic synapses beyond the developmental stage at which lethality

399    occurs in homozygous animals. However, it is not known how the reduced GlyR levels in the

400    *Glra1*$^{\text{spd-ot/WT}}$ hypomorph can affect (and sustain) functional motor networks. We

401    characterized the molecular organization of heterozygous *oscillator* synapses and show that

402    GlyR packing follows the same principle as in WT synapses, even though the total number of

403    available functional receptors is reduced, resulting in smaller synapses in the ventral spinal

404    cord. This further emphasizes that the stereotypic arrangement of GlyRs dictates the size of

405    the PSD. Most of the synapses that are formed in heterozygous *oscillator* likely achieve a size

406    threshold capable of sustaining glycinergic signaling without serious motor defects. The lack

407    of fundamental structural changes at glycinergic synapses further suggests that no or only

408    limited compensatory effects take place in *oscillator*, in agreement with earlier findings that

409    α1β GlyR complexes cannot be compensated for by other subunit configurations, α1-

410    homopentamers or GABA$_A$Rs (Schaefer et al., 2012). Our findings thus provide a new

411    perspective into the molecular basis of GlyRα1-deficiency in an animal model of human

412    hyperekplexia.

413

414    Taken together, our data show that dorsal and ventral synapses are distinct populations.

415    Ventral horn synapses have much higher GlyR copy numbers, even though receptor density is

416    not different. In contrast to the relatively compact, macular synapses in the dorsal horn,

417    ventral horn synapses achieve a greater receptor number by enlarging the synaptic surface,

418    thus multiplying the sites of signal transmission. These region-specific glycinergic synapse

419    morphologies are likely to underlie functional differences at sensory (dorsal) versus motor

420    (ventral) circuits.

445

446 **Data and materials availability**

447 All data are available upon request.

448

449 **Materials and Methods**

450 **KI mouse model generation**

451 The knock-in (KI) mouse line C57BL/6N-$Glrb^{tm1Ics}$ (MGI:6331106) carrying the mutant allele

452 $Glrb^{tm1(Eos4)Ics}$ (MGI:6331065) was created by homologous recombination at the Institut

453 Clinique de la Souris (ICS, Illkirch, France). Flanked by 5' and 3' homology arms of 1.23 kb

454 and 3.49 kb, respectively, the targeting vector encompassed exon 2 of the $Glrb$ gene with an

455 insertion of the coding sequence of mEos4b, as well as a *floxed* neomycin selection cassette

456 containing the Cre recombinase under control of protamine promoter in intron 2-3. The

457 selection cassette was excised in the F1 generation by germline expression of Cre, resulting in

458 a single *loxP* site in intron 2-3 of the $Glrb$ locus (Fig. S1A). The correct insertion of the

459 mEos4b coding sequence was confirmed by sequencing of genomic $Glrb^{Eos/Eos}$ tail DNA.

460 Genotyping was done using three primers (primer 1: TACCTTCTTGTTTTCTCTCC; primer

461 2: GTCTGTTTTCCCTCATAAGG; primer 3: TCGCTTTTGTAAATGATATGG) for the

462 amplification of the mutant $Glrb^{Eos}$ (243 bp product) and/or the wild-type alleles (404 bp).

463

464 Purified spinal cord mRNA of $Glrb^{Eos/Eos}$, $Glrb^{Eos/WT}$ and $Glrb^{WT/WT}$ animals was reverse

465 transcribed (primer 6: GGAGTCTAACAGTAATCTGG), and amplified (primer 4:

466 AGGCGCGTCAAACTCGG; primer 5: CCATACCAACCAATGAAAGG). The correct

467 splicing of the mutant transcript was confirmed by sequencing of amplified cDNA. For semi-

468 quantitative RT-PCR, the $Glrb^{Eos/Eos}$ mRNA was spiked with wild-type cDNA at a ratio of

469 1:2, 1:1 and 2:1 and amplified (Fig. S1B).

470

471    All experiments (with the exception of the data in Fig. S1A-B, 4, 5 and S8) were carried out

472    with F2 animals resulting from a cross between the KI line C57BL/6N-$Glrb^{tm1Ics}$ (see above)

473    and a KI mouse line expressing mRFP-tagged gephyrin (Machado et al., 2011) in the

474    C57BL/6J strain, meaning that the mice had a mixed C57BL/6N x C57BL/6J genetic

475    background.

476

477    Adult $Glra1^{spd-ot}$ mice (*oscillator*, JAX stock #000536) from Jackson Laboratories (Bar

478    Harbor, ME, USA) were transferred to the animal facility of the Institute of Clinical

479    Neurobiology (Würzburg, Germany). Genotyping was done using primer 7:

480    GCCTCCGTGCTTTCTCCCTGC and primer 8: CCAGCCACGCCCCAAAG for the

481    amplification of the mutant $Glra1^{spt-ot}$ (187 bp product) and/or the wild-type alleles (194 bp).

482    *Oscillator* mice were backcrossed into the C57BL/6J background for at least 15 generations.

483    Heterozygous $Glrb^{Eos/WT}$ animals were crossed with heterozygous *oscillator* mice for two

484    generations giving rise to F2 heterozygous *oscillator* animals that are homozygous for the

485    $Glrb^{tm1(Eos4)Ics}$ allele ($Glra1^{+/spd-ot}$/$Glrb^{Eos/Eos}$). These animals had a mixed C57BL/6N x

486    C57BL/6J genetic background and were used for the experiments shown in Fig. 4, 5 and S8.

487

488    All experiments were in accordance with European Union guidelines and approved by the

489    local veterinary authorities. Animals at IBENS were treated in accordance with the guidelines

490    of the French Ministry of Agriculture and Direction Départementale des Services Vétérinaires

491    de Paris (École Normale Supérieure, Animalerie des Rongeurs, license B 75-05-20).

492    Procedures carried out at the Institute for Clinical Neurobiology were approved by the

493    Veterinäramt der Stadt Würzburg and the Committee on the Ethics of Animal Experiments

494    (Regierung von Unterfranken, Würzburg) and authorized under reference numbers 55.2-

495    2531.01-09/14; 55.2.2-2532.2-949-31.

496

497    **Spinal cord and brain tissue preparation and vibratome slices**

498    Mice were sacrificed at 2 and 10 months of age by perfusion with 4% w/v paraformaldehyde

499    (PFA; Polysciences, EM grade) and 0.1% v/v glutaraldehyde (GA; Cliniciences) in

500    phosphate buffered saline (PBS, pH 7.4). Perfused animals were kept on ice for 30 min,

501    followed by the dissection of the brain and spinal cord in PBS. Tissue was post-fixed in 4%

502    w/v PFA in PBS overnight at 4 °C. Brain and spinal cord tissue was rinsed in PBS, cut into

503    smaller segments of thoracic and lumbar regions of the spinal cord and sliced on a vibratome

504    (Leica) at a thickness of 40 μm (for confocal imaging) and 300 μm (for Tokuyasu

505    preparation), and stored in PBS at 4 °C.

506

507    **Confocal imaging and analysis**

508    In order to label the gephyrin in the oscillator and WT littermates, free-floating vibratome

509    slices (40 μm thickness) were blocked and permeabilized in PBS containing 0.25% Triton

510    X100 (Sigma) and 0.1% fish gelatin (Sigma) for 1 h, and immunolabeled with a primary

511    antibody against gephyrin (mouse, mAb7a, 1:500 dilution, Synaptic Systems, #147011) in

512    PBS containing 0.1% Triton X100 and 0.1% fish gelatin overnight, followed by 3 hour

513    incubation with a Cy3-conjugated secondary antibody (goat anti mouse,1:1000, Invitrogen).

514

515    Glass slides (Vector Laboratories) were cleaned with 70% v/v ethanol (Sigma) and vibratome

516    sections were rinsed 3 times in PBS and mounted onto the glass slides. The glass slides were

517    then briefly rinsed in distilled water and dried. A drop of VectaShield (Vector Laboratories)

518    was added to each spinal cord section and covered with a #1.5 glass coverslip, which was

519    sealed with PicoDent Twinsil Speed (equal weights of catalyst and base). Slides were stored

520    at 4 °C for confocal imaging.

521

522    Confocal imaging was carried out on a Leica SP8 TCX microscope using a Leica HC PL

523    APO 40x/1.30 NA oil-immersion objective (Leica) and captured in 8-Bit using the Leica

524    LAS-X software with setting HyD3. Images were captured sequentially, with laser

525    illumination at wavelength 570 nm (mRFP, Cy3) imaged first, followed by laser illumination

526    at 491 nm wavelength (mEos4). A cross-section from the dorsal horn to the ventral horn was

527    imaged at a zoom of 5, speed of 25, 512 x 512 pixel (px) format. For decay analysis, 8

528    consecutive frames were captured at a zoom of 5, speed 25, 512 x 512 px format. To tile the

529    whole spinal cord, images were captured in at a zoom of 1, speed 100, 256 x 256 px format.

530

531    To ensure alignment of the clusters for the decay traces, images were opened in the image

532    analysis software ICY, and the rigid registration plug-in used, taking the first frame of mRFP-

533    gephyrin as reference. The mRFP-gephyrin/ and mEos4b-GlyRβ channels were then

534    separated and the Spot Detector plug-in (de Chaumont et al., 2012) used to identify the

535    clusters in each frame in the mRFP-gephyrin channel, with the identified clusters saved as a

536    region of interest (ROI) set. Using the image analysis software FIJI, the identified mRFP-

537    gephyrin positive cluster ROI-Set was used to identify inhibitory synapses in the first frame of

16

538    the mEos4b-GlyRβ channel. These inhibitory synapses were binned based on mEos4b

539    intensity gray levels (5-12, 13-24, 25-49, 50-74, 75-99, 100-124, 125-255) in frame 1 and a

540    new ROI-Set generated for each bin. Using the frame 1 intensity ROI-Sets, the integrated

541    intensity of mEos4b was then measured at individual clusters across the 8 frames. This

542    enabled decay analysis of mEos4b intensity at synapses relative to their starting intensity, see

543    Fig. 1C.

544

545    In order to analyze the intensity of mRFP-gephyrin and mEos4b-GlyRβ clusters within the

546    spinal cords from mice of different genotypes, the identified mRFP-gephyrin clusters from the

547    first frame of the decay traces (as measured by the ICY Spot Detector plug-in, see above)

548    were used to measure the relative intensity of mRFP-gephyrin and mEos4b-GlyRβ clusters at

549    those locations. The ROI-Set of all mRFP-gephyrin positive clusters was used in FIJI to

550    identify inhibitory synapses, where the integrated intensity of mRFP and mEos4b was

551    measured for each synapse (Fig. 1B).

552

553    For the cross-sectional analysis, the mRFP-gephyrin/gephyrin-7a clusters were identified

554    across the imaged tissue using the ICY Spot Detector plug-in, as described above, and saved

555    as an ROI-Set. In FIJI the integrated intensity of these identified clusters was measured in the

556    mRFP-gephyrin/gephyrin-7a channel and the mEos4b-GlyRβ channel (Fig. 1D and 1F).

557

558    **Cryosectioning of sucrose impregnated spinal cord tissue**

559    Sucrose impregnated cryosections were prepared using a ultracryotomy protocol adapted from

560    (Tokuyasu, 1973). The 300 μm spinal cord vibratome slices were transferred into a 2.3 M

561    sucrose solution in PBS overnight at 4°C and micro-dissected to isolate gray matter of the

562    dorsal and the ventral horn region. These fragments were placed individually on top of drops

563    of sucrose solution on aluminium EM pins (Leica) and immediately frozen in liquid nitrogen.

564    Sections of 2 μm thickness were sliced on an ultramicrotome (Leica EM UC6) at -80°C and

565    placed onto gridded coverslips (type 1.5 H, Ibidi GmbH), covered in PBS, and stored at 4°C

566    for a maximum of 5 days before imaging.

567

568    **Single molecule localization microscopy (SMLM)**

569    Sucrose cryosections on gridded coverslips were rinsed once in PBS, and imaged in PBS.

570    Dual-colour super resolution images were acquired on an inverted Nikon Eclipse Ti

571    microscope with a 100x/1.49 NA oil-immersion objective, with an additional 1.5x lens in the

572      emission path, using an Andor iXon EMCCD camera (16-Bit, 107 nm pixel size), and NIS-

573      Elements software (Nikon). An emission filter 607/36 was chosen for imaging both mRFP-

574      gephyrin and mEos4b-GlyRβ. Brightfield images were taken of the whole grid square

575      identifying tissue structures. Lamp images were taken of the unconverted mEos4b-GlyRβ and

576      mRFP-gephyrin (10 frames of 100 ms, ND8). mRFP-gephyrin movies of 10,000 frames were

577      recorded with HiLo 561 nm continuous laser illumination (output power 50% 400 mW, 50 ms

578      frames). This was followed by 2 min of 100% 561 nm laser illumination to ensure all mRFP-

579      gephryin was bleached. Movies of 25,000 frames were recorded with photoconversion of

580      mEos4b-GlyRβ by 0.5 ms pulsed 405 nm laser illumination (gradually increased to 100% by

581      frame 22,000) with continuous 561 nm laser illumination (output power 50% 400 mW, 50 ms

582      frames). The focal plane was maintained using a Nikon perfect focus system.

583

584      **SMLM image analysis (SRRF and PALM)**

585      Frames 100-6000 of the mRFP-gephyrin movies were taken for analysis (to remove saturated

586      frames at the beginning and bleached frames at the end) and were drift corrected and

587      reconstructed using SRRF plugin for FIJI (Gustafsson et al., 2016).

588      Quantification of mEos4b-GlyRβ was carried out using a lab script for MATLAB

589      (Mathworks). The mEos4b single fluorophores were detected by Gaussian fitting. The

590      resulting pointillist images were drift corrected in the x/y plane using 5 dense clusters of

591      detections over a sliding window of 2000 frames. Rendered images were produced with a

592      pixel size of 10 nm, sigma 0.01.

593

594      The mRFP-gephyrin and mEos4b-GlyRβ rendered images were aligned by rigid registration

595      using the FIJI plug-in TurboReg. The co-localization of mRFP-gephyrin and mEos4b-GlyRβ

596      was carried out by individually cropping each synapse as separate images. The FIJI plug-in

597      Intensity correlation quotient (ICQ) was then applied to each synapse (Li et al., 2004). The

598      occupancy analysis was analyzed by thresholding the synapses in the mEos4b-GlyRβ images

599      and measuring the intensity of each synapse in both channels. To analyse the PALM mEos4b-

600      GlyRβ clusters, a lab written script for MATLAB (CountMol; (Patrizio et al., 2017)) was used

601      to identify synapses (minimum number of detections 250, minimum cluster size 200 nm,

602      maximum cluster size 3000 nm) and an intensity threshold of 0.1. For molecule conversion,

603      CountMol was used to identify extrasynaptic receptor complexes (minimum number of

604      detections 5, minimum cluster size 10 nm, maximum cluster size 120 nm). The number of

605      detections per burst (identified as a minimum of 2 detections, with 1 burst per 1000 frames)

18

606  and the probability of detection $P_{det} = (1 - \frac{N_1/N_2}{2+N_1/N_2})$ were calculated, and used to convert

607  the detections to mEos4b-GlyRβ molecules (Durisic et al., 2014; Patrizio et al., 2017).

608

**Electron microscopy (EM)**

610  Cryosections used for SMLM imaging on gridded coverslips were postfixed by incubation in

611  1% osmium tetroxide for 1 h at 4 °C, dehydrated in graded ethanol concentrations, and

612  embedded in araldite epoxy resin. Grid squares imaged in SMLM were identified using the

613  grid pattern imprinted in the resin. Serial ultra-thin 70 nm sections of these regions were cut,

614  transferred onto formvar-coated EM grids (0.432 mm slot grids) using a UC6 ultramicrotome

615  (Leica). Sections were counterstained with 5% uranyl acetate in 70% methanol for 10 min,

616  then washed in distilled water and air dried before observation on a Philips TECNAI 12

617  microscope (Thermo Fisher Scientific).

618

619  For 3D synapse reconstruction, synapses were manually outlined in each serial section image

620  using FIJI, followed by manual rotation and coarse alignment using the software GIMP, then

621  fine alignment of the synaptic area with the Microscopy Image Browser (MIB) software. The

622  aligned images were then opened in IMOD software to generate the 3D reconstruction.

623

624  The length of the PSD of identified synapses was measured in high magnification EM images

625  with ImageJ software. The total PSD area was calculated as the cumulative length of the PSD

626  in the entire stack of serial sections multiplied by the thickness of each section (70 nm). The

627  segmentation index is the number of gaps in the PSD that were detected in the x/y plane of the

628  images or along the z-axis (i.e. an interruption of the PSD in one or several continuous

629  sections in the stack), and represents an estimate of the morphological complexity of the

630  synapse.

631

**Graphing and statistical analysis**

633  All graphing and statistical analysis was carried out using the software GraphPad Prism v.8.

634  Data were tested for normality of distribution using D'Agostino-Pearson and Kolmogorov-

635  Smirnov tests. Data is represented as dot plots with median ± interquartile range (IQR), or

636  histograms, unless otherwise stated. *p < 0.05, ** p < 0.01, *** p < 0.001, ns = not

637  significant.

777  **Figures and Legends**
778

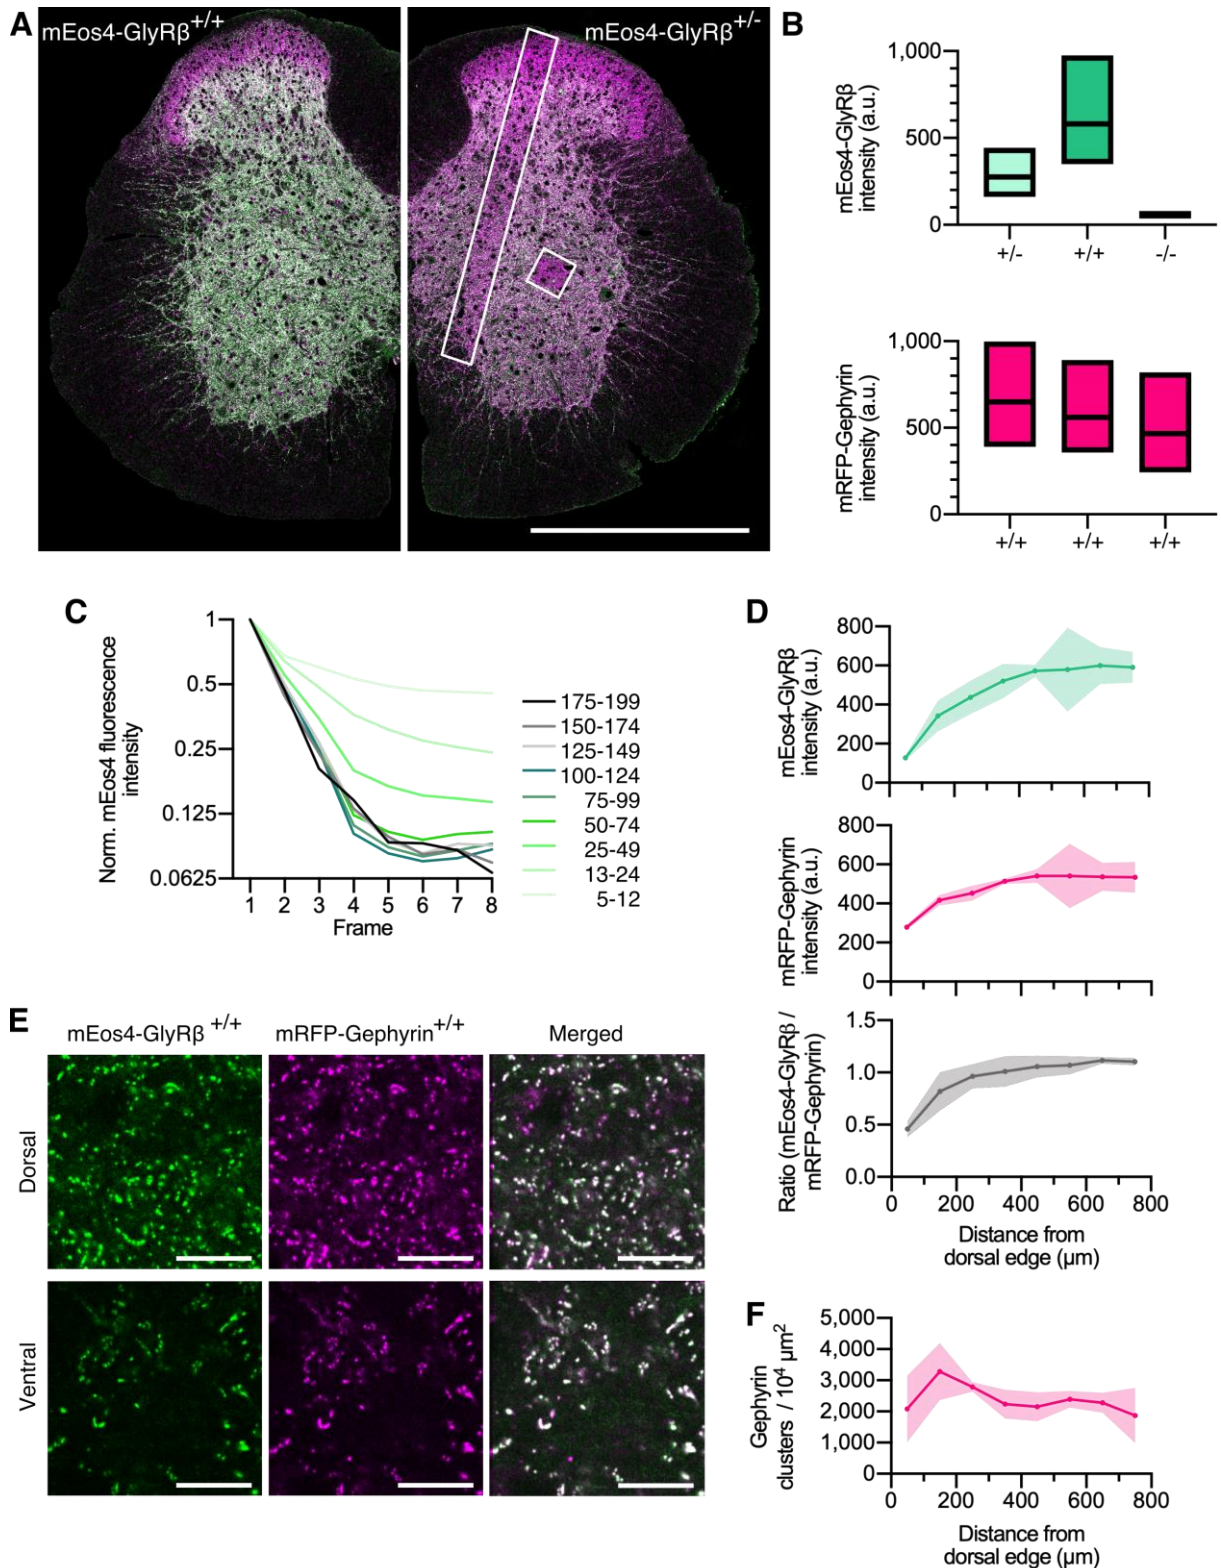

779
780
781  **Fig. 1. Quantitative confocal imaging.** (A) Representative confocal images of 40 μm spinal
782  cord tissue sections from homozygous (+/+) and heterozygous (+/-) mEos4b-GlyRβ mice
783  (green). Both mice are homozygous for mRFP-gephyrin (magenta). Scale bar = 0.5 mm. (B)
784  Quantification of mEos4b-GlyRβ and mRFP-gephyrin fluorescent intensity of homozygous
785  and heterozygous 2 month old animals. Plots show median and quartiles. N = 5 images per

23

786   condition. (C) Normalized fluorescent decay traces of homozygous mEos4b measured in the
787   area indicated by the white square in (A) over 8 consecutive frames. Intensities were binned
788   in the first image and tracked on an individual synapse basis across the 8 frames. (D) Mean
789   intensity ± 95% confidence interval of mEos4b-GlyRβ and mRFP-gephyrin measured from
790   distal edge of spinal cord in 2 month old homozygous mice. Intensities measured in region as
791   indicated by white rectangle in (A). N = 3 images. (E) Representative images of homozygous
792   mEos4b-GlyRβ and mRFP-gephyrin at dorsal and ventral synapses. Scale bar = 10 μm. (F)
793   Quantification of numbers of gephyrin clusters across the spinal cord. Plot shows mean ±
794   95% confidence interval. N = 3 images.
795
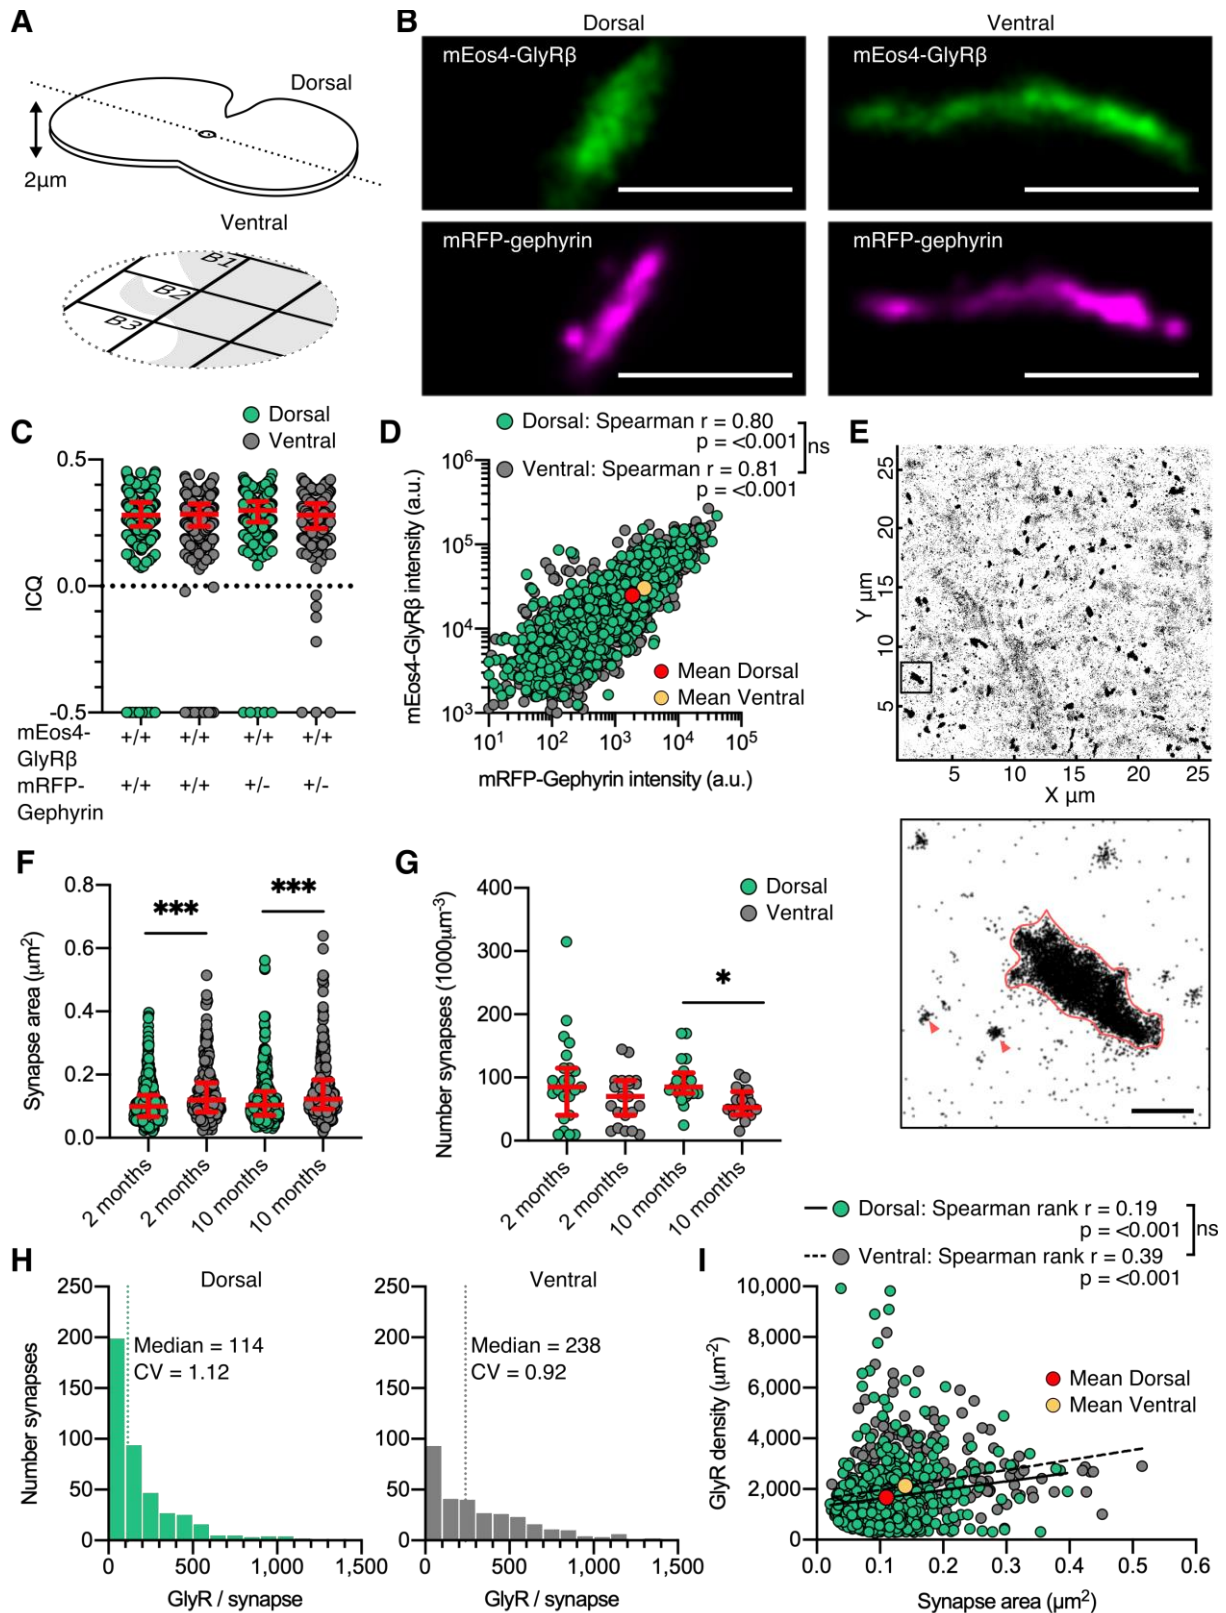

**Fig. 2. Dual-color super-resolution imaging.** (A) 2 μm cryosections of spinal cord tissue were cut from dorsal and ventral tissue and placed on gridded glass coverslips. (B) Representative SMLM reconstruction of mEos4b-GlyRβ and SRRF reconstruction of mRFP-gephyrin at single dorsal and ventral synapses. Scale bar = 500 nm. (C) Intensity correlation quotient (ICQ) of mEos4b-GlyRβ and mRFP-gephyrin in heterozygous and homozygous 2

803    month old mice. N = 357-604 synapses from 22 dorsal and 22 ventral images. (D)

804    Quantification of GlyR-gephyrin occupancy. Non-parametric Spearman's rank shows the

805    same positive correlation at dorsal and ventral synapses. (E) Pointillist reconstruction of

806    mEos4b-GlyRβ detections. Insert shows a single synapse; red arrows indicate extrasynaptic

807    receptor complexes. Scale bar = 500 nm. (F) Area of dorsal vs ventral synapses in 2 and 10

808    month old homozygous mice. N = 234-433 synapses. Nonparametric Kruskal Wallis ANOVA

809    with Dunn's multiple comparison test. (G) Number of synapses in dorsal and ventral tissue in

810    2 and 10 month old homozygous mice. N = 20-23 images. Nonparametric Kruskal Wallis

811    ANOVA with Dunn's multiple comparison test. (H) Histogram of the number of GlyRs per

812    synapse calculated from the molecular conversion of detections (see Fig. S4 and S5). N = 433

813    dorsal synapses and 304 ventral synapses. CV = coefficient of variation. (I) Scatter plot of

814    GlyR density vs synapse area shows no difference between dorsal and ventral synapse

815    densities. N = 433 dorsal synapses and 304 ventral synapses. *$p < 0.05$, **$p < 0.01$, ***$p <$

816    $0.001$.

817
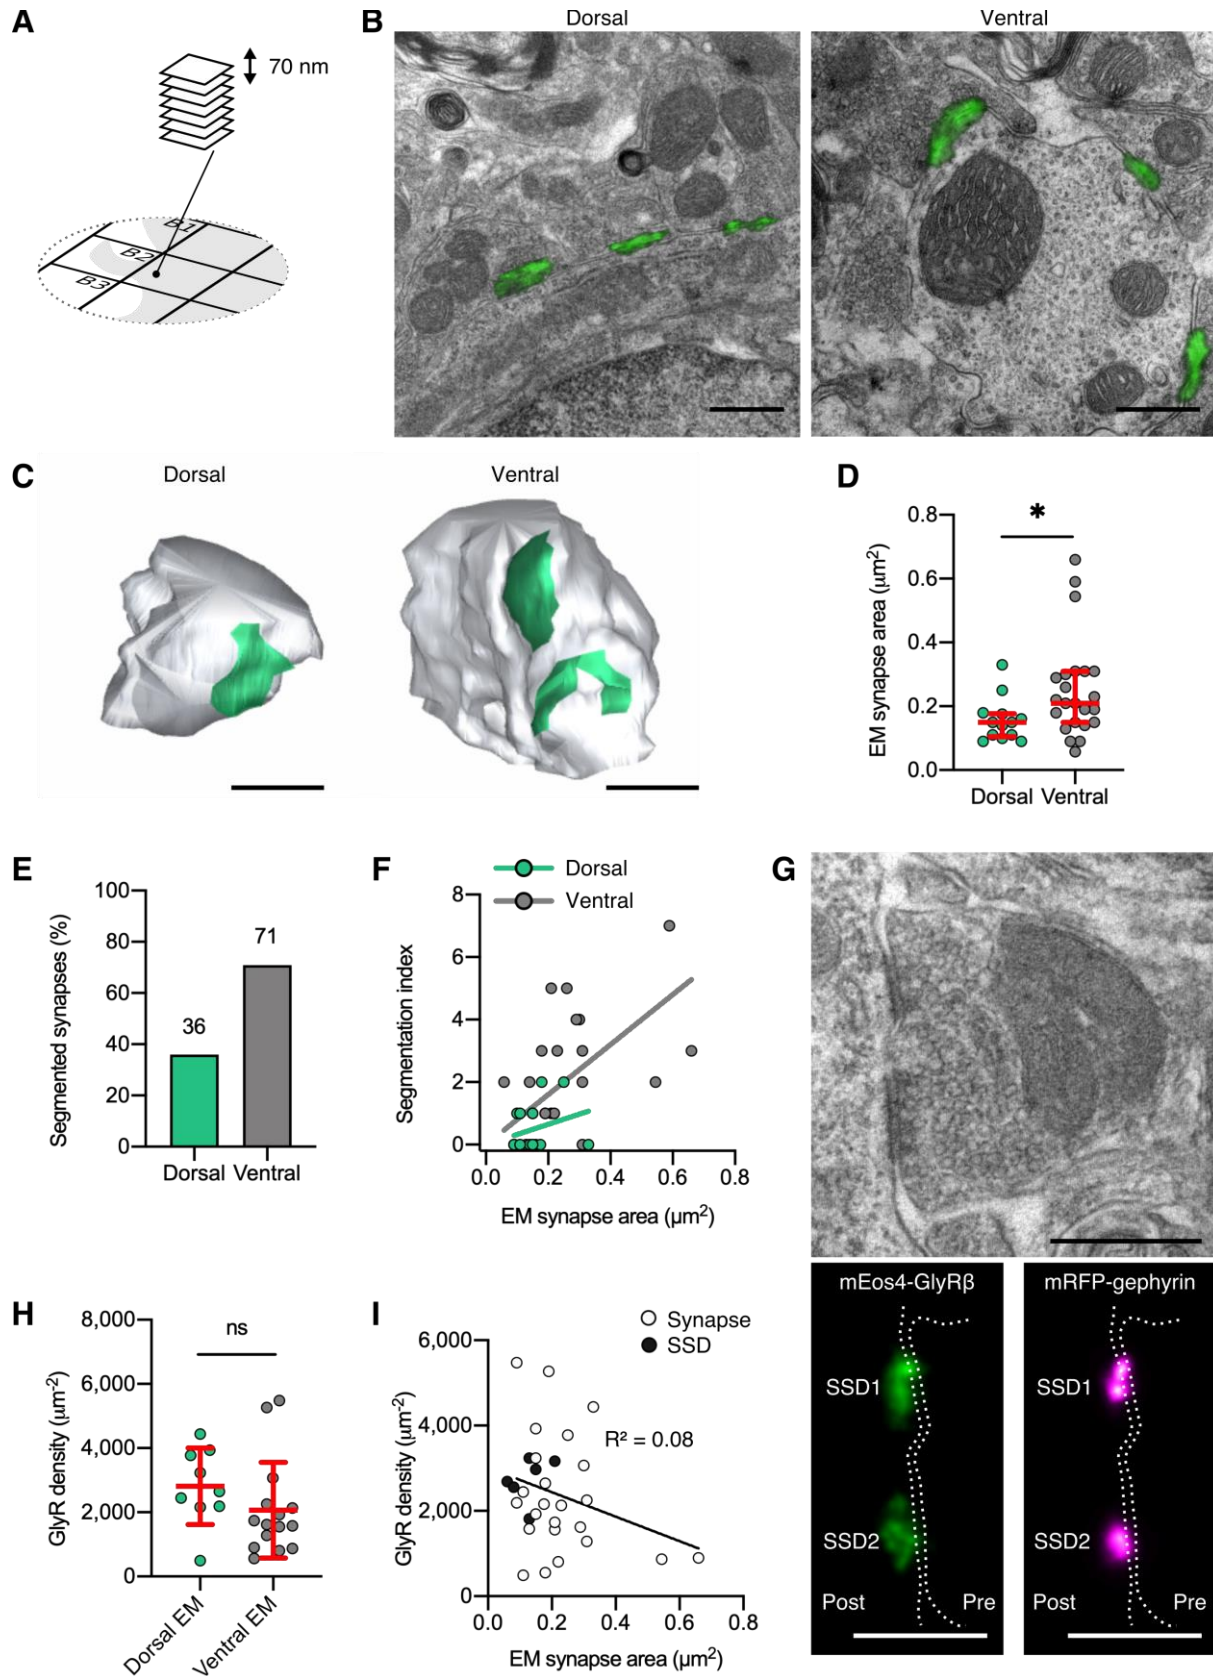

**Fig. 3. Quantitative SR-CLEM.** (A) Samples used for PALM were re-sectioned as serial ultra-thin 70 nm sections for CLEM. (B) Representative dorsal and ventral synapses imaged with PALM (green) and super-imposed with their corresponding electron micrographs. Scale bar = 500 nm. (C) Representative 3D reconstructions of dorsal and ventral synapses. Green =

824 PSD, gray = presynaptic bouton. Scale bar = 500 nm. (D) Area of dorsal and ventral synapses
825 measured by EM. Nonparametric unpaired two-tailed t-test, Mann-Whitney post hoc. (E)
826 Percentage of total synapses measured in EM with segmented shapes. (F) Comparison of
827 segmentation index with synaptic area in dorsal and ventral synapses. (G) Juxtaposition of a
828 raw electron micrograph and reconstructed PALM/SRRF images of sub-synaptic domains
829 (SSDs) in the same ventral synapse. Scale bar = 500 nm. (H) Analysis of GlyR density
830 following correction for EM area measurements. (I) Combined scatter plot of dorsal and
831 ventral synapse densities shows density is independent of synapse size. White = all synapses,
832 black = SSDs. N = 13 dorsal and 23 ventral synapses. $*p < 0.05$, ns = not significant.
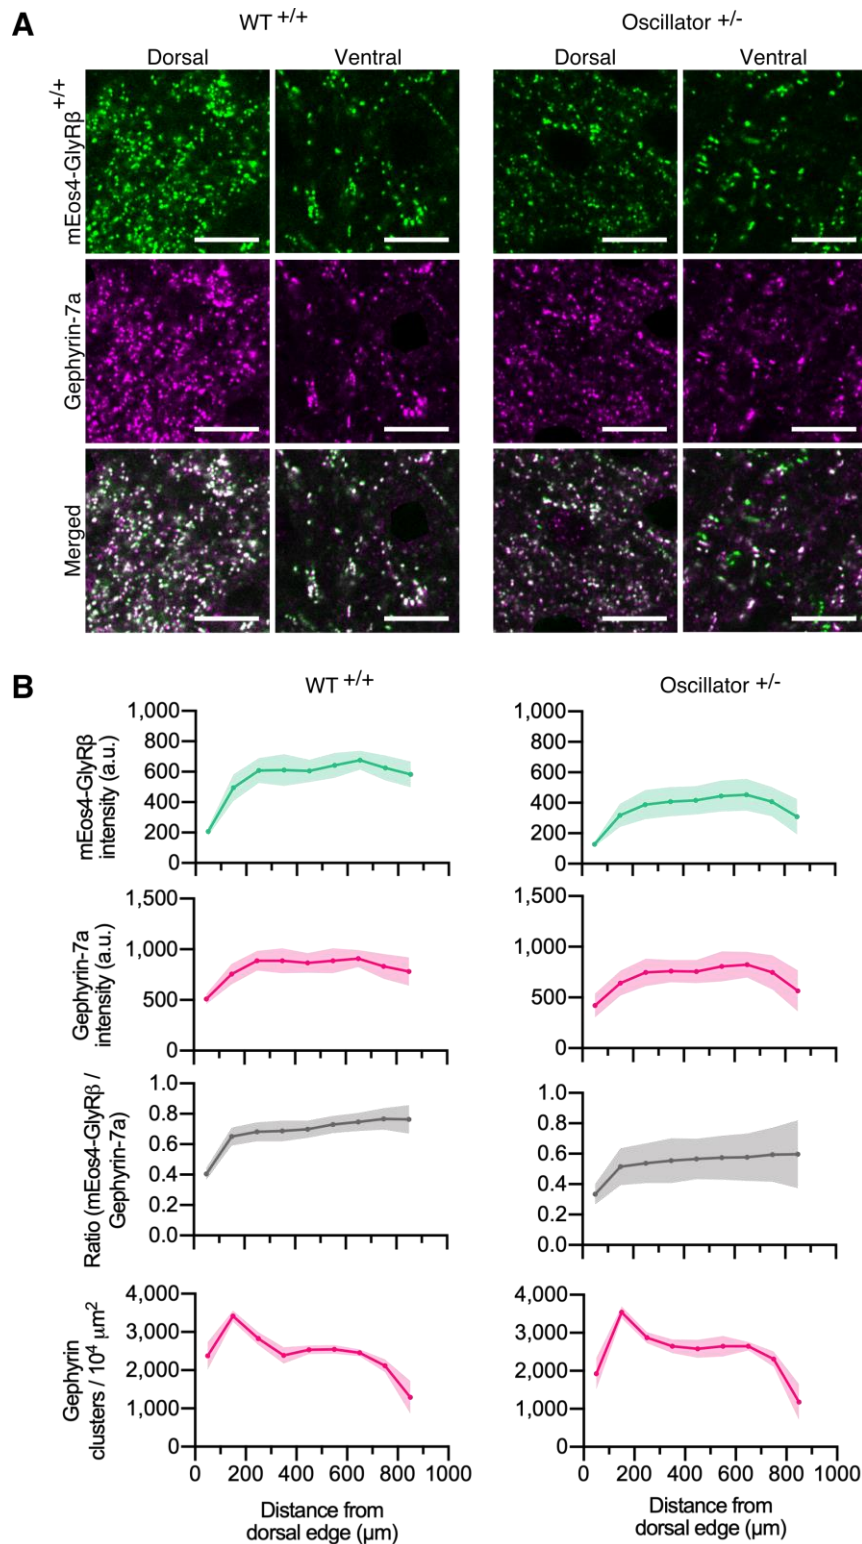

833
834
835 **Fig. 4. Quantitative confocal imaging of the *oscillator* mouse model.** (A) Representative
836 confocal images of dorsal and ventral synapses from heterozygous *oscillator* mice (+/-)
837 compared to homozygous WT (+/+) littermates. All mice are homozygous for mEos4b-GlyRβ
838 (green), with gephyrin-7a immunolabeling (magenta). Scale bar = 10 μm. (B) Mean intensity
839 ± 95% confidence interval of mEos4b-GlyRβ and gephyrin-7a at gephyrin-positive puncta,
840 and numbers of gephyrin clusters measured from distal edge of spinal cord in 2 month old
841 mice. N = 9-11 images per genotype.

842

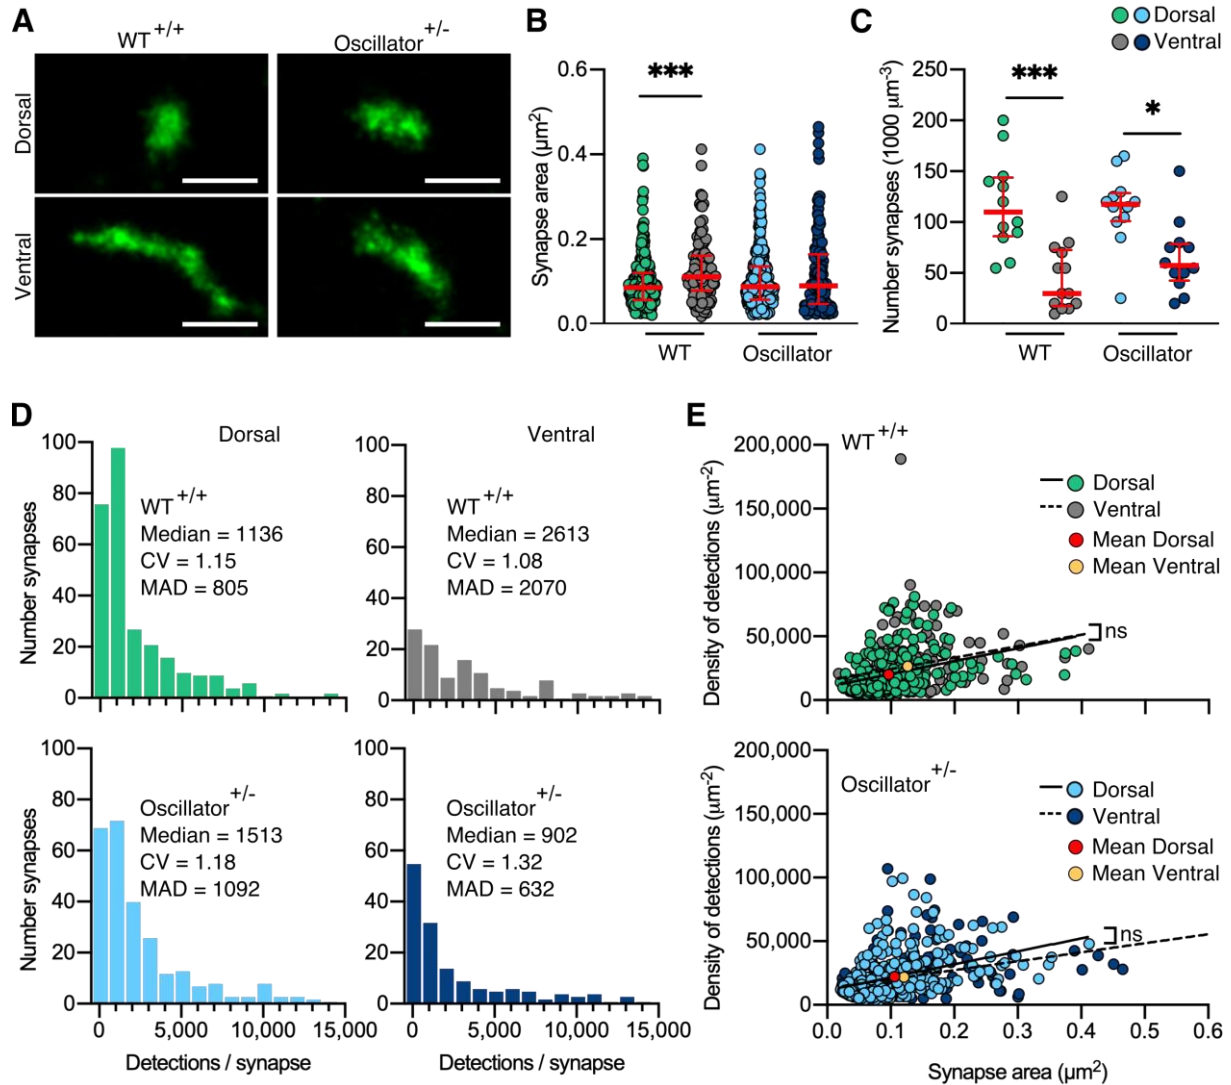

843
844
845 **Fig. 5. PALM imaging of the GlyR in the *oscillator* mouse model.** (A) Representative
846 PALM reconstructions of mEos4b-GlyRβ at single dorsal and ventral synapses in
847 heterozygous (+/-) *oscillator* and homozygous (+/+) WT littermates. Scale bar = 500 nm. (B)
848 Area of dorsal vs ventral synapses in heterozygous *oscillator* vs WT littermates. N = 120-282
849 synapses. Nonparametric Kruskal Wallis ANOVA with Dunn's multiple comparison test. (C)
850 Number of synapses in dorsal and ventral tissue in heterozygous *oscillator* vs WT mice. N =
851 12-13 images. Parametric one-way ANOVA with Tukey's multiple comparison test. (D)
852 Histogram of the number of mEos4b detections per synapse. N = 282 WT dorsal and 120
853 ventral synapses, 273 *oscillator* dorsal and 156 ventral synapses. CV = coefficient of
854 variation, MAD = median absolute deviation. (E) Scatter plots of mEos4 detection density vs
855 synapse area shows no difference between dorsal and ventral synapse densities in *oscillator*.
856 N = same as in (D). *p < 0.05, ***p < 0.001, ns = not significant.
857
