- 11 Keywords: Genome Reduction; Genome Streamlining; Extremophile; Acidophile; Evolution of
- 12 Acid Resistance; Chemolithoautotroph; Gene Gain and Loss; Protein Size Reduction and
- 13 Expansion.
- 14 Abstract
- 15 Genome streamlining theory suggests that reduction of microbial genome size optimizes energy
- 16 utilization in stressful environments. Although this hypothesis has been explored in several cases of
- 17 low nutrient (oligotrophic) and high temperature environments, little work has been carried out on
- microorganisms from low pH environments and what has been reported is inconclusive. In this study,
- 19 we performed a large-scale comparative genomics investigation of more than 260 bacterial high-
- 20 quality genome sequences of acidophiles, together with genomes of their closest phylogenetic
- 21 relatives that live at circum-neutral pH. A statistically supported correlation is reported between
- reduction of genome size and decreasing pH that we demonstrate is due to gene loss and reduced
- 23 gene sizes. This trend is independent from other genome size constraints such as temperature and
- 24 G+C content. Genome streamlining in the evolution of acidophilic Bacteria is thus supported by our
- 25 results. Analyses of predicted COG categories and subcellular location predictions indicate that
- 26 acidophiles have a lower representation of genes encoding extra-cellular proteins, signal transduction
- 27 mechanisms and proteins with unknown function, but are enriched in inner membrane proteins,
- 28 chaperones, basic metabolism, and core cellular functions. Contrary to other reports for genome
- 29 streamlining, there was no significant change in paralog frequencies across pH. However, a detailed
- analysis of COG categories revealed a higher proportion of genes in acidophiles in the following
- 31 categories: "Replication and repair", "Amino acid transport" and "Intracellular trafficking". This
- 32 study brings increasing clarity regarding genomic adaptations of acidophiles to life at low pH while
- 33 putting elements such as the reduction of average gene size under the spotlight of streamlining
- 34 theory.

1. Introduction

- 36 Significant differences in genome sizes (number of base pairs per genome) have been detected
- 37 between closely related lineages of prokaryotes isolated from a broad spectrum of environments and
- 38 across multiple phylogenetic lineages, with genome sizes down to 1.2 Mb in free living Bacteria and
- 39 differences of over 45% genome size between members from the same genus (Konstantinidis and
- 40 Tiedje, 2004, Dufresne et. al., 2005, Lynch, 2006, Giovannoni et. al., 2014, Martinez-Cano et. al.,
- 41 2015, Bentkowski et. al., 2015, Rodríguez-Gijón et. al., 2021). Small or reduced genomes, also
- 42 termed streamlined genomes, have been widely observed in microorganisms adapted to live in low
- 43 nutrient niches, such as cosmopolitan marine bacterioplankton (Giovannoni et. al., 2005, Schneiker
- 44 et. al., 2006, Swan et. al., 2013, Luo et. al., 2014, Sun and Blanchard, 2014, Graham and Tully,
- 45 2021), rivers (Nakai et. al., 2016), slow growers in anoxic subsurfaces (Chivian et. al., 2008,
- 46 McMurdie et. al., 2009), and in a wide range of extremophiles such as bacteria adapted to
- 47 supersaturated silica (Saw et. al., 2008), halophiles (López-Pérez et. al.2013, Min-Juan et. al., 2016),
- 48 thermophiles (Sabath et. al., 2013, Saha et. al., 2015, Gu et. al., 2020), psychrophiles (Dsouza et. al.,
- 49 2014, Goordial et. al., 2016), and alkaliphiles (Suzuki et. al., 2014). Differences in genome size have
- been reported for aerobes versus anaerobes (Nielsen et. al., 2021) and for microorganisms living in
- warmer versus cooler environments (Lear et. al., 2017, Sauer and Wang, 2019) and in bacterial
- 52 pathogens (Murray et. al., 2021).
- 53 Streamlining theory proposes that genome reduction is a selective process these organisms undergo
- 54 that promotes their evolutionary fitness (reviewed in Giovannoni et. al., 2014). The theory suggests
- 55 that a smaller genome reduces the energy cost of replication and, by encoding fewer gene products,
- 56 there is a concomitant reduction of cell size that could optimize transport and nutrient acquisition
- 57 (Button, 1991, Sowell et. al., 2009). Some marine microorganisms with streamlined genomes have
- 58 been found to have proportionately fewer genes encoding transcriptional regulators and an overall
- 59 lower abundance of mRNA transcripts per cell, potentially reducing the cost of transcription and
- 60 translation (Cottrell and Kirchman, 2016). These results are congruent with the observed correlation
- between regulatory network complexity and genome size (Konstantinidis and Tiedje, 2004). Genome
- 62 size reduction is also observed in symbiotic microorganisms (Baker et. al., 2010, Gao et. al., 2014),
- but it has been theorized that this phenomenon differs to the streamlining of free-living bacteria as
- 64 the former lose genes by genetic drift due to function redundancy between the host and the symbiont,
- 65 while the latter would lose them by intense selective pressure (McCutcheon and Moran 2012,
- 66 Giovannoni et. al., 2014), although recent evidence has argued otherwise (Gu et. al., 2020).
- 67 Any organism that grows optimally at low pH can technically be classified as an acidophile.
- 68 However, because there are many neutrophiles (optimum growth ~pH 7) that successfully grow at
- around pH 6 or lower, it is useful from a practical point of view to define acidophiles as those
- 70 microorganisms that grow optimally below pH 5 and make a distinction between moderate
- acidophiles that grow optimally between pH 5 and about pH 3.0 (Foster, 2004, Dopson, 2016,
- 72 Benison et. al., 2021) and extreme acidophiles that grow below pH 3 (Johnson, 2007). The latter are
- 73 particularly challenged for survival and growth as they face a proton concentration across their
- membranes of over 4 orders of magnitude (Baker-Austin and Dopson, 2007, Slonczewski et. al.,
- 75 2009). Acidophilic microorganisms have been identified in all three domains of life (Johnson and
- Hallberg, 2003), but currently more genomic information is available for prokaryotic acidophiles
- 77 (Archaea and Bacteria) (Cárdenas et. al., 2016, Neira et. al., 2020).
- 78 Our current understanding about genome streamlining in acidophiles comes from a limited number of
- 79 observations. It has been reported that the genomes of several acidophilic microorganisms, such as

- 80 Methylacidiphilum, Ferrovum and Leptospirillum (domain Bacteria) and Picrophilus (domain
- Archaea) are smaller (2.3, 1.9, 2.3 and 1.5 Mb, respectively) compared to their closest neutrophilic
- 82 phylogenetic relatives (Angelov and Liebl, 2006, Hou et. al., 2008, Ullrich et. al., 2016, Vergara et.
- 83 al., 2020). Genome reduction in acidophiles has been discussed as a mechanism to reduce energy
- 84 costs to survive in extremely low pH environments where organisms must deploy multiple energy-
- intensive acid resistance mechanisms to maintain a circumneutral cytoplasmic pH (Hou et. al., 2008,
- 86 Ullrich et. al., 2016, Zhang et. al., 2017, Vergara et. al., 2020) while thriving in often nutrient scarce
- and heavy metal polluted low pH environments (Johnson 1998, Dopson et. al., 2003, Johnson and
- Hallberg, 2008). Despite this progress, there remains much to be discovered about genome reduction
- 89 in acidophiles. With the increased availability of genome sequences of acidophiles (Cárdenas et. al.,
- 90 2016, Neira et. al., 2020), we shed light on whether there is a statistically supported correlation of
- 91 genome reduction with low pH and, if so, what are its biological implications.

92 **2.** Materials and Methods

93 **2.1 Data procurement and management**

94 **2.1.1** Genome information

- 95 Genomes of 345 bacterial acidophiles together with their associated growth and taxonomic data were
- obtained from AciDB (Neira et. al., 2020). This set of genomes was modified for the present study in
- 97 three ways: i) only free-living Bacteria were considered. For example, symbionts such as *Ca*.
- 98 Micrarchaeum were discarded; ii) organisms without an identified phylum affiliation were also
- 99 discarded and iii) seven new genomes and their associated metadata from acidophiles have been
- added since the publication of AciDB. This resulted in an initial dataset of 342 genomes of
- acidophiles. In addition, 339 genomes were collected from non-acidophiles (growth optima, pH 5-8).
- These included 222 genomes of neutrophiles (growth optima, pH 6-8) that were the closest
- phylogenetic relatives to the acidophiles as identified using NCBI taxonomy (Schoch et. al., 2020),
- 104 GTDB (Chaumeil et. al., 2020) and AnnoTree (Mendler et. al., 2019), resulting in an equal
- taxonomic representation of genomes of acidophiles and their neutrophilic phylogenetic relatives.
- 106 Genome sequences were downloaded from the National Center for Biotechnology Information
- 107 (NCBI) and the Joint Genome Institute (JGI). Genomes were filtered for quality using CheckM
- 108 v1.0.12 with cutoffs for completeness >80% and contamination <5% (Parks et. al., 2015). This
- resulted in a final data set of 597 high quality bacterial genomes, comprising 264 genomes from
- acidophiles (pH <5) and 333 genomes from non-acidophiles (pH 5-8). Genome information is
- 111 provided in Supplementary Table 1.
- Genome average nucleotide identity (ANI) was determined using fastANI v1.3 with 4 threads (Jain
- et. al., 2018). A cutoff of 95% average nucleotide identity was defined (Kim et. al., 2014) to group
- identical or highly similar genomes into species clusters. Genomic characteristics, proteomic data and
- associated metadata are reported as the means of each group for all plots. This reduced data bias due
- to over-representation of some highly sequenced species.

117 **2.1.2** Growth pH and temperature

- Optimal growth pH and temperature of a species were downloaded from AciDB (Neira et al., 2020).
- For new species with sequenced genomes not yet deposited in AciDB, information for optimal
- growth pH and temperature was extracted from the literature. When no description of these optima
- was available, they were defined as the midpoint of the growth range reported for the strain or closely

- related strain as described by Neira et al., 2020. For metagenomes, the reported environmental data
- were used to determine optimum pH and temperature.

124 **2.2 Proteome analyses**

125 **2.2.1** Protein annotations

- Genome annotations were downloaded from NCBI (www.ncbi.nlm.nih.gov) or JGI
- 127 (img.jgi.doe.gov). Genomes without an existing annotation were annotated with prokka v1.13.3
- 128 (Seemann, 2014). A proteome table was generated for each genome, that includes information for
- each predicted protein, including size, predicted subcellular localization, functional annotation with
- 130 COGs and Pfams, COG category, presence of signal peptide and ortholog group. Unless stated, all
- 131 software was run with default options.

132 **2.2.2 Ortholog groups**

- To define ortholog groups, reciprocal BLASTP was performed within each genome by using all the
- proteins in its predicted proteome as queries against a database of the same proteins. A coverage of
- 135 50%, a sequence identity of 50% and an e-value of 10-5 were used as cutoffs (Tettellin et. al., 2005,
- Naz et. al., 2020). Protein pairs that follow these conditions were assigned to the same ortholog
- family if one or both were the best scored BLASTP hit of the other. Ortholog groups will also be
- 138 referred as protein families.

139 **2.2.3 Subcellular localization**

- Subcellular locations were assigned to each predicted protein using PSORTb v3.0 (Yu et. al., 2010),
- which predicts either cytoplasmatic, inner membrane, exported, outer membrane, periplasmic for
- gram negative Bacteria and cell wall for gram positive Bacteria. An "unknown" tag is assigned to
- proteins whose subcellular location could not be predicted. This was complemented with signal
- peptide identification, which was assigned using SignalP v5.0b that predicts the presence of signal
- peptides for translocation across the plasmatic membrane by either the Sec/SPI (standard system),
- 146 Sec/SPII (lipoprotein signal peptide system) or the Tat/SPI (alternative system) translocation/signal
- peptidases (Almagro et. al., 2019). All three positive predictions were binned together and tagged as
- 148 "Has Signal Peptide". Proteins were sorted by both subcellular localization and signal peptide
- 149 presence.

150

2.2.4 Pfam and COG functional annotations

- 151 Pfams were assigned to predicted proteins using Pfam_scan v1.6 (Finn et. al., 2016) under Pfam
- version 32.0 (El-Gebali et. al., 2019), which contains a total of 17929 different functional annotations
- including protein families and clans. An e-value of $<10^{-5}$ was applied as a cutoff for Pfam predictions
- of protein function. The pfam with the lowest e-value was assigned to each protein. COG annotations
- were assigned with the web tool eggNOG-mapper v5.0 (Huerta-Cepas et. al., 2019) under the
- December 2014 version of the COG database, which contains 4632 functional annotations (Galperin
- et. al., 2015). The percentage of ortholog groups that have a Pfam assignment (Mistry et. al., 2021) or
- a COG assignment (Galperin et. al., 2021) were calculated for each proteome. The percentage of
- ortholog groups belonging to each COG category was also calculated. In addition, Pfam assignments
- were used for the analysis of intra-protein family size variation and to determine the percentage of
- 161 proteins with an annotation.

2.2.5 Paralog frequencies

- Paralog families were defined as ortholog groups with two or more proteins from the same proteome. 163
- The percentage of proteins that belong in paralog families was calculated for each COG category in 164
- 165 relation to the total number of proteins in the category. The same procedure was repeated for the full
- 166 proteome.

162

167

184

2.3 Statistical analyses

- 168 A python script was developed to gather, filter, organize and analyze the data from the organisms'
- 169 genomes and proteomes (van Rossum, 1995). Data distributions were statistically analyzed using the
- 170 following methods. The scipy library (Virtanen et. al., 2020) was used for linear fittings (with the
- "linregress" module), binomial test (with the "stats.binom test" module) and Pearson's linear 171
- correlation coefficient (with the "stats, pearsonr" module). A two-sided mode was used for all the 172
- 173 tests. P-value thresholds used for statistical significance were 0.05, 0.01 and 0.001. For estimation of
- correlation in potentially heteroscedastic distributions, a Generalized Least Squares was applied 174
- 175 using the module "regression.linear_model.GLS" within the statsmodels library (Seabold and
- 176 Perktold, 2010). For multi-testing analyses, the false discovery rate (FDR) was used to determine
- statistical significance using the Benjamini/Hochberg procedure (Benjamini and Hochberg, 1995) 177
- 178 with the "stats.multitest.multipletests" module also within the statsmodels library. A q-value of 0.05
- 179 was used for Pearson's correlation p-values. The q-value is the upper limit of the rate of the findings
- (null hypothesis rejections) that is expected to be a false positive. Principal component analysis 180
- 181 (PCA) was performed with the "decomposition.PCA" module within the sklearn library (Pedregosa
- 182 et. al., 2011). The number of components for dimensionality reduction was set to 2. Data was plotted
- 183 using the matplotlib library (Hunter, 2007).

3. Results and Discussion

3.1 Phylogenetic distribution and associated metadata of genomes interrogated

- 187 From the 342 publicly available genomic sequences (264 high quality plus 78 low-quality genomes)
- of acidophilic Bacteria, 331 genomes with well-defined taxonomies (phylum and class) were mapped
- on to a rooted cladogram (Figure 1). The genome sequences come from 177 species distributed in 17
- classes and 8 phyla out of a total of 37 recognized bacterial phyla (55 if candidate phyla are included)
- 191 (Schoch et. al., 2020) (Figure 1 and Supplementary Table 1). The acidophiles are widely distributed
- in the cladogram supporting the idea that acidophile lineages have emerged independently multiple
- times during evolution (Cárdenas et. al., 2016, González et. al., 2016, Colman et. al., 2018, Khaleque
- 194 et. al., 2019, Vergara et. al., 2020).
- Figure 2 shows the distribution of acidophilic species with sequenced genomes by phylum across pH,
- where pH represents the optimum for growth for each species. The total number of species declines
- 197 from about 60 species in the range pH 4-5 to about 10 at pH 0.5-1.5 (Figure 2A) consistent with the
- observation that species diversity declines in low pH environments (Bond et. al., 2000, Baker and
- 199 Banfield, 2003, Johnson and Hallberg, 2003, Méndez-García et. al., 2014, Lukhele et. al., 2020,
- Hedrich and Schippers, 2021). These estimates are based on the distribution of acidophiles with
- 201 publicly available sequenced genomes; the true richness of acidophile diversity is likely to be much
- 202 higher and will probably increase as more acidic econiches are sampled using metagenomics
- approaches.

215

185

186

- Figure 2B shows the distribution of species by percentage across pH. The results have been divided
- into three sections (a-c) for discussion. Section (a) with a pH range of 1.0 to 2.0 is dominated by
- species in the phyla Proteobacteria, Firmicutes and Nitrospirae in approximately equal proportions
- around pH 2 and by Firmicutes at pH 1. Section (b) shows the species distribution in the range pH 2
- 208 to 4. Acidophilic species of the phylum Proteobacteria are the most prevalent in this range but exhibit
- a declining percentage with decreasing pH. Species of Actinobacteria and Verrucomicrobia are
- 210 represented about equally but both phyla have few representatives below pH 2. Species of Aquificae
- are present in a low percentage (~ 3%) down to about pH 3, beyond which there are no representative
- 212 genomes. Section (c) shows the species distribution in the range pH 4 to 5. All seven phyla (eight, if
- one includes the one species from Armatimonadetes) have species in this range but Acidobacteria
- show a declining percentage from pH 5 to pH 4 below which there are no representative genomes.

3.2 Genome size as a function of pH

- 216 A scatterplot of genome size across optimal growth pH shows declining genome sizes from about
- 4.5Mb for circum-neutrophiles to an average of about 3.4Mb for extreme acidophiles (Figure 3).
- There are no large genomes (>5Mb) for bacteria that grow below about pH 4, whereas large genomes
- 219 including up to about 10Mb are present in acidophiles that grow between pH 4 and pH 5 and in
- 220 neutrophilic relatives of the acidophiles that grow from pH 5 to pH 8. A linear regression model
- 221 fitted to the data shows a tendency that is statistically significant with a positive Pearson's correlation
- coefficient of 0.19 and a p-value of 2.97*10⁻⁵, implying genomes are smaller at lower pH. However,
- 223 there is evidence of heteroscedasticity in the plot. We applied Generalized Least Squares Regression
- 224 (GLS) to take into account heteroscedasticity, and a p-value of 1.8*10⁻³ was obtained supporting the
- proposed relationship between pH and genome size.
- However, the presence of heteroscedasticity suggests the possibility that other variables, in addition
- 227 to pH, may contribute to the determination of genome size. To address this issue, we investigated

- 228 potential contributions of growth temperature and genomic G+C content on the distribution of
- 229 genome size across pH. Many acidophiles are also moderate or even extreme thermophiles (Johnson
- 230 and Hallberg, 2003, Capece et. al., 2013, Colman et. al., 2018) and temperature has been suggested to
- 231 be a driving force for genome reduction (Sabath et. al., 2013). Genome size has also been associated
- 232 with G+C content, where organisms with relatively low genomic G+C content tend to have smaller
- 233 genomes (Veloso et. al., 2005, Almpanis et. al., 2018).
- 234 We evaluated how these factors are correlated with genome size and pH. Temperature is negatively
- correlated with genome size (Pearson's correlation coefficient, -0.34; p-value, 2.9*10⁻¹³) (Figure 4A) 235
- 236 and G+C is positively correlated with genome size (Pearson's correlation coefficient, 0.48, p-value
- 1.9*10⁻²⁵) (Figure 4C). A negative correlation between genome size and temperature has recently 237
- 238 been reported for extreme acidophiles of the Acidithiobacillus genus (Sriaporn et. al., 2021).
- 239 However, no statistically supported correlation is observed between temperature and pH (Pearson's
- 240 correlation coefficient, -0.01; p-value 0.84) (Figure 4B), nor between G+C content and pH (Pearson's
- 241 correlation coefficient, -0.06; p-value 0.22) (Figure 4D). Therefore, while both temperature and G+C
- 242 content have a strong influence on genome size, they appear to act independently of the relationship
- 243 between pH and genome size.
- 244 To investigate further the interplay of pH, temperature and G+C content with genome size, we
- 245 performed dimensionality reduction and visualization via principal component analysis (PCA)
- 246 (Jolliffe, 2005). As seen in Figure 5, the directions of the loading vectors show temperature is
- 247 negatively correlated with both G+C content and genome size, while genome size is positively
- 248 correlated with both G+C content and pH. This is also depicted in how the smallest genomes are
- 249 found in thermophiles (optimal temperature >55°C, rightmost cluster) followed by extreme
- 250 acidophiles (optimal pH < 3, upmost cluster), while the biggest genomes are found in a high G+C
- 251 content group (leftmost cluster). Conversely, the orthogonality of the loading vectors suggests no
- 252 correlation is observed between pH and temperature or between pH and G+C content. Therefore,
- 253 when considering all variables at once, the same results are observed as when the variables were
- 254 individually assessed (Figure 4), providing additional evidence that neither G+C content nor
- 255 temperature affect the correlation between pH and genome size, rather multiple driving forces can
- 256 independently exert their influence on genome size.

Genetic mechanisms involved in genome size changes 257 3.3

258 3.3.1 Hypothetical schema

- Given the observation that genome size is negatively correlated with pH in acidophiles, we aimed to 259
- 260 determine what genomic processes influence this relationship. Figure 6 shows a diagrammatic
- 261 representation of genetic mechanisms that have been postulated to be involved in genome expansion
- 262 or reduction in Bacteria and Archaea (Keeling and Slamovits, 2005, Sabath et. al., 2013, Giovannoni
- et. al., 2014, Gillings, 2017, Kirchberger et. al., 2020, Rodríguez-Gijón et. al., 2021, Westoby et. al., 263
- 264 2021). Genome size changes could result from having (i) changes in number of orthologous families
- 265 (A, Figure 6) or paralogous genes (B, Figure 6); (ii) genome compaction/expansion resulting from
- 266 changes in the number of intergenic nucleotides including alteration in the frequency of overlapping
- genes (C, Figure 6) (reviewed in Kirchberger et. al., 2020) and (iii) smaller or larger genes, including 267
- 268 loss/gain of domains (D, Figure 6).
- 269 Based on the schema shown in Figure 6, we investigated the contribution of the different mechanisms
- 270 in genome size changes in acidophiles across pH. Annotated open reading frames (ORFs) were used

- as surrogates for "genes". A caveat is that ORF prediction depends on the quality of the genome
- sequence, where poor quality genomes frequently have incorrectly annotated chimeric and truncated
- 273 ORFs that confound subsequent identification of genes (Klassen and Currie, 2013). We minimized
- 274 these potential errors by analyzing only genomes that had passed a high quality CheckM filter (Parks
- et. al., 2015). However, even high-quality genomes are prone to errors of ORF annotation especially
- in the identification of correct translation start sites (Korandla et. al., 2020) which will impact
- 277 predictions of gene and intergenic spacer sizes. Currently, there are no computational program for
- ORF prediction that is flawless, including GenBank (Korandla et. al., 2020), and we expect that
- 279 future work will improve the annotations of ORFs used in our study.

3.3.2 Reduction/expansion of gene (ORF) number

- 281 The number of protein coding genes (ORFs) of each genome under interrogation was plotted as a
- 282 function of optimal growth pH of the species. The results indicate that there is a statistically
- significant reduction (Pearson's coef.: 0.18; P-value: 1.25*10⁻⁴) of the average number of ORFs per
- organism across pH from an average of about 4100 ORFs/organism at pH 7 to about 3200
- ORFs/organism at pH 2 (Figure 7A). This has been regarded as possibly the most predominant
- 286 mechanism for genome size changes (Konstantinidis and Tiedje, 2004) and this is likely also true for
- our dataset (Supplementary Figure 1).

280

304

288 3.3.3 Reduction of intergenic spacers as a possible contributor to genome compactness.

- 289 It is well established that bacteria have compact genomes with an average protein-coding density of
- 290 87 % with a typical range of 85–90 % (McCutcheon and Moran 2012). Genome size reduction could
- 291 occur by decreasing the amount of DNA occupied by intergenic spacers, for example by promoting
- the frequency of overlapping genes (Veloso et. al., 2005, Saha et. al., 2015, Kreitmeier et. al., 2021).
- 293 This strategy has been especially exploited in compacting viral genomes (Pavesi, 2021).
- 294 To evaluate whether a reduction in the fraction of the genome dedicated to non-protein coding DNA
- 295 contributed to smaller genomes observed in acidophiles, we calculated the percentage of intergenic
- spaces (IG) dedicated to the total genome content across pH. IG was calculated as genome size (bp) -
- Σ bps of all ORFs in a genome, expressed as a percentage of the total bps in the genome. A smaller
- 298 % IG implies greater genome compaction. A tendency was observed for % IG to increase as pH
- 299 growth optima declines (Figure 7B), however, this trend is not statistically significant (Pearson's
- 300 coef. = -0.11, p-value 0.06). A potential problem in the interpretation of this result stems from
- 301 uncertainties in the identification of ORFs, most notably by errors in the identification of the correct
- site of initiation of protein coding regions (Korandla et. al., 2020). This influences the estimation of
- 303 the percentage of intergenic genomic DNA.

3.3.4 Reduction/increase of gene (ORF) size

- 305 The average size of ORFs (as the number of amino acids of the predicted proteins) per genome was
- 306 plotted as a function of pH (Figure 7C). There is a statistically supported positive correlation (p-value
- 307 4.03*10⁻⁸) between average ORF size and pH, with an average size of 320 amino acids at pH 7 to 300
- at pH 2. This indicates acidophiles have shorter proteins in average, which could be produced by a
- 309 loss of larger proteins or by gene size reduction (Figure 6, mechanism D) or possibly both.
- 310 To quantify gene size reduction in acidophiles, we analyzed the protein sizes of several conserved
- 311 Pfams in the dataset (Figure 8). We observed that the conserved Pfams with reduced protein sizes in
- acidophiles are over 5 times as many as the conserved Pfams with increased sizes (Figure 8 A,

- 313 binomial test p-value 2.1*10⁻¹³). This result accounts mainly for changes in the predominant domain
- 314 architectures, implying these proteins in acidophiles likely have fewer domains. For example, the
- 315 biotin requiring enzyme was mainly found in single domain proteins below pH 5, while in
- 316 neutrophiles it can often be found next to other domains such as the dihydrolipoamide acyltransferase
- 317 (Supplementary Table 3). This inclination towards protein size reduction is also observed in a
- 318 collection of conserved Pfams that are also in single copy and predominantly in single domain
- architectures (Figure 8 B, binomial test p-value 7.4*10⁻³). This result accounts mainly for loop size
- reductions and domain size reductions. Such is the case of the ribosomal protein L19 that in
- 321 acidophiles lacks long loops and is 4 amino acids shorter on average (Supplementary Table 4).

322 3.4 Gene representativity across pH

- 323 Having established that there is a statistically supported negative correlation between genome size
- and optimal pH for growth and that gene gain and loss events likely contributed to this correlation,
- we investigated in more detail what types of genes were involved these events.

326 3.4.1 Changes in ortholog groups representativity in acidophiles

- 327 To gain insight into the contribution of gains or losses of genes in the observed genome size changes
- of acidophiles (mechanism A, Figure 6), we first clustered the genes into ortholog families and
- 329 systematically classified the predicted proteomes of each genome by (i) subcellular location and (ii)
- functional category as predicted by Pfam annotations (Mistry et. al., 2021) and COG categories
- 331 (Galperin et. al., 2015). Subsequently, we mapped the frequencies of ortholog families of these
- 332 categories in the genomes across pH.

333

3.4.1.1 Changes in ortholog frequencies by sub-cellular location

- Figure 9 shows the frequency of occurrence of protein families with sub-cellular location and/or
- signal peptide predictions expressed as a percentage of the total protein families per genome. The
- frequency of proteins predicted to be in the cytoplasm does not change across pH (blue data points
- and line, Figure 9). However, there is a statistically significant decrease (Pearson's correlation
- coefficient 0.22, p-value 1.4*10⁻⁶) in the frequency of proteins predicted to have a signal peptide with
- decreasing pH (red data points and line, Figure 9) and a statistically significant increase (Pearson's
- 340 correlation coefficient -0.19, p-value 4.4*10⁻⁵) in the frequency of proteins predicted to be in the
- inner membrane with decreasing pH (orange data points and line, Figure 9). There is a small, but
- nevertheless statistically significant decrease (Pearson's correlation coefficient 0.21, p-value 7.5*10
- 343 ⁶) in the frequency of proteins predicted to be in the category "periplasm, outer membrane, cell wall
- and exported" with decreasing pH (green data points and line, Figure 9).
- 345 The decrease in proportion of proteins with signal peptides at low pH (Figure 9) is consistent with the
- observation that there are correspondingly fewer proteins predicted in the category "periplasm, outer
- membrane, cell wall and exported" at low pH since most of these proteins require a signal peptide
- export mechanism to pass through the periplasmic membrane (Green and Mecsas 2016). We
- 349 hypothesize that the decrease in relative frequency of proteins found outside the inner membrane in
- acidophiles could be due to physico-chemical challenges that such proteins would encounter as they
- are exposed to high concentrations of protons at low pH, potentially limiting the diversity of proteins
- 352 that have evolved to survive such challenges (D'Abusco et. al., 2005, Chi et. al., 2007, Duarte et. al.,
- 2009, 2011, Panja et. al., 2020, Chowhan et. al., 2021). We speculate that the observed enrichment of
- protein families predicted to be in the inner membrane in acidophiles (Figure 9) reflects the

- importance of such proteins in acid stress management (Lund et. al., 2014, Zhang et. Al., 2016,
- 356 Vergara et. al., 2020, Hu et. al., 2020).

357

3.4.1.2 Changes in ortholog frequencies by functional category

- 358 The contribution of gene gain or loss to genome size changes across pH were also analyzed using
- 359 gene functional classification using COG and Pfam annotations. 25 functional categories are
- recognized in the 2014 COG database (Galperin et. al., 2015) and Pfam v32.0 contains a total of
- 361 17,929 families (El-Gebali et. al., 2019, https://pfam.xfam.org). The combination of COG and Pfam
- analyses provides deep and accurate coverage for searching for predicted protein function in our
- dataset. Figure 10 shows that the percentage of proteins per genome with a COG or Pfam annotation
- decreases at lower pH with statistical significance (Pearson's correlation coefficients 0.24 and 0.14,
- p-values $2*10^{-7}$ and $2.6*10^{-3}$), which is not observed for small neutrophilic genomes (Supplementary
- Figure 3). This indicates that acidophiles have a higher proportion of putative protein coding genes
- that are not recognized by neither COG nor Pfam. These proteins can be classified as non-conserved,
- 368 hypothetical proteins with no functional prediction, which do not have protein clusters with sufficient
- entries to have their own functional annotation in the COG or Pfam databases. It is possible that some
- of these represent poorly annotated sequences and pseudogenes. However, an intriguing possibility is
- that some could correspond to *bona fide* protein coding genes that are enriched in acidophiles. Their
- analysis could potentially yield clues about novel acid-tolerance mechanisms and other functions
- enriched in acidophiles. Examples of such proteins have recently been detected, although their
- function remain unknown (González et. al., 2016, Vergara et. al., 2020).
- 375 An analysis of the distribution of functional categories across pH using COGs shows that acidophiles
- are enriched in several functions that could possibly be attributed to their distinctive metabolisms and
- environmental challenges (Table 1). For example, enrichment in COG L (replication, recombination,
- and repair) and COG O (Chaperone, post-translational modification) might reflect their need for
- 379 DNA repair and protein refolding when confronted by potentially damaging stresses such as low pH,
- 380 high metal concentrations and oxidative stress (Crossman et. al., 2004, Baker-Austin and Dopson,
- 381 2007, Cárdenas et. al., 2012, Dopson and Holmes, 2014). The increase in frequency of COGs C, F
- and H (Energy production and transport; nucleotide metabolism and transport and coenzyme
- 383 metabolism and transport, respectively) could reflect enzyme and pathway requirements associated
- with obligate autotrophic metabolism that has been found in many acidophiles (Johnson, 1998,
- Johnson and Hallberg 2008). As for COG J, it is possible that as ribosomal proteins are very
- 386 conserved across prokaryotic life (Lecompte et. al., 2002), they are less likely to be discarded. Future
- research could investigate what are the functions in this category overrepresented in acidophiles.
- 388 On the contrary, genomes of acidophiles are depleted in COG T (Signal transduction mechanisms). A
- depletion of signal transduction mechanisms has been observed in some marine microbes especially
- 390 those that are slow growing (Gifford et. al., 2013, Cottrell and Kirchman, 2016), in the streamlined
- 391 genome of the extreme acidophile Methylacidiphilum infernorum (Hou et. al., 2008) and in
- metagenomic profiling data of acidic environments (Chen et. al., 2015). The abundancy of signal
- transduction mechanisms generally declines with decreasing genome size, as it has been found that
- 394 the number of one and two component signal transduction systems is proportional to the square of the
- 395 genome size (Konstantinidis and Tiedje, 2004, Ulrich et. al., 2005, Galperin, 2005). Extensive
- research has been conducted on the different signal pathways and regulatory networks of acidophiles
- 397 (Rzhepishevska et. al., 2007, Shmaryahu et. al., 2009, Moinier et. al., 2017, Díaz et. al., 2018, Osorio
- 398 et. al., 2019). However, additional research is needed to uncover what signal pathways are not
- 399 present in these organisms. Acidophiles possess several features which may explain their

- 400 underrepresentation in proteins from this category, such as having small genomes, and having
- relatively slow growth speeds (Fang et. al., 2006, Mykytczuk et. al., 2010).
- 402 The genomes of acidophiles also have a proportionately reduced number of COG S (unknown
- 403 function). These are proteins with unknown function that are conserved across multiple species and
- 404 so are distinct from the category described above (Figure 10) that are not conserved across multiple
- species. As both are proteins with no known function, the representativity of unknown function
- 406 proteins remains relatively constant across pH, but a greater number of these proteins are in multiple
- 407 species in neutrophiles. It is possible that many functions assigned to COG S are found principally in
- 408 neutrophilic heterotrophs whose genome sequences are the most prevalent in databases (extrapolated
- from the limited number of genomic sequences of acidophiles, Neira et. al., 2020) and therefore can
- 410 potentially dominate the COG database.

411

3.4.2 Paralog frequency across pH

- We next examined whether the gain or loss of paralogs contributed to genome size changes
- 413 (mechanism B, Figure 6). In contrast to what has been described above concerning gain or loss of
- specific COG and Pfam gene functions, here we explored how genome size could be influenced by
- 415 the expansion or contraction of the number of genes in such families. Gene duplication, followed by
- 416 functional diversification has been invoked as a major contributor to gene evolution (reviewed in
- Innan and Kondrashov, 2010 and Copley, 2020) and gene paralogs can be present as a significant
- 418 proportion of a genome (Swan et. al., 2013). An increase in the number of paralogous protein copies
- 419 (including in- and out- paralogs and xenologs, Remm et. al., 2001, Darby et. al., 2017) has been
- observed to be correlated with a better performance in a specific function, such as heavy metal
- resistance or adaptation to other multiple stressors (Kondratyeva et. al., 1995, Dulmage et. al., 2018).
- Relatively high paralog frequencies for proteins linked to acid resistance mechanisms have been
- detected in acidophiles (Ullrich et. al., 2016, Vergara et. al., 2020).
- We analyzed paralog frequency changes in genomes across pH by COG categories. The COG
- annotation has been proved useful for gene enrichment analyses across several genomes (Galperin et.
- 426 al., 2021). As seen in Figure 11 and Supplementary Figure 5, acidophiles have relatively high paralog
- 427 frequencies in the COG categories "Replication, repair and recombination", "Intracellular trafficking
- 428 and secretion" and "Energy production and conversion", but low frequencies in the COG categories
- 429 "Signal transduction", "Translation and ribosome" and "Amino acid metabolism", as shown by
- 430 statistically significant correlations (p-value <0.01). Some of the results are in concordance with the
- protein family representativity results (Table 1) which increases the importance of the putative
- 432 contribution of these functions on acidophilic survival and adaptation.
- 433 High paralog frequencies in the "Replication, repair and recombination" category in acidophiles
- 434 might be attributed to a large number of transposases and integrases. The high prevalence of mobile
- elements in acidophilic genomes has been previously pointed out as a key factor for acidophilic
- evolution (Aliaga et. al., 2009, Navarro et. al., 2013, Acuña et. al., 2013, Ullrich et. al., 2016, Zhang
- et. al., 2017, Colman et. al., 2018, Vergara et. al., 2020). As discussed in the previous section (Table
- 438 1), DNA repair proteins might also be in several copies. These have been found to protect against
- oxidative stress and heavy metal stress, which acidophiles are exposed to in higher levels (Crossman
- 440 et. al., 2004, Baker-Austin and Dopson, 2007, Cárdenas et. al., 2012).
- The increased number of paralogous proteins from the "Intracellular trafficking and secretion"
- category in the acidophile genomes could result from an abundance of type II secretory systems

- involved in conjugation. It has been observed that these systems are frequently associated with
- 444 mobile elements and are found to be particularly abundant in the flexible genomes of acidophiles
- 445 (Acuña et. al., 2013, Beard et. al., 2021), suggesting that they are shared between organisms in a
- 446 common econiche. In addition, vesicle related proteins might also be duplicated in acidophilic
- genomes, as studies show that vesicular transport (whose related functions belong in this category) is
- linked to biofilm formation (Jan, 2017), which in turn has been widely observed in acidophiles
- 449 (Baker-Austin et. al., 2010, González et. al., 2013, Díaz et. al., 2018, Vargas-Straube et. al., 2020).
- 450 Similarly to the results of genome representativity (Table 1), the increased paralog frequencies of
- 451 proteins from the "Energy production and conversion" category in acidophiles, might be related with
- 452 their overrepresentation of chemolithotrophic metabolism. Some of the enzymes involved in iron or
- sulfur oxidation belong to this category, such as the cytochrome C, heterodisulfide reductase and
- 454 quinone related proteins (Quatrini et. al., 2009, Zhan et. al., 2019). Additionally, several proteins in
- 455 this category are involved in proton exporting functions, such as the H+-ATPase and the overall
- electron transfer chain proteins such as the ubiquinone oxidoreductase (Walker, 1992, Fütterer et. al.,
- 457 2004, Feng et. al., 2015). This indicates that some genes in this category might be in high copy
- numbers to increase the acid resistance of acidophiles. Alternatively, it could be a consequence of the
- 459 high energy requirements of maintaining a neutral internal pH (Baker-Austin and Dopson, 2007,
- 460 Slonczewski et. al., 2009).
- 461 The reduced paralog frequencies in the "Signal transduction" category are concordant with their
- reduced genome representativity in acidophiles, and thus might be accounted by the same phenomena
- as previously exposed (Table 1).
- The reduced number of paralogs in acidophiles in COG E "Amino acid transport and metabolism",
- 465 might be accounted for by a reduction in the number of amino acid importers that are not common in
- acidophiles. The predominancy of autotrophic metabolism in acidophiles could result in an
- 467 inclination for these organisms towards biosynthesis of amino acids rather than uptake by active
- 468 transporters. Additionally, uptake of amino acids could be harmful to acidophiles as organic acids
- 469 carry protons into the cytoplasm of these organisms, short circuiting acid resistance mechanisms
- 470 (Kishimoto et. al., 1990, Lehtovirta-Morley et. al., 2014, Carere et. al., 2021). The current hypothesis
- 471 is that organic acids are protonated in the extremely acid medium where acidophiles grow (pH <3)
- becoming non-ionic and soluble in bacterial membranes, permitting diffusion into the cytoplasm (pH
- 473 around 7) where they uncouple from the proton. A similar phenomenon could occur with amino acids
- but involving membrane transporters, as amino acids are unlikely to diffuse passively through the
- 475 membrane.
- 476 As for COG J "Translation and ribosome", their reduced paralog frequency is opposite to the
- 477 increased representativity of protein families from this category in the genomes of acidophiles (Table
- 478 1). In other words, acidophiles tend to discard (or not evolve) duplicated genes from this category
- 479 rather than losing core functions by relinquishing unique protein families. Further exploration is
- 480 needed to determine what are the changes this category in acidophiles.
- 481 Concordantly, as there was an equilibrium between COG categories with increased and decreased
- paralog frequencies in acidophiles, the overall paralog frequency had no statistically significant
- 483 correlation with optimal pH and remained at a relatively constant 8% average, ranging from 2% to
- 484 20% (Supplementary Figure 4). These relatively low percentages indicate that paralog frequencies
- are only a minor contributor to genome size changes in our dataset. Still, the constant paralog
- 486 frequency across pH contradicts what has been found for other streamlined organisms, which have

- relatively low number of paralogs (Giovannoni et. al., 2005, Swan et. al., 2013). This unusual finding
- 488 could be partially a consequence of acid resistance genes in multiple copies that would compensate
- 489 the evolutionary pressure of discarding paralogs.

4. Additional Discussion

- We have shown acidophilic Bacteria possess several streamlining elements, such as having smaller
- 492 genomes, fewer ORFs and an underrepresentation of signal transduction proteins (Gifford et. al.,
- 493 2013, Giovannoni et. al., 2014, Cottrell and Kirchman, 2016). However, there are several
- 494 streamlining elements that we could not identify in acidophiles, such as having lower intergenic
- space percentages, lower paralog frequencies and proportionately fewer pseudogenes (Giovannoni et.
- 496 al., 2005, Swan et. al., 2013). This could be partially attributed to the high prevalence of HGT and
- 497 recombination elements in acidophiles (Aliaga et. al., 2009, Navarro et. al., 2013, Acuña et. al., 2013,
- 498 Ullrich et. al., 2016, Zhang et. al., 2017, Colman et. al., 2018, Vergara et. al., 2020). A high
- 499 recombination activity is prone to increase the abundancy of pseudogenes present in a genome (Holt
- et. al., 2009, Tutar, 2012) and could cause the observed high paralog frequencies in the Cog category
- 501 L "Replication, recombination and repair", which in turn increases the overall paralog frequencies of
- acidophiles. This is supported by the low paralog frequencies in COG category J "Translation and
- Ribosome", which are amongst the most conserved proteins (Lecompte et. al., 2002) and thus could
- be an index of general paralog frequency tendencies. Additionally, streamlining as a phenomenon has
- been mainly described for extremely small genomes (<2Mb). While genomes as small as 1.7Mb exist
- in our dataset, most of the genomes are between 2-4 Mb, which could explain the absence of some
- 507 streamlining elements in acidophiles.
- What is observed for acidophiles then appears to differ from the classic examples of extremely
- streamlined organisms. However, as opposed to statistical analyses of multiple acidophilic clades,
- most of the studies that defined genome streamlining traits focus on a single clade and reflect on the
- underlying ecological variable to which attribute its genome reduction (Dufresne et. al., 2005,
- Giovannoni et. al., 2005, Chivian et. al., 2008, Sowell et. al., 2009, López-Pérez et. al., 2013, Luo et.
- al., 2014, Sun and Blanchard, 2014, Nakai et. al., 2016, Cottrell and Kirchman, 2016, Graham and
- Tully, 2021). The divergence in the observations from this study and others could be attributable to
- such difference, as single clade studies do not consider counter examples such as *Rhodococcus*
- 516 erythropolis, an extreme oligotroph with a genome of over 7 Mb (Yano et. al., 2016, Retamal-
- Morales et. al., 2018). Nevertheless, streamlining in the evolution of acidophiles appears to be a less
- robust phenomenon than in thermophiles when comparing to other multi-clade statistical studies
- 519 (Sabath et. al., 2013). This was also observed in our study, as shown by the stronger correlation
- between genome size and temperature (Figure 4A) than with pH (Figure 3) and the positioning of the
- 521 lowest genome sizes in the PCA plot (Figure 5).
- 522 In terms of physiology, acidophiles possess several characteristics of streamlined Bacteria, such as
- relatively small cell sizes (Clark and Norris, 1996) and high generation times (Kishimoto and Tano,
- 524 1987, Fang et. al., 2006, Mykytczuk et. al., 2010). Chemolithoautotrophic metabolism is widespread
- amongst acidophiles (Johnson and Hallberg, 2008), which could be a bias in our study as the reduced
- 526 genomes of acidophiles might be related to this overrepresentation of chemolithoautotrophs.
- However, some of the smallest genomes in free-living prokaryotes are heterotrophs (Giovannoni et.
- 528 al., 2005, 2014) and are smaller than some of the smallest known genomes of chemolithoautotrophic
- 529 prokaryotes besides methylotrophs (Raven et. al., 2013). Therefore, this is unlikely to be a major
- 530 issue.

- 531 In agreement with what has been observed in Archaea (Colman et. al., 2018), the bacterial
- acidophiles are all nested within higher order neutrophilic lineages and no examples are observed of
- regression of acidophile lineages to neutrophiles, suggesting that the evolution of acidophilia is
- unidirectional. However, the current taxonomic distribution of acidophilic genomes is possibly
- affected by sampling bias, as acidic mine drainages are one of the most studied acidic environments
- 536 (Johnson and Hallberg, 2003, Sharma et. al., 2016) which possibly produces an overrepresentation of
- organisms from these environments in the databases. Advances in metagenomics should attenuate
- this issue by increasing the genomic information from less studied acidophilic econiches, such as
- deep-sea vents (Simmons and Norris, 2002, Reysenbach et. al., 2006) and to a lesser extent solfataric
- 540 fields (Itoh et. al., 2011). Possibly, entirely novel acidophilic lineages from different phyla could be
- 541 discovered.
- Some of the genomic traits observed in acidophiles have not been described as general features of
- streamlined organisms, such as lower average protein sizes and higher representativity of inner
- membrane proteins. These features could be novel characteristics of streamlined organisms or
- 545 perhaps are specific for acidophilic adaptation. The increased representativity of inner membrane
- proteins is likely to be specific for acidophiles, as no statistically supported correlation was found
- 547 between the representativity of these proteins and genome size in neutrophiles (Supplementary
- 548 Figure 2). This is also likely true for the lower representativity of proteins found outside the inner
- membrane of acidophiles. In contrast, average protein size has been analyzed in previous
- streamlining studies on adaptation to high temperatures (Sabath et. al., 2013). A decrease in average
- protein size was reported for thermophiles, and a conclusion regarding thermostability adaptations
- (Thompson and Eisenberg, 1999, Chakravarty and Varadarajan, 2000) was reached. However,
- protein size changes might be a major contributor to genome size changes besides gene gain or loss.
- Our discovery of a decrease in average protein size in acidophiles expands the possibility beyond
- 555 thermophiles that protein size reduction might be a more general mechanism for genome streamlining
- 556 in stressful environments. Further research on this feature is necessary to determine whether other
- streamlined organisms have smaller proteins than their counterparts. Nevertheless, smaller proteins in
- acidophiles could also be attributable to protein stability adaptations, such as the shorter loops
- observed for some proteins in the inner membrane of acidophiles (Duarte et. al., 2009, 2011). The
- 560 investigation of which specific protein size changes or domain rearrangements might be attributable
- to a survival mechanism in acidic econiches is a potential topic for future research.
- Acidophiles pay the energetic toll of maintaining a proton gradient of several orders of magnitude
- across the inner membrane (Baker-Austin and Dopson, 2007, Slonczewski et. al., 2009). This, while
- proliferating in often nutrient scarce environments with multiple stressors (Johnson, 1998, Dopson et.
- al., 2003, Johnson and Hallberg, 2008). It is then congruent that these organisms would optimize
- transport and reduce replication costs to save energy by streamlining their genomes (Button, 1991,
- Sowell et. al., 2009). Several of our findings shed light on the ever-expanding knowledge about
- acidophiles ecology and the acid resistance systems that maintain this proton gradient. Mainly, the
- 569 increased paralog frequencies in COG categories possibly related to energy production, DNA repair
- and biofilm formation. The investigation of which functions might be in greater copies in acidophiles
- 571 is an interesting topic for future research, as it may uncover novel survival mechanisms for
- is an interesting topic for reactive research, as to hay uncover novel survival incommission
- 572 acidophiles. Similarly, acid related genes shared between acidophiles could be hidden amongst the
- 573 proteins without functional annotation.

5. Conflict of Interest

- 575 The authors declare that the research was conducted in the absence of any commercial or financial
- 576 relationships that could be construed as a potential conflict of interest.

577 **6.** Author Contributions

- 578 DC, GN and DH designed the research. DC performed the research. DC, DH and GN analyzed the
- 579 data. DC and DH wrote the paper. GC and EV participated in the construction of the final
- 580 manuscript. All authors read and approved the final manuscript.

581 7. Acknowledgments

- 582 DH was supported by Fondecyt 1181717 and Programa de Apoyo a Centros con Financiamiento
- 583 Basal AFB170004 to Fundación Ciencia & Vida.

Figure Captions

- 1042 Figure 1. Taxonomic distribution of acidophilic genomes interrogated. A rooted cladogram
- displaying phyla, classes, and metadata of acidophiles with genomic data. The acidophiles are
- classified into those that grow optimally at pH <3 or at pH 3-5. The cladogram was constructed using
- AnnoTree (Mendler et. al., 2019) as a guide for phylogenetic positioning and rooted as described by
- Parks et. al., 2018. Phyla with acidophiles were broken down into classes. Lineages with known
- acidophiles are highlighted and their branches are shown with thick red lines. Dashed lines connect
- the acidophilic lineages with the taxon's information when necessary. Growth pH pie charts represent
- the percentage of species that grow optimally at pH <3 (red) and at pH 3-5 (yellow). For both pH
- ranges, the percentage of acidophilic species by phyla are shown in the blue box. Genome source pie
- charts represent the percentage of acidophilic genomes sequenced from laboratory pure strains (dark
- green) versus metagenome assemblies (grey). The totals of both pie charts for all the phyla combined
- are shown in the yellow box. Ph. = Phylum; Sph. = Superphylum. *Mean values for the acidophiles in
- the taxon. A more detailed table with the classes' information can be found in Supplementary Table
- 1055 2.

- Figure 2. Distribution of acidophilic species with sequenced genomes by phylum across pH.
- 1057 Phylum Armatimonadetes has only one acidophilic species and is not shown. (A) Histogram of
- species number grouped by phyla across pH in overlapping increments of one pH unit. Phyla are
- 1059 color coded. (**B**) Cumulative plot of relative abundance (%) of acidophiles across pH. Percentages
- indicate species that can live at or below a given pH. Color coding of phyla is the same as A. (a), (b)
- and (c) indicate pH ranges 1-2, 2-4 and 4-5 respectively.
- Figure 3. Scatterplot of genome size (Mb) of bacterial acidophiles and their most closely related
- extant, circum-neutral relatives versus optimal growth pH. Each point corresponds to a different
- species. A linear regression curve has been fitted to the data with a Pearson's correlation coefficient
- of 0.19 and a p-value of 2.97*10⁻⁵. Generalized Least Squares (GLS) p-value was 1.8*10⁻³.
- 1066 Figure 4. Scatterplots showing correlation of genome size and pH versus optimal growth
- temperature and G+C content of the species in the dataset. (A) Genome size vs optimal growth
- temperature. Pearson's correlation coefficient is -0.34 with p-value 2.9*10⁻¹³. (**B**) Optimal growth pH
- versus optimal growth temperature. Pearson's correlation coefficient is -0.01 with p-value 0.84. (C)
- 1070 Genome size versus G+C content. Here, data were separated by pH ranges. Pearson's correlation
- 1071 coefficients were 0.34 and 0.50, with p-values $4.7*10^{-3}$ and $1.5*10^{-22}$ respectively for pH 0-4 and pH
- 4-8. The overall Pearson's correlation coefficient and p-value were 0.48 and 1.91*10⁻²⁵, respectively.
- 1073 **(D)** Optimal growth pH versus G+C content. Pearson's correlation coefficient is -0.06 with p-value
- 1074 0.22.
- Figure 5. Principal component analysis of multiple variables potentially influencing genome
- size. Dimensionality reduction was performed by PCA, inputting the optimal growth pH, optimal
- 1077 growth temperature, G+C content and genome size of each species in the dataset. A biplot was
- 1078 constructed showing the loadings of each variable as arrows at the center of the plot and the
- distribution of the principal components. The average genome size of each species is shown as a
- 1080 color scale. Three clusters within the dotted circles are highlighted for their distinctives features.
- Figure 6. Diagrammatic representation of genetic mechanisms involved in genome size changes.
- 1082 **Top row**, five genes of a hypothetical genome. Orange boxes indicate paralogous genes. **Middle**
- 1083 **row,** processes involved in genome size changes where A and B represent gene loss/gain of single

- 1084 copy genes or paralogous genes respectively, C shows intergenic space reduction or expansion,
- which we refer to as genome compaction, and D shows gene size reduction or increase. **Bottom row**
- reduced or streamlined genome relative to the starting genome shown in top row; alternatively, the
- starting genome before expansion to genome shown in top row. Large blue arrows indicate time or
- direction of evolutionary events. Small dotted bidirectional arrows show hypothetical insertion or
- 1089 deletion events.
- 1090 Figure 7. Factors influencing genome size of acidophiles across optimal growth pH. Every point
- 1091 corresponds to the average for a different species. (A) Number of genes (ORFs, open reading frames)
- across pH. Pearson's correlation coefficient is 0.18 with p-value 1.25*10⁻⁴. (**B**) Intergenic space vs
- pH. Intergenic space is defined as genome size minus the sum of the nucleotide length of all protein
- 1094 coding genes as defined by ORFs of a genome divided by genome size, in percentage. A stricter
- 1095 genome quality filter of 97% completeness and 2% contamination was used in this analysis to
- 1096 minimize missannotation errors due to fragmented genomes. Pearson's correlation coefficient is -0.11
- 1097 with p-value 0.06. (C) Average ORF length per genome across pH. Pearson's correlation coefficient
- 1098 is 0.25 with p-value $4.03*10^{-8}$.
- 1099 Figure 8. Protein size versus pH correlations for conserved Pfams. (A) Pfams present in over
- 1100 90% of species and in a pH span of at least 6 pH units were selected for analysis. For each Pfam, the
- 1101 Pearson's correlation coefficient for protein size vs organism optimal growth pH was calculated,
- using the species averages as data. Each point corresponds to a different Pfam. Positive correlations
- 1103 (91 red points to the right) indicate Pfams whose proteins are shorter at low pH while negative
- 1104 correlations (17 purple points to the left) are Pfams whose proteins are larger at low pH. The 25
- 1105 Pfams with the lowest p-values are listed in Supplementary Table 3. (**B**) Analog to (**A**), but for a list
- of Pfams that in addition to being present in over 90% of the species and in a span of at least 6 pH
- units were also in a unique copy in the genomes (proteins with the Pfam per genome <1.1) and only
- one domain architecture was dominant in the proteins. These Pfams are listed in Supplementary table
- 4. For both plots, an FDR q-value of 0.05 was used for statistical significance. Significant
- correlations are shown as big points which are red for positive correlations and purple for negative
- 1111 correlations. Non-significant correlations are shown as small grey points.
- Figure 9. Subcellular localization and signal peptide presence of protein families across pH.
- PSORTb and SignalP were used to predict subcellular location of proteins and signal peptide,
- respectively. Each point corresponds to a species, and either subcellular localization or signal peptide
- presence are expressed in terms of percentage of the protein families (ortholog groups). Linear
- regression curves have been plotted for each category. Pearson's correlation coefficient and p-value
- 1117 respectively are -0.01 and 0.77 for cytoplasmic, -0.19 and $4.4*10^{-5}$ for inner membrane, 0.21 and
- 1118 $7.5*10\Box^6$ for Periplasmic, Outer membrane, Cell wall and Exported, and 0.22 with $1.4*10\Box^6$ for
- 1119 proteins with a signal peptide.
- Figure 10. Percentage of protein families with functional classification across pH. Each point
- 1121 corresponds to a species. Blue data points and the blue line correspond to proteins with a COG
- annotation and orange data points and the orange line correspond to proteins with a Pfam annotation.
- Pearson's correlation coefficients and p-values are respectively 0.24 and $2*10\square^7$ for proteins with a
- 1124 COG annotation, and 0.14 with $2.6*10^{\circ}$ for proteins with a Pfam annotation.
- Figure 11. Paralog frequency vs pH by COG category. The percentage of genes (relative to the
- proteome size) belonging to paralog families (paralog frequency) were calculated for each COG
- category. Categories where the paralog frequency had a statistically significant correlation with pH

1128 (p-value <0.01) are shown. The mean duplication frequencies at pH 1 and 7 are displayed, calculated with linear regression (Supplementary Figure 5). ** p-value<0.01, *** p-value<0.001.

Tables

Table 1 | Genomic representativity of protein families by function as defined by COG categories in acidophile genomes

COG Category	Pearson's correlation coefficient	p-value
Increased representativity in acidophiles (p-value<0.01)		
(L) Replication, recombination, and repair	-0.25	3.6*10-8
(F) Nucleotide metabolism and transport	-0.21	$5.4*10^{-6}$
(C) Energy production and conversion	-0.21	$8.0*10^{-6}$
(H) Coenzyme metabolism and transport	-0.19	3.0*10 ⁻⁵
(D) Cell cycle control and cell division	-0.16	$5.2*10^{-4}$
(J) Translation and ribosome	-0.15	$1.1*10^{-3}$
(O) Chaperones, post-translational mod.	-0.13	6.3*10 ⁻³
Decreased representativity in acidophiles (p-value<0.01)		
(S) Function unknown	0.30	1.3*10 ⁻¹⁰
(T) Signal transduction mechanisms	0.26	3.4*10 ⁻⁸
