Abstract:

C-type inactivation is a process by which ion flux through a voltage-gated K⁺ (Kᵥ) channel is regulated at the selectivity filter. While prior studies have indicated that C-type inactivation involves structural changes at the selectivity filter, the nature of the changes have not been resolved. Here we report the crystal structure of the Kᵥ1.2 channel in a C-type inactivated state. The structure shows that C-type inactivation involves changes in the selectivity filter that disrupt the outer two ion binding sites in the filter. The changes at the selectivity filter propagate to the extracellular mouth and the turret regions of the channel pore. The structural changes observed are consistent with the functional hallmarks of C-type inactivation. This study highlights the intricate interplay between K⁺ occupancy at the ion binding sites and the interactions of the selectivity filter in determining the balance between the conductive and the inactivated conformations of the filter.
Introduction:

Voltage gated K⁺ channels (Kᵥ) are essential for the generation and conduction of electrical signals by neurons, muscle and endocrine cells. Kᵥ channels are tetrameric proteins that contain a central pore domain and peripheral voltage sensor domains (VSD, Fig.1a). The pore domain houses the pathway for K⁺ ions across the membrane (Fig. 1b). The activation of a Kᵥ channel takes place upon membrane depolarization and involves an outward movement of the VSDs. This movement of the VSD is coupled to the opening of pore domain to turn on the K⁺ flux across the membrane. On sustained activation, the flux of K⁺ through the Kᵥ channel is turned off through mechanisms that are referred to as inactivation.

In the Shaker family of Kᵥ channels, there are two types of inactivation, N-type and C-type. In N-type inactivation, the N-terminus of the channel binds to the open pore domain and occludes the ion pathway. Shaker channels with the N-terminal deleted do not undergo N-type inactivation but inactivate through a different mechanism called C-type inactivation. This mechanism is also referred to as slow inactivation as the timescale is generally slower, on the order of seconds, compared to the millisecond time scale observed for N-type inactivation. C-type inactivation is a physiologically important process that can regulate cell excitability by determining channel availability.

The mechanism of C-type inactivation has been investigated using functional, spectroscopic, structural and computational approaches. All these approaches suggest that C-type inactivation involves changes at the selectivity filter. The selectivity filter refers to the narrow region of the ion pathway in the pore domain, where selection for K⁺ takes place (Fig. 1c). The selectivity filter consists of a row of K⁺ binding sites (called S1-S4 extracellular – intracellular) that are constructed from the main chain carbonyl atoms and the threonine side chain from the protein sequence T-V-G-Y-G.

The structures of the selectivity filter of K⁺ channels are highly conserved. The structures determined mainly show the selectivity filter in a conductive state, the state of the selectivity filter that supports the flux of K⁺ through the channel. During C-type inactivation, there are structural changes at the selectivity filter that convert the selectivity filter from a conductive to a non-conductive conformation.

Understanding the mechanism of C-type inactivation requires the structure of the selectivity filter in the C-type inactivated state. The structure of a non-conducting mutant of the Kᵥ1.2 channel has been proposed to show the selectivity filter in the C-type inactivated state. However, the structural changes observed were minimal, which raises a question on
whether this structure truly represents the C-type inactivated state. Other structural studies on C-type inactivation have used the K⁺ channel KcsA. KcsA does not belong to the Kv family but undergoes an inactivation process that bears some functional similarity to C-type inactivation in Kv channels. Structural studies on the KcsA channel under conditions that favor inactivation show a constriction of the selectivity filter. However, the relevance of this constricted conformation to C-type inactivation in Kv channels has been debated.

Here we report the crystal structure of the Kv1.2 channel in the C-type inactivated state. We carry out structural studies on a mutant of the Kv1.2 channel that shows a vastly increased rate of C-type inactivation. We observe that C-type inactivation involves a dilation of the outer ion binding sites of the selectivity filter along with changes in the extracellular mouth and the turret regions of the pore domain. Our studies highlight the selectivity filter interactions that are important for C-type inactivation and suggest a molecular pathway for this process.

Results:

C-type inactivation in the Kv1.2-2.1 channel.

Our strategy for determining the structure of the Kv1.2 channel in the C-type inactivated state was to use mutants of this channel that show an enhanced rate of inactivation with the expectation that these mutants will trap the selectivity filter in the C-type inactivated state. In the Shaker channel, the W434F substitution dramatically increases the rate of inactivation and this substitution has been extensively used in functional studies to mimic the C-type inactivated state. The corresponding mutation, W366F in the Kv1.2 channel has been shown to have an increased rate of inactivation (Supplementary fig. 1). For our studies, we used a variant of the Kv1.2 channel referred to as the Kv1.2-2.1 chimera (referred henceforth as Kv1.2-2.1) as this construct affords crystals that diffract to a higher resolution. In the Kv1.2-2.1 channel, residues 267-302 in the S3-S4 loop in the voltage sensor domain are substituted by residues 274-305 of the Kv2.1 channel. The Kv1.2-2.1 channel shows similar functional properties to the Kv1.2 channel and the W362F (equivalent to W366F in Kv1.2) substitution in the Kv1.2-2.1 channel shows a similar enhancement in the rate of inactivation (Fig. 1d).

Our attempts at structural studies of the Kv1.2-2.1-W362F channel were stymied as the channel showed poor expression and suboptimal biochemistry (Fig. 1e). We therefore screened for additional amino acid substitutions that improved protein expression and
biochemical behavior while maintaining an enhanced rate of C-type inactivation. These efforts identified a construct with two additional substitutions, S367T and V377T, which exhibited good biochemical behavior and an enhanced rate of inactivation (Fig. 1d, e). We refer to the Kv1.2-2.1 channel with the W362F, S367T and V377T substitutions as the Kv1.2-2.1-3m channel. At high K⁺, the Kv1.2-2.1-3m channel showed a ~2000-fold increase in the rate of C-type inactivation while at low external K⁺, the rate of C-type inactivation was very fast and could not be accurately determined. Based on the rapid rate of inactivation, we anticipated that the crystal structure of the Kv1.2-2.1-3m channel would reveal the selectivity filter in the C-type inactivated state.

**Structure of the Kv1.2-2.1-3m channel.** For structural studies, the Kv1.2-2.1-3m channel was co-expressed with the beta subunit and the channel-beta complex was crystallized in the presence of 150 mM K⁺. We obtained crystals of the same space group (P4 2₁ 2) as reported for the Kv1.2-2.1 channel but with slightly altered unit cell parameters.(3) Data from multiple crystals were combined to obtain a complete data set to 3.35 Å resolution and the structure was determined by molecular replacement using the Kv1.2-2.1 (pdb: 2r9r) channel structure as the model (Supplementary table 1). There are two copies (molecule I and II) of the channel-beta complex in the asymmetric unit. The beta subunit and the T1 domain in both molecules were well resolved while the transmembrane region in molecule I was better resolved than in molecule II. For the transmembrane region, we observed stronger electron density for the pore domain compared to the voltage sensor. Within the pore domain, the electron density for Y373-D375 was weaker compared to the neighboring residues and electron density for the carbonyl group for the G374 residue was not observed. Electron density corresponding to the pore helix and the selectivity filter are shown in figure 2a, b. In the voltage sensor domain, the electron density was sufficient for modelling the transmembrane segments (Supplementary fig. 2) while electron density for the loops connecting the TM segments and the linker connecting the T1 domain to the first transmembrane segment were not observed and these regions were therefore not modelled. A superposition of the various domains in the Kv1.2-2.1-3m channel to Kv1.2-2.1 channel shows that the structural changes observed are mainly in the selectivity filter region and in the extracellular mouth of the pore (Supplementary fig. 3).
**The selectivity filter in the K\(_{\text{v}1.2-2.1-3m}\) channel.** A comparison of the selectivity filter in K\(_{\text{v}1.2-2.1-3m}\) to the wild type channel shows substantial changes in the sidechain and backbone conformations (Fig. 2c, d). A major change observed is a reorientation of the Tyr side chain (Fig. 2e, f). In the K\(_{\text{v}1.2-2.1}\) channel, the Tyr side chain interacts with the Trp363 and Ser 367 of the adjacent subunit while in the K\(_{\text{v}1.2-2.1-3m}\) channel, these H-bond interactions are broken and the Tyr side chain undergoes a 77° rotation and the hydroxyl group in the Tyr side chain is now oriented towards the extracellular surface.

Another major change observed in the K\(_{\text{v}1.2-2.1-3m}\) channel is a flip of the Asp375 side chain (Fig. 2g, h). In the K\(_{\text{v}1.2-2.1}\) structure, Asp375 forms an H-bond with Trp362 in the pore helix. This H-bond is disrupted in the K\(_{\text{v}1.2-2.1-3m}\) channel due to the W362F substitution. The Asp375 side chain is now oriented towards the extracellular solution and forms a H-bond with Thr377 in the adjacent subunit (distance of 3.32 Å). The K\(_{\text{v}1.2-2.1}\) channel has a Val at this position, which is substituted by Thr in the K\(_{\text{v}1.2-2.1-3m}\) channel. The flip of the Asp side chain as observed changes the side chain from being oriented towards the channel interior (in K\(_{\text{v}1.2-2.1}\)) to facing the extracellular solution.

The changes in the Tyr373 and Asp375 side chain conformations cause a widening of the selectivity filter towards the extracellular side. Due to this widening, the S1 and S2 ion binding sites are disrupted and instead form a vestibule (Fig. 2c, d). In K\(_{\text{v}1.2-2.1}\), K\(^+\) binding is observed at the S1 and the S2 sites while in the K\(_{\text{v}1.2-2.1-3m}\) channel only a weak electron density is observed in this vestibule region (Fig. 2b, Supplementary fig. 4). The electron density in vestibule region can correspond either to a low occupancy K\(^+\) ion or a water molecule. The distances between the carbonyl oxygens in the vestibule region are however too large to tightly coordinate either a water or a K\(^+\) ion. In contrast to the changes seen at the S1 and the S2 sites, the S3 and the S4 sites in the K\(_{\text{v}1.2-2.1-3m}\) filter are well superimposed on the corresponding sites in the K\(_{\text{v}1.2-2.1}\) filter and electron density corresponding to ion binding at these sites is observed. Previous studies have implicated the outer sites in the selectivity filter in C-type inactivation (24, 25) and the K\(_{\text{v}1.2-2.1-3m}\) structure indicates that inactivation involves a disruption of the S1 and the S2 sites in the selectivity filter. A key characteristic of C-type inactivation is a dependence on the extracellular K\(^+\) concentration. (26, 27) The structure suggests that extracellular K\(^+\) is protective for the filter against C-type inactivation as higher extracellular K\(^+\) concentration will increase the ion occupancy at the S1/S2 sites to prevent the dilation of these sites.
Changes in the extracellular mouth of the Kv1.2-2.1-3m pore. The changes in the selectivity filter in the Kv1.2-2.1-3m structure are propagated to the loop region linking the selectivity filter to TM6 (Fig. 3a). The changes observed in this region are mainly due to the repositioning of the Asp375 side chain (Fig. 3b,c). Studies on the Shaker K+ channel have suggested that residues corresponding to 376-378 in the Kv1.2-2.1-3m channel change accessibility on C-type inactivation. Studies on Shaker have also shown that a Cys substitution at 448 (376 in Kv1.2-2.1-3m) exhibits an enhanced rate of formation of a disulfide bond while a Cys substitution at 449 (377 in Kv1.2-2.1-3m) can form a high affinity metal (Cd²⁺ or Zn²⁺) binding site in the inactivated state. Comparison of the 376-378 region in the Kv1.2-2.1-3m to the Kv1.2-2.1 shows an increase in surface exposure of these residues (Supplementary fig. 5), which may underlie the changes in modification observed (for Cys substitutions at these sites) on C-type inactivation. In the Kv1.2-2.1-3m structure, the Cα-Cα distance between the 376 sidechains in the adjacent subunits is similar to the distance observed in the Kv1.2-2.1 structure (Fig. 3b, c). The Kv1.2-2.1-3m structure therefore does not account for the enhanced rate of disulfide bond formation by Cys 376 in the C-type inactivated state. Similarly, the change in the Cα-Cα distance of the 377 sidechains in these structures is 0.51 Å (14.06 to 13.55 Å), and this distance is still longer than expected for the formation of a metal coordination site by the Cys 377 sidechains from adjacent subunits. The Kv1.2-2.1-3m channel structure therefore does not directly account for some of the changes in the extracellular mouth of the pore on C-type inactivation as inferred from the functional studies. One possibility is that the full extent of changes in the extracellular mouth of the pore on C-type inactivation are not revealed in the Kv1.2-2.1-3m structure. Another possibility is that these experimental findings reflect greater flexibility in the extracellular mouth of the channel in the C-type inactivated state. An increased flexibility in the extracellular mouth on C-type inactivation could explain the poor electron density observed in the Y373-D375 region in the Kv1.2-2.1-3m channel.

C-type inactivation also involves changes in the turret region present between TM5 and the pore helix. Fluorescent probes introduced into the turret region show a change in fluorescence on C-type inactivation. We see structural changes in the turret region of the Kv1.2-2.1-3m corresponding to the sites of introduction of the fluorescence probes (Fig. 3a). A key interaction that is altered in the Kv1.2-2.1-3m channel is that of the E346 residue, which is towards the top of TM5 (Fig. 3d, e). Mutations at this Glu (E418 in the Shaker channel) increase the rate of inactivation. In the Kv1.2-2.1 channel, E346 interacts with the pore-S6 loop region of the channel through H-bond interactions with the protein backbone of Thr379.
and the side chain of Thr380. In the Kv1.2-2.1-3m structure, we observe a change in the E346 side chain conformation and correspondingly the interactions of the E346 side chain with the T379-T380 residues are altered.

Structure of the Kv1.2-2.1-W362F, S367T channel.

To test the importance of the interaction between Asp375 and Thr377 for C-type inactivation, we investigated the functional properties of a Kv1.2-2.1 channel with the native Val at 377 along with the W362F and S367T substitution (referred to as Kv1.2-2.1-2m). We observed that the inactivation was slow in this mutant compared to the very rapid inactivation observed in the Kv1.2-2.1-3m channel. Inactivation in the Kv1.2-2.1-2m channel was similar to the inactivation observed in the Kv1.2-2.1 channel (Fig. 4a). We crystallized and determined the structure of the Kv1.2-2.1-2m channel at 150 mM K+ (Fig. 4b, Supplementary table 1). In the Kv1.2-2.1-2m structure, we observed the selectivity filter in a conductive conformation as anticipated based on the similarity of the inactivation properties of the Kv1.2-2.1-2m to the Kv1.2-2.1 channel (Fig. 4c). These findings suggest a role for the inter-subunit Asp375-Thr377 interaction in stabilizing the selectivity filter in the C-type inactivated state. The equivalent position in the Shaker channel (Thr449) is an important locus for C-type inactivation and substitution of T449 in the Shaker channel with Val results in a non-inactivating phenotype.(26) Our studies suggests that substitutions at this site affect C-type inactivation through an effect on the interaction with the Asp residue.

Discussion:

Here we report the structure of the Kv1.2 channel in the C-type inactivated state (Fig. 5a). The structure shows that the C-type inactivation involves a dilation of the selectivity filter at the S1 and S2 ion binding sites, which is caused by structural changes at the conserved Tyr and Asp side chains. The disruption of the S1 and the S2 ion binding sites of the filter perturbs K+ flux through the channel. The structure shows that the changes in the selectivity filter on C-type inactivation are propagated to the extracellular mouth and the turret region of the pore domain of the channel. The structure of the selectivity filter in the C-type inactivated state is consistent with the dilation model for inactivation previously proposed by Hoshi and Armstrong.(9)
Based on our structural studies, we propose the following transitions at the selectivity filter during C-type inactivation (Fig. 5b). The process initiates with a loss of ion occupancy at the S1 and S2 sites in the selectivity filter. The loss of ion occupancy causes a flip of 1’ and the 2’ carbonyl groups, which is accompanied by a rotation of the Tyr373 side chain. The movement of the Tyr side chain sets up a clash with the Asp375 sidechain and as a result, the Asp375-Trp362 H bond interaction is broken and the Asp side chain switches to facing the extracellular side. Asp375 in this conformation is stabilized by an interaction with Thr377. This change in the conformation of Asp375 flips the 0’ carbonyl group. The changes in the 0’ – 2’ carbonyl groups result in a dilation of the S1 and the S2 sites in the selectivity filter, which prevents ion coordination at these sites and thereby affects ion conduction through the channel. The changes in the Tyr and the Asp side chain also change the surface accessibility and dynamics in the filter-TM6 region. These changes are also transmitted to the pore turret through changes in the interaction of E346 with the filter-TM6 loop. Through this process, structural changes that are initiated by changes in ion occupancy at the selectivity filter are propagated throughout the selectivity filter and the extracellular mouth of the pore.

A structure of the Kv1.2-2.1-V406W channel has been reported as presenting the selectivity filter in the C-type inactivated state (Supplementary fig. 6).(14) The structural change observed in the selectivity filter, compared to the conductive state, is a small distortion of the S1 site.(15) This is in contrast to the abrogation of the S1 and S2 sites observed in the Kv1.2-2.1-3m structure. The proposed inactivated state in the KcsA channel shows a distortion of the S2 and the S3 sites of the selectivity filter and is distinct from the structure of the selectivity filter in the Kv1.2-2.1-3m channel (Supplementary fig. 6). Gating of K+ flux through two-pore K+ (K2P) channels takes place at the selectivity filter by a mechanism that shares a functional resemblance to C-type inactivation in Kv channels.(35) A recent structural study on the TREK-1 K2P channel suggested that the gating process involves a loss of the S1 and the S2 ion binding sites in the selectivity filter while a structure of the TASK 2-P K+ channel indicated a loss of the S1 (and potentially the S0) binding site in the inactivated state.(36, 37) These structures suggest that K+ channels, which have essentially identical selectivity filters, can have distinct mechanisms of inactivation or gating at the selectivity filter.

C-type inactivation is widespread in the Kv channel family with the inactivation properties that are tuned for the specific physiological roles of these channels. Structural studies of these other Kv family members will be necessary to determine whether conformational changes similar
to that observed in the Kv1.2-2.1-3m structure underlie inactivation or gating at the selectivity filter in diverse Kv channels.
