Abstract

The transition to independent foraging represents an important developmental stage in the life cycle of most vertebrate animals. Juveniles differ from adults in various life history traits and tend to survive less well than adults in most long-lived animals. Several hypotheses have been proposed to explain higher mortality including that of inadequate/inferior foraging skills compared to adults, young naïve individuals combining lack of experience and physical immaturity. Thus a change in behaviour, resulting in an improvement of skills acquired from growing experience, is expected to occur during a period of learning through the immaturity phase. Very few studies have investigated the ontogeny of foraging behaviour over long periods of time, particularly in long-lived pelagic seabirds, due to the difficulty of obtaining individual tracking data over several years. We investigated the foraging behaviour, through activity patterns, during the three life stages of the endangered Amsterdam albatross by using miniaturized activity loggers on naïve juveniles, immatures and adults. Naïve juveniles during their first month at sea after leaving their colony exhibited lower foraging effort (greater proportion of time spent sitting on water, longer and more numerous bouts on water, shorter and fewer flying bouts). Patterns of activity parameters in juveniles after independence suggested a progressive change of foraging performances during the first two months after fledging. We found sex differences in activity parameters according to time since departure from the colony and month of the year, consistent with the important sexual dimorphism in the Amsterdam albatross. Regardless of life stage considered, activity parameters exhibited temporal variability reflecting the modulation of foraging behaviour. This variability is discussed in light of both extrinsic (i.e. environmental conditions such as variability in food resources or in wind) and intrinsic (i.e. energetic demands linked to plumage renew during moult) factors.
Keywords: activity data loggers; foraging behaviour; southern Indian Ocean; Amsterdam albatross;

Diomedea amsterdamensis
Introduction

The transition from parental food dependency to independent foraging represents an important developmental stage in the life cycle of most vertebrate animals (Mushinsky et al. 1982; Margrath and Lill 1985; Martin and Bateson 1985; Marchetti and Price 1989; Langen 1996; Burns et al. 2004) and is increasingly documented in a wide range of taxa (reptiles, birds, and some mammals). A widely accepted hypothesis is inadequate/inferior foraging skills of juveniles compared to adults, young naïve individuals combining lack of experience and physical immaturity (Lack 1954; Daunt et al. 2007). Thus, a change in behaviour, resulting from an improvement of skills acquired from increasing experience is expected to occur during a period of learning through the immaturity phase. Learning often refers to stimulus-response associative learning (‘trial and error’; Ruaux et al. 2020), although other forms of learning (such as social learning or imprinting) are also taken into account when considering the ontogeny of complex behaviours (Heyes 1994; Wynn et al. 2020). Such a learning process has been studied on various taxa from insects to primates (Bruner 1972; Caubet et al. 1992; Dukas 2006; Rapaport and Brown 2008).

Juvenile birds are known to undertake vagrant erratic journeys during the post-fledging period in passerines (Naef-Daenzer and Grüebl 2008; Becker 2014; Evans 2018; Boynton et al. 2020), in raptors (Urios et al. 2010; Krüger et al. 2014; Harel et al. 2016) and in seabirds (Riotte-Lambert and Weimerskirch 2013; Collet et al. 2020). Recent studies highlighted that the flight capacities and foraging behaviour of juveniles differed from those of adults in storks (Rotics et al. 2016), raptors (Harel et al. 2016; Nourani et al. 2020) or seabirds (Ydenberg 1989; Péron and Grémillet 2013; de Grissac et al. 2017; Corbeau et al. 2020). Most flight components were found to improve over time to tend towards those of adults (Riotte-Lambert and Weimerskirch 2013; de Grissac et al. 2017; Corbeau et al. 2020).

However, studies focusing on the foraging behaviour of juveniles remain scarce because of the difficulty to obtain individual tracking data for long periods, especially for long-lived pelagic seabirds with deferred maturity. Moreover, existing studies comparing flight capacities and foraging behaviour
between juveniles and adults in such species only collected data during the first few months that juveniles spent at sea. Since juveniles may spend several years at sea before returning to a colony to breed, our understanding of the ontogeny of flight capacities and foraging behaviour remains fragmentary.

The Amsterdam albatross *Diomedea amsterdamsensis* is a large and long-lived pelagic seabird with an extended immaturity stage (~9 years, Rivalan et al. 2010). Similarly to a closely related species, the wandering albatross *D. exulans*, their foraging strategy relies on very low flight costs as a result of their dynamic soaring flight, whereby individuals optimize the orientation of their movement with wind direction to maximize the daily distance covered (Pennycuick 1982). During initial post-fledging movements juveniles wander alone over very long distances from their colony. At sea distribution during every stage of the life-cycle of Amsterdam albatross was studied by Thiebot et al. (2014) and de Grissac et al. (2016) who compared flight trajectories (i.e. departure direction or orientation toward specific areas) of juveniles and adults. Both studies concluded on slight differences among stages in distribution due to the extensive area they used. However, foraging behaviour is known to be constrained by intrinsic factors such as sex, age, reproductive status and body size across a wide range of taxa and hence play a key role in shaping activity (King 1974; Alerstam and Lindström 1990; Wearmouth and Sims 2008). To understand the changes in foraging proficiency according to experience (life-history stages), longitudinal studies of individuals spanning critical periods of their lives are thus required. Advances in animal-borne instrumentation enable key component of foraging behaviour such as foraging effort and activity to be recorded over long periods.

In this study, we benefited from a unique dataset of different life stages (juveniles, immatures and adults) and a remarkable duration (up to 28 months for juveniles) to characterise and compare the changes in behaviour at sea when birds leave the colony (for several months: immatures and adults, or years: juveniles before returning to land). We analyse the foraging behaviour, through activity patterns,
of naïve juveniles (first years of independence at sea), immatures (individuals that never bred, age 2-10 years) and adults (individuals that bred at least once, age 8-28 years) of Amsterdam albatross (Table 1). By using miniaturized activity loggers (Global Location Sensing; GLS) to infer foraging behaviour (activity) throughout the successive life stages we addressed the following questions: i) do individuals belonging to different life-stages behave differently? ii) are there detectable progressive changes in activity patterns? It is noteworthy that the loggers used do not yet allow to have longitudinal data (maximum 2-3 years of recorded data) and to cover the entire period until an individual is recruited into the population as a breeding adult, i.e. at least 8 years.

Previous knowledge of the ecology of large albatrosses and Amsterdam albatross described above provides a practical framework for testing predictions about variability in foraging behaviour associated with stage, time elapsed since departure from the colony, seasons and sex which are summarised in Table 2. Given the overlap of spatial distribution between life-stages (not presented here but see Thiebot et al. 2014; de Grissac et al. 2016; Pajot et al. 2021) we predicted that juveniles would compensate for any lack of foraging proficiency by increasing foraging effort and time (i.e. lower time spent on water and longer flying bouts, in other words decreasing time sitting on water and increasing number and duration of flight bouts; Hypothesis (A), Table 2). We also predicted changes in activity of juveniles early in post-fledging followed by more progressive changes. Based on results found on wandering albatross fledglings (Riotte-Lambert and Weimerskirch 2013; Pajot et al. 2021) showing that juveniles reached some adult foraging performances in less than two months, we predicted that changes should be detected in activity parameters early after the juvenile left the colony (within few first months). Overall, juveniles should show contrasted foraging effort (i.e. longer time spent on water, shorter flying effort with fewer and shorter flying bouts) early in post-fledging compared to other life-stages. Due to seasonal changes in food availability individuals will face at sea after leaving the colony and the alleviation of energetic constraints linked to reproduction (for breeding adults) or to alternate
foraging trips at sea and period on land for pair bonding and mating display (for immature birds), we predicted that adjustments of activity will occur according to the time spent (i.e. in months elapsed) since the departure from the colony (Hypothesis (B), Table 2). In juveniles, we predicted early and rapid changes during post-fledging and then more progressive changes. The two hypotheses (A & B) are not mutually exclusive. While our main objective was to study post-fledging foraging behaviour activity as described above, we also accounted for other sources of changes in foraging behaviour. These included temporal (i.e. related to the month of the year) changes in activity parameters for all life-stages due to (i) environmental changes occurring throughout the seasons, to (ii) partial moulting which is suspected to occur outside the breeding period and to (iii) result in reduced activity for adults and immatures (i.e. more time spent on the water; Weimerskirch et al. 2015, 2020), or to sex differences in flight performances (Shaffer et al. 2001; Riotte-Lambert and Weimerskirch 2013; Clay et al. 2020).

Materials and methods
Study species and data loggers
Amsterdam Island (37° 50’ S; 77° 33’ E) is located in the subtropical part of the southern Indian Ocean. The Amsterdam albatross, like other great albatrosses, is a biennial breeder (Roux et al. 1983; Jouventin et al. 1989), with high survival during juvenile, immature and adult phase (Rivalan et al. 2010). The adults that raised a chick successfully do not start a new breeding cycle after chick fledging, but remain at sea for a sabbatical period (~1 yr; Table 1; Rivalan et al. 2010). However, early failed breeders may start to breed the following year (Rivalan et al. 2010). Immature birds may visit the colony when they are 4–7 yrs old, but generally only start breeding at 9 yrs old (Table 1; Weimerskirch et al. 1997a). Juvenile birds fledge and migrate independently from the adults in January (Table 1). Exact fledging dates were not known for juveniles but were assessed from activity pattern as juvenile birds land on water quickly after leaving the colony (Weimerskirch et al. 2006). Amsterdam albatrosses were
monitored annually since 1983 and all individuals were individually marked (numbered stainless steel
and plastic engraved colour bands; see Rivalan et al. (2010) for details). Unbanded birds of unknown age
(79 individuals since the beginning of the study) and chicks of the year were banded, weighed (body
mass ± 50 g using a Pesola® spring balance) and measured (wing length ± 1 mm with a ruler, tarsus
length, bill length, and bill depth ± 0.1 mm with calipers).

In Amsterdam Island oceanic area, the southern subtropical front (SSTF) delimits the warmer subtropical
from the colder sub-Antarctic waters (Belkin & Gordon 1996). Though the diet and foraging strategy of
Amsterdam albatross remains poorly known, it is presumed to have very similar foraging behaviour
compared to that of the wandering albatross, although subtle differences can appear (Pajot et al. 2021;
see Supplementary for species biological aspects). The wandering albatross is known to forage over
extensive distances, detecting prey visually or by olfaction during the day (Nevitt et al. 2008) referred as
‘foraging-in-flight’, the lowest energy consuming feeding strategy. However, the strategy tends to change depending on breeding stage (Phalan et al. 2007; Louzao et al. 2014), and could result in more frequent and shorter bouts on the water in a ‘sit and wait’ technique.

Thiebot et al. (2014) showed that adult Amsterdam albatrosses during their post-breeding sabbatical
period moved widely (31° to 115° E), mostly exhibiting westwards wider-scale migratory movements
(sensu Weimerskirch et al. 2015a) reaching >4000 km from the colony exploiting continuously warm
waters (~18°C; see Supplementary). The immature birds moved widely in longitude (0° to 135° E),
exploiting exclusively warm waters 17°-18° C. Juveniles exhibited very large migratory capacities over
the southern Indian Ocean after fledging (15° to 135° E, ~ 4500 km from the colony), through a large
range of latitudinal gradient (27° to 47° S). De Grissac et al. (2016) compared trajectories (i.e. departure
direction or orientation toward specific areas) of juveniles and adults and showed that juveniles
performed an initial rapid movement taking all individuals away from the vicinity of their native colony, and secondly performed large-scale movements similar to those of adults during the sabbatical period. GLS are archival light-recording loggers used to study activity of birds over periods lasting up to ~2 years. GLSs record the ambient light level every 10 min, from which local sunrise and sunset hours can be inferred to estimate location every 12 h (Wilson et al. 1992). GLS also recorded saltwater immersion data by testing for saltwater immersion at regular intervals, storing the number of samples wet (>0) at the end of each 10 min period. We used saltwater immersion to estimate daily activity budget. Despite the higher mean spatial error of location estimates with these devices (over 100 km; Phillips et al. 2004a), GLS loggers allowed us to track the birds for prolonged periods with minimal disturbance to them. We considered the following stages with respect to the ages when GLS were deployed (see Table 1): juvenile, as a fledgling equipped with a GLS just before leaving the colony for the first time; immature, as a non-breeding young bird that had never bred equipped with a GLS when visiting the colony; adult, as a breeding adult equipped with a GLS during the incubation or brooding period which successfully fledged a chick and thereafter took a sabbatical year. To date, we have retrieved 40 of the 50 GLS loggers deployed in total over 4 years, from which 33 individual tracks were estimated (Table 1).

Our original aim was to collect activity data on the three stages over a long period of time (>1 year). These data are available from a total of 10 adults tracked throughout their sabbatical period, 13 immature birds and 10 juvenile birds (up to 3.2 years).

Data processing

The raw immersion data were values from 0 (no immersion or dry, in flight or sitting on the ground) to 200 (permanently immersed in sea water or wet, indicating the number of 3 s periods during 10 min blocks when the sensor was immersed in saltwater). Loggers recorded the proportion of time in seawater at 10 min intervals, which we summarized as hours in the water per day (hereafter time spent...
on water; 10 min blocks immersion data > 0). This measure is a reliable proxy of foraging effort linked to foraging behaviour of the species which enters the water principally to forage (Weimerskirch and Guionnet 2002). Additionally, the duration of the bouts spent entirely immersed (10 min blocks immersion data = 200) was calculated daily (hereafter referred as wet bouts duration). Conversely, when birds are not on land, the time spent dry was interpreted as flying (and thus not feeding). The duration of the bouts spent entirely dry (10 min blocks immersion data = 0) was calculated daily (hereafter referred as dry bouts duration). Additionally the numbers of bouts (number of wet bouts - sitting on water-and of dry bouts -flying) were obtained daily. Although the loggers integrated activity within each 10 min block and so did not provide the exact timing of landings and take-offs, Phalan et al. (2007) found for comparative purposes that bouts defined as a continuous sequence of 0 values for flight (dry) and a sequence of values of 1 or greater for wet bouts, were suitable proxies for activity.

To select the data corresponding to periods spent at sea after leaving the breeding site, we used the following criteria on activity to define the departure time from the colony for each stage: 1) juveniles, the first bout spent on seawater (wet bouts duration) > 1h based on Argos Platform Transmitters Terminals (PTT) tracking data (data obtained in a other project and not shown here, Weimerskirch et al. unpublished data); 2) immatures and adults, the last bout spent flying (dry bouts duration) > 12h based on PTT tracking data (Weimerskirch et al. unpublished data). Using these criteria we obtained departure months as follows: 1) the juveniles fledged from the colony from January to March, 2) the immatures left between April and August, and 3) the departures of sabbatical adults were spread over two periods, first between December and February and then from May to July.

Statistical analyses

Variation in activity parameters
The aim was to determine whether distinct foraging behaviours could be detected across the patterns of variation of wet/dry data, and then to appraise how these behaviours varied over time and among individuals. First, to deal with the fact that wet/dry metrics were interrelated (number of wet bouts sitting on water and time spent on water, wet bouts duration and dry bouts duration, wet bouts number and dry bouts number) and to avoid redundancy, we ran principal components analyses (PCA built with the ‘PCA’ function, FactoMineR package (Lê et al. 2008)) to circumvent collinearity issues. To describe changes in behaviour over time and stages using gradients of activity we ran PCA for i) all stages (PCS; based on activity data collected during the first ten months post-departure) and for ii) juveniles only, as an additional goal was to determine changes in activity patterns during the first two years of life (PCJ; based on activity data collected during the first twenty-nine months post-departure).

Considering all stages, the first three principal components (PCS) explained 94.2% of the total variance. For juveniles, the first three principal components (PCJ) explained 92.2% of the total variance. The detailed results of PCA and the variables retained for each axe are summarised in Table 3.

Second, we used generalized additive mixed models (GAMMs, built with the ‘gam’ function, itsadug and mgcv package (Lin and Zhang 1999; Wood 2015)) with the values associated with each of the three first axes of the PCA as the dependent variables. We ran separate models testing for variability in activity parameters i) for all stages combined (PCS) and ii) for juveniles (PCJ), based on different duration of datasets (28 months since departure for juveniles and 9 months since departure for immatures and adults; see Supplementary; Table S1). Thus, for i) we considered the lowest number of months elapsed since departure available (9 months since departure). Months elapsed since departure (the duration elapsed since fledging expressed in month, i.e. the first month after fledging and so on), month of the year (i.e. January and so on), sex, and stage (only for ii)) were included as fixed effects. The interactions between stage and time were included as fixed effects to test for the prediction that differences should
vanish with time passed since fledging. To test for the importance of individual variability in our results we built models with or without random effects. We compared models without random effect, models with random intercepts, and models with random slopes and intercepts to test whether the rate of change of activity parameters as a function of time elapsed since departure varied between individuals (Zuur 2009a). Models included month elapsed since departure as a continuous covariate modelled with non-parametric smoothing functions (Wood 2017). We limited the amount of smoothing (k) with the ‘gam.check’ function following Wood (2017) for each spline to avoid excessive flexibility and model overfitting that would have no ecological meaning. Models including all combinations of explanatory variables and random effects were then tested and ranked using their Akaike Information Criterion (AIC) values and Akaike weights following the Information-Theoretic Approach (Burnham and Anderson 2002). The model with the lowest AIC was considered as the best model. Two models separated by a difference in AIC values of less than 2 were assumed to fit the data similarly.

Although sexes and stages differed for some body size measurements (see details in Supplementary), we could not include body size as an additional explanatory variable in GAMMs testing for factors of variation in activity patterns due to small sample sizes in each sex and stage category (see Table 1).

Spatial and statistical analyses were performed using R (R Core Team 2021). Values are means ± SD.

Results

The most parsimonious models explaining variations in activity parameters in the Amsterdam albatross included time elapsed since departure from the colony, month of the year, stages and sexes (Tables 4 and 5; Supplementary Figures S1 - S5; Tables S1), whatever the synthetic activity variables considered (PC1S, PC2S and PC3S; Table 4). The interaction between stage and time elapsed was significant for the first synthetic activity variable (PC1S). Selected models also included random effects on intercepts and
slopes, indicating inter-individual variability in activity and inter-individual variability in the rate of change of activity as a function of time elapsed since departure from the colony.

In juvenile Amsterdam albatrosses, the most parsimonious models explaining variations in activity included time elapsed since departure from the colony, month of the year for all three activity variables considered (Table 5 and 6; PC1J, PC2J and PC3J), and sex was retained only for two variables (PC2J and PC3J). Selected models also included random effects on intercepts and slopes, indicating inter-individual variability in activity and variability in the rate of change of activity as a function of time elapsed since departure from the colony (Supplementary Figures S6).

Changes in activity for all stages

The two synthetic activity variables (PC1S, PC2S) varied significantly with time exhibiting clear nonlinear temporal patterns (Figure 1). These variations were related to the time elapsed since their departure from the colony and showed seasonal changes (indicated by the month of the year; Supplementary Figures S1 - S5; Tables S1 and S2). With increasing time since departure, birds spent lower percentage of time on water and made shorter wet bouts. They spent less percentage of time on water during the period March to July compared to rest of the year (PC1S, Supplementary Figures S1 - S5). They made longer and fewer bouts on water during the period April to November, and shorter flying bouts during the period November to February. Juveniles showed strong temporal changes in activity linked to the time elapsed since departure from the colony in the first two months after fledging (Supplementary, Figure 2). In immatures and adults the temporal pattern appeared reversed compared to juveniles (Supplementary, Figure 2).

Compared to adults, immatures and even more so juveniles, spent a lower percentage of time on water (Table 5, Supplementary Figures S1) and made more flying bouts (PC1S; Supplementary Figures S2), made shorter and fewer bouts on water (PC2S; Supplementary Figures S4-S5), and made longer flying
bouts (PC3S; Supplementary Figures S2). Males spent a higher percentage of time on water and made fewer flying bouts (PC1S), longer and more numerous bouts on water (PC2S) and shorter flying bouts (PC3S) compared to females.

Changes in activity of juveniles during the first two years after fledging

PC1J and PC2J varied significantly with time exhibiting clear nonlinear temporal patterns (Figure 3; Supplementary Figures S7 - S11; Tables S1 and S3a, 3b). Juveniles seemed to alternate periods of lower percentage of time spent on water combined with more numerous flying bouts (April) with periods of higher percentage of time on water combined with fewer flying bouts (February, July-October; PC1J, not illustrated). The seasonal change was also observed through longer and fewer bouts spent on water and shorter flying bouts at the end of the year (PC2J: September-December). Juveniles, during the first 28 months after fledging, increased the time spent on water while decreasing the number of flying bouts (Figure 3a).

PC2J and PC3J varied significantly with sex (Supplementary Figures S7 - S10; Tables S5b, 5c), indicating that juvenile males made shorter and more numerous bouts on water (PC2J) and shorter flying bouts (PC3J) compared to females (Supplementary Figures S7 - S10; Tables S5b, 5c).

Discussion

In this study, we benefited from a unique comprehensive dataset of remarkable duration (up to 28 months) to characterise the post-fledging behaviour of naïve seabirds. Using miniaturized activity loggers (GLS), we showed clear differences and changes in activity characteristics depending on life-stages. By comparing changes in behaviour at sea and foraging parameters of juveniles after their departure at sea with those of immatures and adults in the Amsterdam albatross, we showed that
juveniles differed from immatures and adults in their activity values and patterns. Activity also varied according to time and sex. Our study allows us to compare foraging behaviour among life stages in a long-lived endangered seabird species, while also providing new insights into the development of foraging patterns in naïve individuals over a multi-year period.

Stage specific changes

The birds were found to behave differently according to their stage whatever the activity variables considered, indicating differences in foraging behaviour. Overall, juveniles spent lower percentage of time on water compared to immatures and adults. During the first months following their departure from the colony the proportion of time spent on water by immatures and adults showed a dome-shaped curve peaking three to five months after departure. During the same period of time, the proportion of time spent on water by the juveniles changed strongly, with values dropping off in the first two months and then remaining low and overall lower than in adults and immatures. This might indicate a lower foraging activity in naïve birds. During the same period, the duration and number of water bouts also exhibited progressive change. These patterns suggest an early and gradual change in foraging behaviour so that juveniles progressively could behaved similarly to immatures and adults (reaching similar values in activity covariates). This suggest a progressive behavioural change in movements during the first two months after fledging. It is noteworthy that the multi-monthly bell-shaped pattern observed during the first 10 months after departure in immatures and adults appears to be mirrored in juveniles 15-16 months later (see Figure S11). Despite such possible similarities (% time spent on water), there are still some differences between stages (see Supplementary). Since % time spent on water partly reflects foraging, this seems to indicate that juvenile individuals may have weaker foraging skills during their first two months at sea. Although behavioural changes can often equate to improved performance (e.g. Campioni et al. 2020) this is not always the case. The emergence of juvenile birds as more 'adult like' in
their foraging/flight behavioural patterns is not necessarily a sign of improvement. For example, it could be partly due to individual differences in area use with different environmental conditions encountered (food abundance, wind regimes).

Since all stages of the Amsterdam albatross forage in the same water masses (see Thiebot et al. 2014), differences in foraging behaviour were presumably not due to different oceanographic characteristics as observed in other species (Thiers et al. 2014; Weimerskirch et al. 2014; Frankish et al. 2020b). These differences could be due to a combination of lack of experience, poor knowledge of the environment, use of distinct cues and/or physical immaturity leading to sub-optimal behaviour (Shaffer et al. 2001; Frankish et al. 2020a, 2022). It is likely that increasing exposure to diverse foraging situations allows juveniles to rapidly accumulate foraging experience and improve various aspects of foraging.

Results suggest that immatures may differ from both adults and juveniles in some aspects of their behaviour. While most of the activity parameters and the temporal patterns showed similarities with adults when considering the time elapsed since departure, they seemed rather comparable to juveniles when considering seasonal aspects (month of the year). Such differences can be explained by several non-exclusive explanations: i) similar management of energy constraints than adults, as post-breeding adults and immatures are less constrained in their central-place foraging strategies (Campioni et al. 2016), ii) comparable capacity to respond to local resource availability in their foraging behaviour than juveniles (Frankish et al. 2022), and iii) incomplete acquisition of more long-term learning of complex movement strategies (Thorup et al. 2003; Votier et al. 2011; Rotics et al. 2016). Disentangling these hypotheses can be achieved by combining higher resolution movement data with longer longitudinal studies covering all three life stages for the same individuals.

What might be designated as ‘lower performance’ of juveniles found in our study is consistent with studies on wandering albatrosses and Amsterdam albatrosses (Riotte-Lambert and Weimerskirch 2013;
de Grissac et al. 2017; Pajot et al. 2021) during the first weeks at sea Juvenile albatrosses behaved differently in first month after fledging (i.e. speed and sinuosity of movements) and readily use similar foraging strategies as adults (Frankish et al. 2022). Additional skills (such as detection of prey at the surface, detection of other foraging seabirds, navigational skills...) need to be acquired during the immature period before the efficiency of these behaviours matches that of adults. This is also typical of other seabird taxa, which show progressive improvement in flight performance with the numbers of days since fledging (Yoda et al. 2004; Mendez et al. 2017; Collet et al. 2020; Corbeau et al. 2020; Frankish et al. 2022). For example juvenile brown boobies Anous stolidus improved their flight abilities (Yoda et al. 2004). In contrast, flight capability (flight speed and sinuosity) comparable to that of adults allows juvenile white-chinned petrels Procellaria aequinoctialis to rapidly fly over long distances away from the colony (Frankish et al. 2020).

The progressive change of movement behaviours (foraging parameters estimated from activity parameters improved with time elapsed) quantified in juvenile Amsterdam albatrosses, could be either due to physical development and/or experience gain. Elucidating the mechanisms of the transition to independence in early life stages is however crucial for understanding the causes of higher juvenile mortality in long-lived species (Fay et al. 2015; Payo-Payo et al. 2016).

**Temporal changes and sex differences in activity**

The temporal variability of activity was found whatever the life-stage considered. Part of the activity changes observed following the departure of juvenile Amsterdam albatrosses may illustrate the swift change in travel and movement behaviour, reflecting a more ‘adult-like’ behaviour, not indicating necessarily an improvement of flight performances and of the ability to cope with changing (i.e. increasing wind speed) wind conditions (Sergio et al. 2014), a key parameter for soaring seabirds such as albatrosses. Both extrinsic (i.e. environmental conditions) and intrinsic (i.e. energetic demands linked to
plumage moult) factors could be involved in the modulation of foraging behaviour, which can be
reflected in the temporal variability.

Moult is an intrinsically costly process requiring time, energy and nutrients (Langston and Rohwer 1996;
Ellis and Gabrielsen 2002), and the annual replacement of flight feathers is crucial to ensure efficiency in
both flight and thermoregulation (Murphy 1996; Peery et al. 2008; Gutowsky et al. 2014). Stage-specific
and sex-specific differences in moult extent occur in wandering albatross, suggesting important
constraints (Weimerskirch 1991; see Supplementary). Adult birds during the non-breeding season
appear to spend much more time on the water during winter, suggesting that partial moult may occur at
this time (Weimerskirch et al. 2015b, 2020). Interestingly, immature individuals appear to have a similar
peak in time spent on the water in spring, suggesting different timing of moult.

Consistently, we found that males flew for longer periods (dry bouts duration) compared to females.
When considering all stages, males spent a higher percentage of time on water compared to females.
Males in all stages did more bouts on water and juvenile males shorter wet bouts, compared to females.
Contrary to the wandering albatross (Weimerskirch et al. 2014), male and female Amsterdam
albatrosses forage in similar oceanic water masses and encounter comparable wind conditions (Jaeger
et al. 2013; Thiebot et al. 2014). Therefore, it is unlikely that sex differences in activity parameters were
caused by differences in foraging habitats. Sex-specific behavioural differences are common in sexually
dimorphic seabirds as reviewed in Wearmouth and Sims (2008), where the smaller sex usually
undertakes longer trips. Sexual size dimorphism can result in differences in aerial agility, foraging area
and behaviour, and provisioning rate and preferred prey (Gonzales-Solis et al. 2000; Phillips et al. 2004b,
2011; Weimerskirch et al. 2009; Austin et al. 2019; Barbraud et al. 2021). It has also been suggested that
size matters probably because the smaller and lighter sex has a higher foraging and flight efficiency
(Shaffer et al. 2001; Clay et al. 2020), suggesting that lighter and lower wing loaded female wandering
albatrosses, compared to males, are probably better able to exploit subtropical and tropical waters
where winds are lighter. Following this, it can be hypothesized that female Amsterdam albatrosses have a greater advantage in foraging in the subtropical environment than males. Sex differences in the acquisition of foraging performance during the first months after fledging yet remain to be explored.

**Individual variability in activity**

There was inter-individual variability in almost all activity parameters whatever the stage considered. In juveniles, models indicated inter-individual variability in activity and in the rate of change of activity as a function of time elapsed since departure from the colony. Since the intercept terms in the models were significant, it seems as though individual variability (i.e., specialization on different foraging strategies) was a contributor to observed variability. However, the rate of change of intra-individual variation for some foraging strategies (percentage of time on water-number of flying bouts axis) oscillated during the juvenile period with a seemingly remarkable synchrony (see Fig S7). This suggests that changes in foraging behaviours occurred at the individual level during the juvenile period without stabilizing, at least during the first two years after fledging. This individual variability suggests development of specialized individual foraging behaviours (Harel et al. 2016; Rotics et al. 2016, 2021; Phillips et al. 2017). Nonetheless, given the small sample sizes these results should be interpreted with caution.

**Conclusion**

Very few studies have investigated the ontogeny of foraging behaviour over such a long period of time, particularly in long-lived pelagic seabirds, due to the difficulty of obtaining individual tracking data over several years. We investigated the foraging behaviour, through activity patterns, during the three life stages of the endangered Amsterdam albatross by using miniaturized activity loggers. Naïve juveniles during their first month at sea after leaving their colony exhibited lower foraging activity (greater proportion of time spent sitting on water, longer and more numerous bouts on water, and shorter and
fewer flying bouts). Patterns of activity parameters in juveniles after independence suggested a
progressive change of foraging performances during the first two months after fledging. Regardless of
life stage considered, activity parameters exhibited temporal variability reflecting the modulation of
foraging behaviour presumably linked to both extrinsic (i.e. environmental conditions such as variability
in food resources or in wind) and intrinsic (i.e. energetic demands linked to plumage renew during
moult) factors. Sex differences in activity parameters according to time since departure from the colony
and season were consistent with the sexual dimorphism in the Amsterdam albatross. Overall, an
expected change in behaviour, resulting from the experience gained, may reflect an improvement in
skills occurring during a period of learning through the immaturity phase which still would need to be
confirmed by directly assessing foraging performance. Results from our study suggest that the lower
foraging activity of juvenile Amsterdam albatrosses may partly explain their lower survival compared to
adults. However, despite foraging metrics of juveniles investigated here reached values observed for
adults quite rapidly, immature survival remains lower than adult survival during several years (Rivalan et
al. 2010). Therefore, more detailed information such as foraging performance realized (the amount or
quality of preys obtained by juveniles) or energetic expenditure are needed to better understand age-
specific differences in life history traits such as survival and the dynamics of the species.
Ethics

All work was carried out was approved by the French Polar Institute (IPEV) ethics committee.

Acknowledgements

This study was made possible thanks to all the fieldworkers involved in the monitoring program on Amsterdam albatross, namely Jean-Baptiste Thiebot, Jérémy Demay, Rémi Bigonneau, Romain Bazire, Hélène Le Berre, Marine Quentin, Marine Devaud, Chloé Tanton, Jérémy Dechartre and Anthony Le Nozahic. We acknowledge Dominique Joubert for the management of the demographic CEBC Seabirds database. We are grateful to Richard Phillips, British Antarctic Survey, Cambridge for providing GLS loggers. We thank Bertille Mohring for statistical advices on principal components analyses. We thank our PCI recommender Blandine Doligez and reviewers, Juliet Lamb and an anonymous reviewer for constructive comments on an earlier version of the manuscript.

Funding

This monitoring program was supported financially and logistically by the French Polar Institute IPEV (program 109, PI C. Barbraud/H. Weimerskirch), the Zone Atelier Antarctique (CNRS-INEE), Terres Australes et Antarctiques Françaises.

This study is a contribution to the National Plan of Actions for Amsterdam albatross.

Authors contribution

K.D. and C.B. conceived the study. H.W. secured funding. K.D. prepared and analysed the data. C.B. provided feedback on the analyses. K.D. wrote the first draft and all authors contributed to editing versions of the manuscript.

Species biological aspects

Though the diet and foraging strategy of Amsterdam albatross remains poorly known, it is presumed to have very similar foraging behaviour compared to that of the wandering albatross, although subtle differences can appear (Pajot et al. 2021). Like other large albatross species (Diomedea spp.), the Amsterdam albatross is likely to prey on large squid, fish and carrion found on the sea surface (Delord et al. 2013, Cherel et al. unpublished data). The wandering albatross is known to forage over extensive distances, detecting prey visually or by olfaction during the day (Nevitt et al. 2008). This strategy referred as ‘foraging-in-flight’ is the lowest energy consuming feeding strategy for the wandering albatross (Weimerskirch et al. 1997b). However, this strategy tends to change depending on breeding stage (Phalan et al. 2007; Louzao et al. 2014) leading to a more important utilization of the ‘sit-and-wait’ technique and possibly to vary depending on sites suggesting considerable behavioural plasticity (Phalan et al. 2007). This switch in foraging techniques could result in more frequent and shorter bouts on the water in the former technique (compared to ‘foraging-in-flight’).

Thiebot et al. (2014) showed that adult Amsterdam albatrosses during their post-breeding sabbatical period moved widely (31° to 115° E), mostly exhibiting westwards wider-scale migratory movements (sensu Weimerskirch et al. 2015a) reaching >4000 km from the colony exploiting continuously warm waters (~18°C). No clear longitudinal seasonality existed in the movements of adults, nonetheless they tended to move westwards in June/July and eastwards in November. The immature birds moved widely in longitude (0° to 135° E), exploiting exclusively warm waters 17°-18°C. Similarly to adults no clear longitudinal seasonality synchronicity existed in the movements, except that they also tended to move westwards in June and eastwards in November. Juveniles exhibited very large post-fledging movement capacities over the southern Indian Ocean after fledging (15° to 135° E, ∼4500 km from the colony),
through a large range of latitudinal gradient (27° to 47° S). Juveniles birds tended to move westwards first in March-April and temporarily exhibited synchronous individual movements. De Grissac et al. (2016) compared trajectories (i.e. departure direction or orientation toward specific areas) of juveniles and adults and showed that juveniles performed an initial rapid movement taking all individuals away from the vicinity of their native colony, and in a second time performed large-scale movements similar to those of adults during the sabbatical period. High individual variability and no clear differences between juveniles and adults patterns were found, except that adults foraged at significantly higher latitudes. De Grissac et al. (2016) concluded in an overlap in distribution between adults and juveniles due to the extensive area they used and their differences in latitudinal distribution compared to other Procellariiformes species.

Moult is an intrinsically costly process requiring time, energy and nutrients (Langston and Rohwer 1996; Ellis and Gabrielsen 2002), and the annual replacement of flight feathers is crucial to ensure efficiency in both flight and thermoregulation (Murphy 1996; Peery et al. 2008; Gutowsky et al. 2014). In large-sized albatrosses like Amsterdam albatross, replacement of primary feathers lasts for more than one breeding season, and the moult of primaries never occurs during the breeding season (Furness 1988; Weimerskirch 1991). Stage-specific and sex-specific differences in moult extent occur in wandering albatross, suggesting important constraints that could compete with breeding (immature birds tend to renew fewer feathers compared to adult breeders), and particularly in females (Weimerskirch 1991). In smaller sized seabirds, a link between moult pattern and activity parameters was evidenced, resulting in a clear temporal pattern partly explained by moult (Cherel et al. 2016). Recently Gutowsky et al. (2014) suggested that tropical albatrosses (i.e. Laysan Phoebastria immutabilis and black-footed P. nigripes albatrosses) could compromise flight from active wing moult during the nonbreeding period and induce changes in daily activity budget during a ‘quasi-flightless’ stage. However, there is no such
data for southern albatrosses. Furthermore for large sized species (*Diomedea* spp.) the activity data recorded using GLS never suggested it such a compromise. However, adult birds during the non-breeding season appear to spend much more time on the water during winter, suggesting that partial moult may occur at this time, as observed in many other seabird species that have to moult during the non-breeding season and show reduced activity during specific periods that may correspond to moulting (Weimerskirch et al. 2015b, 2020).

**Statistical analyses**

**Variation in activity parameters between stages with time-lag**

The visual comparison shown on Figure S11 was statistically tested using generalized additive mixed models (GAMMs, built with the ‘gam’ function, itsadug and mgcv package, (Lin and Zhang 1999; Wood 2015)) with the values associated with the first axe of the PCA as the dependent variable. We ran model testing for variability in activity parameters for all stages combined (PC1Slag; Table S4). We applied time lag as illustrated in Figure S11, the first axe was modelled as a function of months spent since departure from the colony (monthelap_lag) with a delay of 16 months.

**Variation in body size**

Differences between sexes in body size measurements were tested using Student’s t-tests and Wilcoxon rank tests. We tested independently if each measurement (wing length, tarsus length, bill length, bill depth and body mass) varied according to sex and stage (juvenile and adult). The effects were tested using generalised linear models (GLMs) with a Gaussian family and identity link function (Zuur 2009b). Model validation and model selection were performed following (Zuur 2009b). GLMs tested for effect of sex and stage and T-tests tested the differences of body size measurements between males and females. Although sexes and stages differed for some body size measurements, we could not include
body size as an additional explanatory variable in GAMMs testing for factors of variation in activity patterns due to small sample sizes in each sex and stage category.

Male Amsterdam albatrosses were larger than females, particularly for tarsus length and bill length and bill depth whatever the stage (juvenile or adult; Tables S5, S5-S6). In juveniles, males were ~13% heavier than females, while the difference was not significant in adults (Table S5). The most sexually dimorphic phenotypic traits were body mass, bill depth and tarsus length in juveniles while in adults they were body mass, tarsus length and bill length.
Table S1 Selected models testing for the effects of sex, stage, number of months spent since departure (monthelap: duration elapsed since fledging expressed in month, i.e. the first month after fledging and so on) and month of the year (i.e. January and so on) on activity parameters of Amsterdam albatrosses.

^1 ratio calculated as Male/Female following Lovich and Gibbons (1992) for species for which males are known to be larger than females cited in (Smith 1999);^2 Student’s t-tests used after check for normality of the data for all measurements except for wing length of juveniles (Wilcoxon rank test).
Figure S1 Daily proportions of time spent on water depending on stage (juveniles, immatures and adults) for every month since departure from the colony (upper panel) and for each month of the year (lower panel). Error bars represent ± 1 sd.
Figure S2 Daily flying bouts duration (dry bouts in hours) depending on sex (females and males) and on stage (juveniles, immatures and adults) for a) time elapsed since departure from the colony expressed in month (left panel) and for b) each month of the year (right panel). One side error bars represent ±1 sd.
Figure S3 Daily flying bouts number (dry bouts) for every month since departure from the colony for juveniles, immatures and adults for females (upper panel) and males (lower panel). Error bars represent $\pm 1$ sd.
Figure S4 Daily wet bouts duration (bouts on water in hours) depending on stage (juveniles, immatures and adults) and on sex (females and males) for every month since departure of the colony (upper panel) and for each month of the year (lower panel). Error bars represent ±1 sd.
Figure S5 Daily wet bouts number (bouts on water) for every month since departure from the colony for juveniles, immatures and adults for females (upper panel) and males (lower panel). Error bars represent ± 1 sd.
Figure S6 Modeled first (left panel) and second (right panel) axis of principal components analysis of activity parameters of juveniles of Amsterdam albatrosses according to time elapsed (e.g., duration elapsed since departure from the colony expressed in month). Models outputs
obtained using random intercepts and slopes (each coloured line representing an individual). Line corresponds to estimated smoother from the GAMM models.
Figure S7 Daily flying bouts duration (dry bouts in hours) for every month since departure of the colony for juveniles, immatures and adults for females (upper panel) and males (lower panel). Error bars represent ±1 sd.
Figure S8 Daily flying bouts number (dry bouts) for every month since departure of the colony for juveniles, immatures and adults for females (upper panel) and males (lower panel). Error bars represent ±1 sd.
Figure S9 Daily wet bouts duration (bouts on water in hours) for every month since departure of the colony for juveniles, immatures and adults for females (upper panel) and males (lower panel). Error bars represent ±1 sd.
Figure S10: Daily wet bouts number (bouts on water) for every month since departure of the colony for juveniles, immatures, and adults for females (upper panel) and males (lower panel). Error bars represent ±1 sd.
Figure S11 Daily proportions of time spent on water for every month since departure of the colony for juveniles during the first 28 months spent at sea (after departure), immatures and adults (upper panel) and with a 15-16 months of delay for immatures and adults compared to juveniles (lower panel). Error bars represent ±1 sd.

Dear Karine Delord,

Your article, entitled The challenges of independence: ontogeny of at-sea behaviour in a long-lived seabird, has now been reviewed.

The referees' comments and the recommender's decision are shown below. As you can see, the recommender found your article very interesting but suggests certain revisions.

We shall, in principle, be happy to recommend your article as soon as it has been revised in response to the points raised by the referees.

When revising your article, we remind you that your article must contain the following sections (see our Guide for Authors in the Help section of the PCI Ecology website):

1) Data, script and code availability (if applicable)

- **Data, statistical scripts, command lines and simulation code must be made available to readers.** They should either be included in the article or deposited in an open repository such as Zenodo with a DOI. A perennial URL can be provided if no DOI is available; please note that GitHub URL are not perennial.
- **If deposited in an open repository, a reference to Data, statistical scripts, command lines and simulation code, with a DOI or a perennial URL, must be provided in the reference list and in the "Data, script and code availability" section**
- **The "Data, script and code availability" section must clearly indicate where and how data can be accessed.**
- **Wherever possible, data, scripts and code should be provided in machine-readable formats. Avoid PDFs other than for textual supplementary information.**
- **Metadata should accompany the data, to make the data understandable and reusable by the reader.**
2) Supplementary information (if applicable)

- Supplementary information (text, tables, figures, videos, etc.) can be referred to in the article. It must be available in an open repository (such as Zenodo, Dryad, OSF, Figshare, Morphobank, Morphosource, Github, MorphoMuseuM, Phenome10k, etc. or any institutional repository, etc...) with a DOI. A perennial URL can be provided if no DOI is available.
- A reference to the supplementary information, with a DOI or a perennial URL, must be provided in the reference list and in the "Supplementary information" section.
- List all documents attached to the manuscript as Supplementary Information in the "Supplementary Information" section.

3) Funding (mandatory)

- All sources of funding must be listed in a separate “Funding section”. The absence of funding must be clearly indicated in this section.

4) Conflict of interest disclosure (mandatory)

- Authors should declare any potential non-financial conflict of interest (financial conflicts of interest are forbidden, see the PCI code of conduct).
- In the absence of competing interests, the authors should add the following sentence to the “Conflict of interest disclosure” section: “The authors declare they have no conflict of interest relating to the content of this article.” If appropriate, this disclosure may be completed by a sentence indicating that some of the authors are PCI recommenders: “XXX is a recommender for PCI XX.”

5) Materials and methods (mandatory)

- Details of experimental procedures and quantitative analyses must be made fully available to readers, in the text, as appendices, or as Supplementary Information deposited in an open repository, such as Zenodo, Dryad or institutional repositories with a DOI.
- For specimen-based studies, complete repository information should be provided and institutional abbreviations should be listed in a dedicated subsection (if applicable). Specimens on which conclusions are based must be deposited in an accessible and permanent repository.

When your revised article is ready, please:

1) Upload the new version of your manuscript onto your favorite open archive and wait until it appears online;
2) Follow this link https://ecology.peercommunityin.org/user/my_articles or logging onto the PCIEcology website and go to ‘For Contributors -> Your submitted preprints’ in the top menu and click on the blue ‘VIEW/EDIT’ button at the right end of the line referring to the preprint in question.

3) Click on the black ‘EDIT YOUR ARTICLE DATA’ button (mandatory step). You can then edit the title, authors, DOI, abstract, keywords, disciplines, and DOI/URL of data, scripts and code. Do not forget to save your modifications by clicking on the green button.

4) Click on the blue ‘EDIT YOUR REPLY TO THE RECOMMENDER’ button (mandatory step). You could then write or paste your text, upload your reply as a PDF file, and upload a document with the modifications marked in TrackChange mode. If you are submitting the final formatted version ready to be recommended, you should only add a sentence indicating that you posted the final version on the preprint server. Do not forget to save your modifications by clicking on the green button.

5) Click on the green ‘SEND RESUBMISSION’ button. This will result in your submission being sent to the recommender.

Once the recommender has read the revised version, they may decide to recommend it directly, in which case the editorial correspondence (reviews, recommender’s decisions, authors’ replies) and a recommendation text will be published by PCIEcology under the license CC-BY.

Alternatively, other rounds of reviews may be needed before the recommender reaches a favorable conclusion. They may also reject your article, in which case the reviews and decision will be sent to you, but they will not be published or publicly released by PCIEcology. They will be safely stored in our database, to which only the Managing Board has access. You will be notified by e-mail at each stage in the procedure.

We thank you in advance for submitting your revised version.

Yours sincerely,

The Managing Board of PCIEcology
The transition to independent foraging represents an important developmental stage in the life cycle of most vertebrate animals. Juveniles differ from adults in various life history traits and tend to survive less well than adults in most long-lived animals. Several hypotheses have been proposed to explain higher mortality including that of inadequate/inferior foraging skills compared to adults, young naïve individuals combining lack of experience and physical immaturity. Thus a change in behaviour, resulting in an improvement of skills acquired from growing experience, is expected to occur during a period of learning through the immaturity phase. Very few studies have investigated the ontogeny of foraging behaviour over long periods of time, particularly in long-lived pelagic seabirds, due to the difficulty of obtaining individual tracking data over several years. We investigated the foraging behaviour, through activity patterns, during the three life stages of the endangered Amsterdam albatross by using miniaturized activity loggers on naïve juveniles, immatures and adults. Naïve juveniles during their first month at sea after leaving their colony exhibited lower foraging effort (greater proportion of time spent sitting on water, longer and more numerous bouts on water, shorter and fewer flying bouts). Patterns of activity parameters in juveniles after independence suggested a progressive change of foraging performances during the first two months since fledging. We found sex differences in activity parameters according to time since departure from the colony and month of the year, consistent with the important sexual dimorphism in the Amsterdam albatross. Regardless of life stage considered, activity parameters exhibited temporal variability reflecting the modulation of foraging behaviour. This variability is discussed in light of both extrinsic (i.e. environmental conditions such as variability in food resources or in wind) and intrinsic (i.e. energetic demands linked to plumage renew during moult) factors.

Keywords: activity data loggers; foraging behaviour; southern Indian Ocean; Amsterdam albatross; Diomedea amsterdamensis
have been nicely addressed and the manuscript is now much clearer and focused, and far
better structured around the main question. I will be happy to recommend it for publication,
after a series of points that I detail below have been corrected. Most of them deal with text
edits / improvements (please read again the whole text carefully as I may have missed some
mistakes), but there are a couple of more conceptual points, in particular the use of AICc, the
differences between fig. 2 and 3, and adding a few more thoughts about the consequences of
the results described for understanding the life-history of the species.

R: thank you for following the manuscript and for your constructive comments.

Please notice that the line numbers mentioned in the answer refers to the revised version (R3, in track
change mode).

- l. 25: replace since by after ?

  R: this was changed accordingly. L25

- l. 64: add a coma after “years” and change the parentheses for the reference

  R: this was changed accordingly. L64

- table 2: although useful as noted by previous reviews, could be simplified to avoid
repetitions for the three different parameters (basically nothing changes but the name of the
parameter and direction of expected change). I believe that this table could be drastically
reduced

  R: the table 2 was accordingly drastically reduced

- table 2 (and/or corresponding text): state clearly that the two hypotheses are not
mutually exclusive?

  R: this was added in the table and in the corresponding text. L110

- l. 111-116: add (i), (ii) and (iii) before to environmental..., to partial molting... and to sex
differences... to clarify the structure of the sentence and ease the reading.

  R: this was added. L113-114

- l. 143: what former strategy? I do not understand here; the sentence may need to be
clarified here

  R: this was clarified. L144
I. 162: replace “regarding” by “with respect to”? Maybe “year” is also not the right term here since it does not refer to specific years but ages

R: this was modified. L164

I. 167-168: “data on the three stages over a long period of time”

R: this was modified. L170

I. 175: so the number of 10 min blocks was divided by 6 to compute a time in hours then?

R: yes exactly

I. 206: “describe behaviours using gradients of activity” is not so clear to me. Do you simply mean here “changes in behaviour over time and stages”?

R: this was modified. L208

I. 206 and 208 (and thereafter): not sure the acronyms PCS and PCJ are useful here (you anyway repeat what they correspond each time after, so I would simply remove them). You can then replace PC1S, PC2S etc. by their names directly.

R: we understand that you may find these acronyms unnecessary, but we would prefer to keep them, in particular to facilitate reader’s understanding between the text and the results (text, tables and figures)

I. 215: double parenthesis

R: note sure to understand the point here because the double parenthesis corresponds to 1) ‘(GAMMs,...’ and to 2) the references ‘(Lin and Zhang 1999; Wood 2015)’

I. 222: I would add here that interactions between stage and time were included as fixed effects to test for the prediction that differences should vanish with time passed since fledging.

R: this was added in the revised version. L225-227

I. 231: have you checked whether using AIC corrected for small sample size (AICc) changed anything? If not, I would do it to test for the robustness of the results, as small samples are likely to lead to model overfitting (l. 469 and 477 indicate AICc, but the text mentions AIC?)

R: yes, it has been checked using AICc and the results appeared to be robust compared to those presented in the manuscript. We have therefore chosen to maintain our current presentation. However, if you think it’s more correct to present AICc, this can be changed. AICc indications were modified in the revised version.

I. 235-244: this section appears strange here, as it looks like a simple check of size dimorphism in this species, but with no apparent link to the main question of interest, here
patterns of foraging activity. I would suggest deleting it completely except the sentence justifying what body size was not included as an explanatory variable (l. 241-244, adding the actual sample sizes) and move the analyses themselves (description and results l. 294-299, including table 7) as an appendix.

R: this section was modified accordingly and a reference to the Table 1 was added regarding the sample sizes. L240-249, 833-849

- I. 253 and 259: you can remove the second “inter-individual variability”

R: removed. L264

- I. 257: replace “found” by “retained”?

R: this was changed in the revised version. L262

- I. 251-252: the interaction was clearly not supported for the second PCA axis for all stages (table 4 shows a difference of AIC of approx. 1000!) so something is wrong here: only the first axis is concerned and not the second? Please correct

R: thank you this mistake was changed in the revised version. L256-257

- I. 270 (and 318): I do not think that the word “abrupt” is needed. It may look abrupt when the whole duration is considered, but may happen gradually during the first month (all being a question of time scale and reference). You can delete this and simply say “strong changes”. In the same vein, I. 320-321: you mention “also exhibited progressive change” and “gradual change” but this is quite opposite to abrupt. Please rewrite here for clarity.

R: this was changed and has been rewritten accordingly. L275, L323

- I. 306-308: I would place this sentence at the very beginning of this paragraph (general presentation of the study)

R: this sentence was moved at the very beginning of this paragraph. L307

- I. 315: “the first months” (plural) – otherwise this is not coherent with the rest of the sentence

R: this was changed in the revised version. L321

- I. 321: replace “and that” by “so that”. Yet, the previous sentences indicate that at least part of the activity parameters still differ between juveniles and other stages (proportion of time spent on water), so maybe be a bit more cautious here with respect to similarity?

R: this was changed in the revised version. L328
not clear here: are the differences you refer to those observed during the first two months only? As said above, you also mention longer-term differences in this parameter. I think clarification is needed here.

R: this was clarified in the revised. L332-333

a transition here before discussing the interpretation in terms of performance?

R: done L.334

provide permit numbers here

R: done L.437

parentheses to be displaced around references

R: this was changed in the revised version. L894

is this really inconsistency? Is it not quite intuitive that immatures may behave “in between” juveniles and adults, and thus resemble the first in some aspects (or ins some periods) and the second in other aspects?

R: this was changed in the revised version. L350

replace “of optimal behaviours” by “leading to sub-optimal behaviour”, and place it at the end of the sentence, since it is true for other mechanisms as well? (but be careful not to overinterpret results in terms of performance as noted by the first reviewer on the first version, and as mentioned here a few lines above).

R: this was modified in the revised version. L344

I would place this paragraph before discussing the case of immatures (so before L. 333), as you mainly mention juveniles (see L. 349).

R: this paragraph was moved accordingly. L340-346

I do not understand this sentence: they behave differently than what: adults? other species? if adults, when? (since you mention that they readily use similar foraging strategies, so they do not behave differently then?). Please clarify here.

R: this was clarified in the revised version. L367-368

not sure that the shag example is a good one here, as it does not illustrate the idea of progressive improvement in flight performance, but compensation strategies for lower flight performance instead.
R: this was removed in the revised version. L375

- I. 363: “fly over long distances away from”
R: this was changed in the revised version. L378

- I. 365-367: I would simplify here by saying “The progressive change... could be either due to physical development or experience gain”.
R: this was changed in the revised version. L380-382

- I. 368: “Elucidating the mechanisms of the transition...” would be more correct I think. Also add “however” to show that this remains a important question to tackle?
R: this was changed accordingly in the revised version. L382-383

- I. 373: juvenile
R: this was modified in the revised version. L388

- I. 378 (and 431): renewal or molt?
R: this was modified in the revised version. L393

- I. 386: replace “this” by “the same” or “a similar”
R: this was modified in the revised version. L401

- I. 388: male and female Amsterdam albatrosses
R: this was modified in the revised version. L403

- I. 391-392: I’d suggest “Males in all stages did more bouts on water and juvenile males shorter wet bouts, compared to females”.
R: this was modified in the revised version. L405-406

- I. 391-394: I would place the description of the differences observed between sexes before discussing its origin (thus before I. 388), and make only one single paragraph about sex differences.
R: the paragraph was modified accordingly. L403-409

- I. 396: double parentheses
R: done L413-414
this suggests strong selective pressures for decreasing size dimorphism. Are pressures that maintain this dimorphism known (e.g. sexual selection)? It could be worth saying a word about it here, as the paragraph ends a bit abruptly otherwise. Also, would a sentence like “Sex differences in the acquisition of foraging performance during the first months after fledging yet remain to be explored”, to get back to the main question of the paper, namely ontogeny of this behaviour. Indeed, you did not test for a sex x phase x month elapsed since fledging interaction (but sample size does of not course not allow it here), which would be needed to test whether males and females acquire foraging skills with different speed (this could be expected if lighter females are more efficient?). Well, something like this to finish off this section would be good!

R: this was changed accordingly in the revised version. L422

no need to repeat the stages here I think

R: this was removed. L442

-R: this was changed. L447

is it possible to conclude from the results of the study that the lower survival observed for the first years in this species is unlikely to be fully explained by such an improvement in foraging ability, since parameters for juveniles reach the values observed for adults quite rapidly (even though some differences seem to remain longer)? I guess more detailed information would be needed to say so, especially data on the actual foraging performance realized (the amount or quality of preys obtained by juveniles), or at least on actual behaviour (the parameters used here remain rough when it comes to describe the behaviour itself). I think some kind of further thoughts on the results would be nice here to provide perspectives for future work or potential consequences for the understanding of the dynamics / evolution in this species... (and go beyond a simple summary of results!)

R: done L454-461

the “therefore” does not relate to the previous sentence (on sex differences). It would be better to rewrite here (“Overall”, or “As a conclusion”?)

R: this was changed. L452

indicate that this still would need to be confirmed by directly assessing foraging performance (see above)?

R: this was changed. L454
- I. 491: quite difficult to read (three “of”)... maybe consider rewriting? (“for all stages”?).

Also, Figure 2 has three panels (a, b and c), which should be described in the legend.

R: this was modified. L520-521

- I. 492: double parenthesis to remove

R: corrected L522

- when comparing fig. 2a with 3a, and 2b with 3b, I do not understand why the pattern observed for the first 9 months in juveniles does not appear in the longer period. I acknowledge that the smoothing and other parameters of the models differ in both cases, but the decline (for the first PCA axis) and the increase (for the second axis) are not observed at all anymore (instead reverse tendencies appear!), which is confusing. This needs to be explained clearly.

R: if we compare fig 2a (green line for juveniles) with 3a (boxplot values) for the first 9 months the same pattern appeared, in this case high value for the first month declining thereafter. When comparing fig 2b (green line for juveniles) and 3b (boxplot values) over the same period, low value the first month then increasing.

- I. 512 and 516: I guess this is fig 3 not 2?

R: this was changed in the revised version
