23 **Abstract**

24 Age is the main risk factor for the development of neurodegenerative diseases. In the aged brain,  
25 axonal degeneration is an early pathological event, preceding neuronal dysfunction, and cognitive  
26 disabilities. Necroptosis activation mediates degeneration of injured axons, but whether necroptosis  
27 triggers neurodegeneration and cognitive impairment along aging is unknown. Here we show  
28 necroptosis activation in hippocampal axons during aging. Loss of the necroptotic effector *Mkl1* was  
29 sufficient to delay age-associated axonal degeneration, protecting against decreased synaptic  
30 transmission and memory decline in aged mice. Moreover, short-term pharmacologic inhibition of  
31 necroptosis in aged mice reverted structural and functional hippocampal impairment. Finally, a  
32 quantitative proteomic analysis revealed that necroptosis inhibition leads to an overall improvement  
33 of the aged hippocampal proteome, including molecular biofunctions associated with brain  
34 rejuvenation. Our results demonstrate that necroptosis contributes to the functional decline of the  
35 aged brain, and necroptosis inhibition constitute a potential geroprotective strategy to treat age-  
36 related disabilities.

## 37 1. INTRODUCTION

38 The current rise in human life expectancy is not precisely accompanied by an equivalent increase  
39 in 'healthspan'<sup>1</sup>, the functional and disease-free period of life in the elderly<sup>2</sup>. The impact of age on  
40 brain function is unquestionable, being the main risk factor for the development of neurodegenerative  
41 diseases and cognitive disabilities<sup>3-5</sup>.

42 As a fundamental structure for human cognition, the hippocampus is particularly vulnerable to the  
43 deleterious effects of aging<sup>6,7</sup>. Microstructural changes at the synaptic level are correlated with  
44 learning and memory impairment during aging. Decreased number of axospinous synapses have  
45 been described in the dentate gyrus of aged hippocampus<sup>8</sup>. The reduced number of synaptic contacts  
46 is correlated with a decreased presynaptic fiber potential due to a reduction of axons<sup>9</sup>, contributing to  
47 the impaired synaptic plasticity and cognitive deficits evidenced in aged organisms<sup>10</sup>. In addition,  
48 white matter abnormalities and axonal degeneration (AxD) have been identified in aged brains of  
49 diverse species<sup>11,12</sup>, particularly in the hippocampus and strictly correlated with impaired memory  
50 performance in humans<sup>13</sup>. Due to the importance of axonal integrity on hippocampal function and  
51 progression of cognitive decline in the elderly<sup>14</sup>, it is imperative to determine the mechanism of AxD  
52 during aging. We were pioneers in identifying necroptosis as the mechanism involved in mechanical  
53 and chemical-induced AxD<sup>15,16</sup>. Recently, in a model of neuronal inflammation it has been  
54 demonstrated that necroptosis activates Sarm1, a central executioner of pathological AxD<sup>17-19</sup>.  
55 Necroptosis is an alternative form of programmed cell death triggered by the tumor necrosis factor  
56 under caspase-8 inhibitory conditions and characterized by a necrotic-like and pro-inflammatory  
57 response<sup>20,21</sup>. Receptor-interacting kinase 1 (RIPK1) recruits and phosphorylates RIPK3, which in  
58 turn phosphorylates the mixed lineage kinase domain-like protein (MLKL). MLKL oligomerizes and  
59 translocate to the plasma membrane, disrupting membrane integrity followed by the release of cellular  
60 components, an exacerbated inflammatory response, and cell death<sup>22</sup>.

61 Age-associated increase in low-grade sterile inflammation is one of the 'seven pillars of aging'  
62 contributing with the development and progression of age-associated diseases<sup>23-25</sup>. Recent studies  
63 have depicted the importance of necroptosis in the aging of the mouse male reproductive system<sup>26</sup>  
64 and the epididymal white adipose tissue<sup>27</sup>. In the context of brain aging, several age-related  
65 neurodegenerative conditions with prominent AxD and neuroinflammation as common features have  
66 shown increased necroptosis activation in the brain, associated with functional impairment<sup>28-32</sup>.  
67 Necroptosis activation has been recently described in the cortex and hippocampus of aged mice,  
68 contributing to age-related neuroinflammation<sup>33</sup>. However, the involvement of necroptosis in the  
69 progression of normal brain aging and its cognitive consequences remain unexplored.

70 Here, we investigated the role of necroptosis in the progression of AxD in the hippocampus and  
71 its impact in brain function along aging. Necroptosis increased in hippocampal subfields with evident  
72 AxD in aged mice. Loss of *Mkl1* was sufficient to delay age-related AxD in the hippocampus, a youthful

73 phenotype also displayed at the synaptic and functional level. Restored synaptic transmission and  
74 facilitation were accompanied by improved learning and memory in aged mice deficient for *Mkl*.  
75 Short-term inhibition of RIPK3 in aged mice demonstrated to be extraordinarily effective on reverting  
76 AxD and hippocampus-dependent functional impairment. Finally, an unbiased quantitative proteomic  
77 analysis demonstrated that necroptosis inhibition improved the aged hippocampal proteomic profile,  
78 restoring the levels of key protein pathways associated with brain aging hallmarks. Our study reveals  
79 that necroptosis contributes to the age-associated deterioration of axons and their function, affecting  
80 hippocampal neuronal connectivity and cognitive function of aged mice.

81 Taken together, our data demonstrates that necroptosis inhibition constitute a potential strategy for  
82 the future development of therapeutic tools to treat age-related brain disabilities and brain  
83 rejuvenation.

84

## 85 **2. RESULTS**

### 86 **2.1. Brain aging is associated with axonal degeneration in the hippocampal dentate gyrus.**

87 In order to establish the progression of hippocampal neurodegeneration throughout aging we  
88 used three groups of mice of different ages: adult (3-6 months), old (12-15 months) and aged (more  
89 than 20 months). Neurodegeneration, evaluated by Fluoro Jade C (FJC) staining (**Fig 1a**),  
90 significantly increases in the dentate gyrus (DG) of the hippocampus of old mice, reaching a plateau  
91 in the aged group (**Fig 1b**). Increased neurodegeneration was restricted to the DG hilus, where DG  
92 granular neurons extend their axons, known as mossy fibers, to connect with CA3 pyramidal  
93 neurons<sup>34</sup>. FJC staining was also analyzed in other brain regions, as the striatum, cerebellum and  
94 spinal cord, in which age-dependent neurodegeneration was also evident (**Fig S1**).

95 To further evaluate age-associated AxD in the hippocampus, we studied the expression of two  
96 phosphorylated forms of neurofilaments (NFs), the main proteins shaping the axonal cytoskeleton.  
97 Most NFs are highly phosphorylated under physiological conditions, while increased non-  
98 phosphorylated NF (non-pNF) immunoreactivity is associated with inflammation, neurodegenerative  
99 diseases and brain injury<sup>35,36</sup>. Almost undetectable immunoreactivity of non-pNF was observed in the  
100 DG of adult mice, while a progressive increase was evidenced during aging (**Fig 1c, d**). Axonal  
101 degeneration evaluated by pan-axonal-NF detection (stable axonal NFs) (**Fig 1e**) showed decreased  
102 axonal integrity index in old and aged hippocampal DG compared with adult mice (**Fig 1f**). Therefore,  
103 by using different degenerative readouts, our results illustrate the progression of AxD in the  
104 hippocampus during aging.

### 105 **2.2. Necroptosis activation in hilar cells and axonal fibers in the dentate gyrus of the aged** 106 **hippocampus.**

107 Previous studies have indicated that axons degenerate by an apoptosis-independent  
108 mechanism<sup>37,38</sup>. We recently demonstrated that mechanical and chemical-induced axonal  
109 degeneration is regulated by necroptosis<sup>15</sup>. To determine whether necroptosis is involved in age-  
110 associated AxD, we assessed necroptosis activation by the expression of the phosphorylated form of  
111 MLKL (pMLKL) in the hippocampus. The analysis was performed in the hilus and the granular cell  
112 layer (GCL) of the DG (**Fig 2b**). The number of pMLKL positive hilar cells increased in aged mice, as  
113 did pMLKL mean intensity (**Fig 2a, c**). Necroptosis activation was also evidenced by an age-  
114 dependent translocation of pMLKL from the nucleus to the cytoplasm (**Fig 2a**, magnified image), as  
115 has been previously described<sup>39</sup>. Non-significant changes in pMLKL levels were observed in GCL  
116 neurons (data not shown), suggesting a selective vulnerability of DG hilus to necroptosis activation  
117 during aging. Axonal pMLKL staining was evaluated in pan-axonal-NF positive hilar fibers of the DG  
118 (**Fig 2d**). Interestingly, pMLKL mean intensity increased earlier in DG axons compared with dentate  
119 hilar somas throughout aging, reaching significant differences in the old mice group (**Fig 2e**).  
120 Increased pMLKL signal was also observed in other brain regions with defined axonal subfields, as  
121 axonal tracts in the striatum, the cerebellar white matter and the ventral horn of the spinal cord, which  
122 also showed progressive AxD along aging (**Fig S2**). The increase in MLKL phosphorylation levels in  
123 the hilus was also accompanied by changes in the pattern of pMLKL signal, from almost non-detected  
124 in adult mice axons, diffuse in the old group, to finally become punctuated in fragmented axons of  
125 aged mice (**Fig 2d**, magnified image). These pMLKL aggregates have been associated with MLKL  
126 oligomerization and its translocation to the plasma membrane, two key steps for necroptosis  
127 execution<sup>22</sup>. A similar pattern of pMLKL was observed by immunohistochemistry against pMLKL in  
128 the aged hippocampus, both in DG hilar cells and in Schaffer collateral axons (**Fig 2f**), which connect  
129 with CA1 pyramidal neurons. These results indicate that necroptosis is activated during aging in the  
130 hippocampus, particularly in the DG hilus, an hippocampal region recognized as one of the most  
131 vulnerable to the cognitive effects of aging<sup>40</sup>.

### 132 **2.3. Age-induced axonal degeneration is reduced in MLKL knockout mice.**

133 Due to the indispensable role of MLKL in executing necroptosis, we evaluated whether age-  
134 dependent AxD in the hippocampus was modified in aged *Mlkl*-knockout mice (*Mlkl*-KO)<sup>41</sup>.  
135 Interestingly, AxD evaluated with a degeneration index (DI) in pan-axonal NF-stained axons was  
136 significantly reduced in aged *Mlkl*-KO mice at levels comparable with adult mice (**Fig 3a, b**).  
137 Moreover, non-pNF degenerated axons profusely present in aged WT hippocampus, were almost  
138 undetected in aged *Mlkl*-KO mice, at levels equivalent to younger WT mice (**Fig 3a, c**). As expected,  
139 we observed age-dependent AxD coupled with neuroinflammation<sup>42</sup> (**Fig S3**). The increased number  
140 of microglia in the hippocampus of aged mice was prevented in aged *Mlkl*-KO mice (**Fig S4**), as was  
141 previously described<sup>33</sup>. Accordingly, measurement of Iba1 mean intensity also indicated that aged  
142 *Mlkl*-KO mice present less microglia activation than their WT littermates (**Fig 3d, e**). To confirm the  
143 contribution of necroptosis to the inflammatory state of the aging brain, we measured the levels of

144 several cytokines and chemokines in hippocampal lysates and serum of adult versus aged WT and  
145 *Mkl1*-KO mice by Luminex High Performance Assay (**Table S1**). Three of the twelve cytokines  
146 analyzed showed significant changes under *Mkl1* deficiency in the hippocampus of aged mice. The  
147 levels of the pro-inflammatory cytokine IL-12 decreased in aged *Mkl1*-KO hippocampus compared  
148 with aged WT mice, reaching levels comparable with adult WT mice (**Fig 3f**). Interestingly, the anti-  
149 inflammatory cytokines IL-2 and IL-10 significantly increased in the hippocampus of aged *Mkl1*-KO  
150 mice (**Fig 3f**). Moreover, the systemic pro-inflammatory profile also decreased in serum samples from  
151 aged *Mkl1*-KO mice (**Fig S5**). These results indicate that necroptosis contributes to brain inflammation  
152 by modulating both pro- and anti-inflammatory cytokines, but also controlling systemic inflammation.

#### 153 **2.4. Loss of MLKL improves hippocampal synaptic transmission, learning and memory in aged** 154 **mice.**

155 To further study whether necroptosis-mediated AxD affects hippocampal function along aging,  
156 we first performed electrophysiological recordings of the CA3-CA1 synapses to evaluate synaptic  
157 transmission. Extracellular field-excitatory post-synaptic potentials (fEPSP) were registered in  
158 hippocampal slices (**Fig 4a**). Average traces of the evoked potential recorded are represented in **Fig**  
159 **4b** for each group. An age-dependent decrease in fEPSP slope was observed in WT mice.  
160 Nevertheless, in aged *Mkl1*-KO mice, the fEPSP slope was maintained at levels comparable to adult  
161 WT mice (**Fig 4c, d**). To specifically evaluate whether axonal alterations contribute to an age-  
162 dependent decrease in synaptic transmission, we analyzed the facilitation index (fEPSP<sub>2</sub>/fEPSP<sub>1</sub>)  
163 using a paired-pulse stimulation protocol (**Fig 4e**). The increased facilitation index observed in WT  
164 aged mice (**Fig 4f**) indicates a decreased neurotransmitter release probability from the axonal  
165 compartment (pre-synapse). Interestingly, the facilitation index of aged *Mkl1*-KO mice was  
166 comparable to adult WT mice (**Fig 4e, f**). These results indicate that *Mkl1* deficiency delays the loss  
167 of synaptic strength in the hippocampus inherent to brain aging, mainly preventing axonal function  
168 defects in aged mice.

169 Since memory capabilities depend on proper hippocampal function and both are affected by  
170 age<sup>43,44</sup>, we evaluated whether *Mkl1* loss improves spatial learning and memory in aged mice. To this  
171 end, a Morris water maze (MWM) navigation task was performed in adult and aged *Mkl1*-KO mice  
172 and compared with their WT littermates. The learning curve of aged *Mkl1*-KO mice was significantly  
173 faster than those of aged WT animals and reached a reduced latency to find the platform from day 3  
174 until the end of the training, showing comparable escape time to adult animals (**Fig 4g**). No  
175 differences were observed between adult WT and *Mkl1*-KO mice in the learning curve. To evaluate  
176 memory, 24 hours after training, mice were challenged to find the original location of the platform,  
177 which was removed. The differences between adult and aged *Mkl1*-KO and WT animals in the time  
178 spent in the quadrant platform (Q4) are shown in the swimming heatmap tracks shown in **Fig 4h**.  
179 Aged *Mkl1*-KO mice travelled a larger distance and spent more time exploring in the target quadrant

180 Q4 compared to aged WT animals (**Fig 4i, j**), without significant changes in the mean swimming  
181 speed between both groups (data not shown), demonstrating that loss of *Mik1* prevents learning and  
182 memory loss associated with aging.

183 Altogether, these results demonstrate that an age-associated increase in brain necroptosis  
184 induces degeneration of axons in the dentate gyrus of the hippocampus, thereby depressing synaptic  
185 transmission, and impairing hippocampal-dependent functions, such as learning and memory in aged  
186 mice.

## 187 **2.5. Pharmacological inhibition of necroptosis reverts key signs of brain aging, improving** 188 **hippocampal function and memory.**

189 To further explore the role of necroptosis in brain aging, we developed a pharmacologic strategy  
190 by using the selective RIPK3 inhibitor, GSK'872<sup>45,46</sup>. In order to evaluate whether necroptosis  
191 inhibition reverts age-associated alterations, we designed a strategy in which GSK'872 was  
192 systemically administrated in 23-month-old mice for only one month. Diffusion pumps were filled with  
193 vehicle or GSK'872, and intraperitoneally implanted to continuously diffuse the inhibitor (2 mg/kg  
194 GSK'872 at 0.11  $\mu$ l/hr) for 28 days. In order to evaluate whether GSK'872 systemically administrated  
195 is capable to cross the blood brain barrier, we performed pharmacokinetic studies. Measurable levels  
196 of GSK'872 were detected 1h post administration in the brain ( $187.6 \pm 17.11$  nm) and plasma ( $18.32$   
197  $\pm 0.85$   $\mu$ m) samples collected from aged animals treated with a single i.p. dose of 10mg/kg of  
198 GSK'872. The efficiency of GSK'872 treatment in the brain was evaluated by measuring  
199 phosphorylated RIPK3 (pRIPK3) levels in the hippocampus, demonstrating decreased pRIPK3 signal  
200 in the hilus of aged GSK'872-treated mice (**Fig S6**). Remarkably, aged mice treated with GSK'872  
201 showed decreased non-pNF staining in comparison to vehicle treated mice of the same age (**Fig 5a**).  
202 In fact, non-pNF levels in GSK'872 treated aged mice were comparable with those observed in adult  
203 animals (**Fig 5b and 3c**), demonstrating that one month of systemic RIPK3 inhibition reverts signs of  
204 AxD associated with brain aging. Moreover, decreased microglia activation was also observed,  
205 indicating that a short-term treatment with GSK'872 is capable of reverting one of the main signs of  
206 brain inflammation associated with aging (**Fig 5c, d**).

207 Since RIPK3 is involved in several pathways that regulate cytokines secretion and the  
208 inflammatory response<sup>47</sup> we performed Luminex High Performance Assay to detect changes in a pool  
209 of selected cytokines (**Tables S1**). Interestingly, the hippocampus of GSK'872 treated mice showed  
210 a pattern of cytokine levels highly similar to those observed in untreated adult mice (**Fig 5e**).  
211 Remarkably, this analysis reveals that RIPK3 inhibition mainly reduces pro-inflammatory cytokines,  
212 such as TNF- $\alpha$ , IL-6, IL-12, and IFN- $\gamma$ , reaching youthful-like cytokine levels equivalent to adult mice  
213 (**Fig 5f**). A similar profile of decrease in pro-inflammatory cytokines was observed systemically in  
214 serum samples of GSK'872 treated mice, as was also noticed in the genetic model (**Fig S5**).

215 At the functional level, electrophysiological recordings in the hippocampus demonstrated  
216 equivalent fEPSP between aged mice treated with GSK'872 and untreated adult mice (**Fig 6a**).  
217 Average traces showed significant differences between aged vehicle-treated mice versus those that  
218 received the RIPK3 inhibitor (**Fig 6b,c**). To evaluate the axonal contribution on this protective effect  
219 of GSK'872 on synaptic transmission, we performed a paired-pulse stimulation protocol (**Fig 6d**).  
220 Facilitation index was significantly lower in the hippocampus of aged mice treated with GSK'872  
221 compared with the aged-vehicle mice (**Fig 6e**), showing that late and short-term necroptosis inhibition  
222 can revert the loss of synaptic strength in aged mice, by promoting axonal function.

223 To further explore the impact of our pharmacologic intervention on hippocampal-dependent  
224 behavioral skills we evaluated spatial learning and memory in aged GSK'872-treated mice.  
225 Remarkably, RIPK3 inhibition significantly improved learning in aged mice from the second day of  
226 training (**Fig 6f**). Memory assessment indicated that aged mice with GSK'872 treatment spent more  
227 time in the target quadrant and travelled larger distance in Q4 compared with aged vehicle-treated  
228 mice. Thus, RIPK3 inhibition is capable to recover aged mice from learning and memory impairment.

229 These results demonstrate that a short-term administration of GSK'872 can revert key hallmarks  
230 of brain aging, including AxD, neuroinflammation, and age-associated memory impairment, proposing  
231 the inhibition of necroptosis as an attractive therapeutic target to improve memory in the elderly.

## 232 **2.6. Proteomic analysis in the hippocampus of aged mice with genetic and pharmacological** 233 **inhibition of necroptosis reveals improvement in key hallmarks of aging and features of** 234 **brain rejuvenation.**

235 In order to elucidate the specific molecular alterations underpinning our necroptosis-inhibitory  
236 approaches toward reducing aging phenotypes, we employed a state-of-the-art single-shot, label free  
237 quantitative proteomic approach. Our aim was to generate a correlative necroptotic proteomic profile  
238 in order to gain insight toward how necroptosis or, conversely, its inhibition influences neuronal  
239 integrity in aging-associated degeneration. To this end, hippocampus of adult and aged WT mice,  
240 aged *Mkl1*-KO mice, and aged GSK'872-treated mice were subjected to single-shot label-free mass  
241 spectrometry (see workflow in **Fig S8a**), obtaining a high degree of coverage of the proteome with  
242 almost 7,000 proteins detected (**Fig S8b**).

243 To determine which molecular processes were likely correlative with the aging-induced  
244 necroptotic events, relative expression ratios were calculated and used to perform expression profile  
245 clustering analyses. We identified and isolated subsets of proteins exhibiting opposing directionality  
246 in expression between the "normal" aging proteome (aged vs adult animals) and the proteomes of  
247 animals subjected to genetic (aged *Mkl1*-KO vs aged WT) or pharmacological (aged GSK'872 vs aged  
248 vehicle) inhibition of necroptosis (**Fig S8 and Fig S9**). In doing so, it was possible to reduce the  
249 number of correlative candidate proteins to 2,516 proteins whose expression increases and 2,307

250 which decrease in the aging hippocampus and where genetic and pharmacological modulation leads  
251 to a degree of reversion (**Fig 7a**). Contextualization of these necroptosis-correlative clusters through  
252 pathway analysis confirmed opposing directionality in the activation status of numerous biological  
253 processes between “normal” and necroptosis-targeted aged animals. These include several  
254 canonical pathways and biological function annotations previously implicated in normal aging<sup>23,25</sup> (see  
255 hallmarks of aging, **Fig S10a**) and in brain rejuvenation<sup>5,48</sup> (**Fig 7b and Fig S10b**). Most of the  
256 molecular cascades belonging to these groups of pathways are typically associated with  
257 neurodegeneration and/or neuronal aging, including all the molecular cascades involved in *synaptic*  
258 *mechanisms*, *senescence* and *cellular homeostasis*, which are indeed affected in the normal aging  
259 proteome and recovered in the genetic and pharmacological models of necroptosis inhibition (**Fig**  
260 **7b**).

261 In order to explore the contribution of necroptosis in age-associated neuronal dysfunction, we  
262 evaluated several biological functions affected by normal aging in our proteomic analysis. These  
263 biofunctions were classified considering their contribution in central brain functions, designated as  
264 *neurodegeneration*, *synaptic function*, *cognitive and behavior*, and *neuronal development*. It is  
265 interesting to note that the patterns of change of these biofunctions show opposing directionality in  
266 both the genetic and pharmacological approaches of necroptosis inhibition compared with normal  
267 aging in most of the biological functions analyzed (**Fig 7c**). Remarkably, key molecular and cellular  
268 functions associated with neurodegeneration, neuronal integrity and function, including cell survival  
269 and viability, cellular homeostasis, synapse development, cognition, motor dysfunction and  
270 cytoskeleton organization, showed a clear reversion in the context of pathway analysis in necroptosis-  
271 targeted aging in comparison with normal aging (**Fig 7c**). This analysis demonstrated that the  
272 inhibition of necroptosis supports proper brain function in aged animals, improving key hallmarks of  
273 aging and restoring (in the case of our pharmacologic treatment with GSK’872) relevant functions  
274 involved in brain rejuvenation.

## 275 **2.7. Necroptosis inhibition induces synaptic-long term potentiation in aged mice.**

276 Among the cascades elucidated in our proteomic analysis with clear opposed profiles between  
277 normal aging and necroptosis inhibitory conditions, those classified as *synaptic mechanisms* showed  
278 the highest predicted z-score. Synaptic long-term potentiation (LTP) is the most common studied form  
279 of synaptic plasticity, a key process directly related with learning and memory, and early impaired  
280 during aging<sup>49</sup>. The contribution of the synaptic LTP signaling at the level of individual molecules is  
281 visually illustrated in **Fig 8a**. These molecular changes are mostly prevented in the aging process of  
282 the *Mikl*-KO mice (red molecules) and partially reverted in the pharmacologic inhibition of necroptosis  
283 with GSK’872 in aged animals (**Fig 8b**). We therefore analyzed hippocampal synaptic plasticity by  
284 studying LTP magnitude in the CA3-CA1 transmission. By the usage of a high-frequency stimulation  
285 protocol, we found that LTP induction was compromised in aged WT mice when compared to adult

286 WT mice (**Fig 8c**). Surprisingly, adult *Mikl*-KO mice presented a higher LTP magnitude than the  
287 control WT group and the loss of *Mikl* in aged mice restored LTP induction and maintenance beyond  
288 adult WT mice potentiation. Synaptic plasticity was also assessed in the pharmacological model of  
289 necroptosis inhibition in aged mice. Similar to KO experiments, we detected a reduction in LTP  
290 magnitude when we compared adult WT mice with aged vehicle-treated mice. Surprisingly, only one  
291 month of GSK'872 treatment was capable to improve LTP magnitude, reaching adult-like levels (**Fig**  
292 **8d**), demonstrating that inhibition of necroptosis either by genetic knock-out of *Mikl* or by  
293 pharmacologic RIPK3 inhibition improved or restore synaptic plasticity in aged mice, a synaptic  
294 process that is crucial to support brain rejuvenation<sup>5</sup>.

## 295 **2.9 Necroptosis activation contributes to the acquisition of the age-associated senescent** 296 **phenotype in the hippocampus during aging.**

297 The accumulation of senescent cells in aged tissue, including the brain, is one of the most  
298 common feature of aging<sup>50,51</sup>. As neuronal senescence has also been detected in the hippocampus  
299 of aged mice<sup>52</sup>, we aimed to determine whether necroptosis contributes to the establishment of the  
300 senescent phenotype of hippocampal neurons along aging. From our proteomic data, the molecular  
301 changes associated to senescence are mostly prevented in the aging process of the *Mikl*-KO mice  
302 and partially reverted in the pharmacologic inhibition of necroptosis with GSK'872 treatment in aged  
303 animals (**Fig S11**). Interestingly, the expression profile of two key proteins involved in the acquisition  
304 of the senescent phenotype, namely CDKN1B and NF $\kappa$ B<sup>53</sup>, is mainly reverted in both *Mikl*-KO and  
305 GK'872-treated mice during aging (blue dotted insets, **Fig S11a** and **Fig S11b**). We therefore  
306 evaluated cell senescence by SA- $\beta$ galactosidase (SA- $\beta$ gal) activity in the hippocampus of aged WT  
307 and aged *Mikl*-KO mice. The accumulation of SA- $\beta$ gal positive neurons was mainly observed in the  
308 CA2/3 subfield of the hippocampus of aged mice<sup>52</sup> (**Fig S11c**), but it was significantly lower in aged  
309 *Mikl*-KO mice (**Fig S11c, d**). A reduced SA- $\beta$ gal activity was also observed in the hippocampus of  
310 aged mice treated with GSK'872 compared with vehicle-treated animals (**Fig S11e, f**), reinforcing the  
311 data obtained from the proteomic analysis, which overall indicates that age-related activation of  
312 necroptosis contributes to the development of key pathological changes that are involved in brain  
313 aging.

314 Together our findings support the conclusion that necroptosis activation participates in the  
315 development of the major causes of brain dysfunction during aging, including AxD, neuroinflammation,  
316 synaptic dysfunction and cognitive disabilities. By contrast, the inhibition of necroptosis prevents  
317 these major features of brain aging, restoring synaptic transmission and axonal function in the  
318 hippocampal circuitry, thus improving learning and memory defects associated with aging.  
319 Furthermore, a short systemic inhibition of necroptosis was capable to revert age-associated  
320 hippocampal changes and restore learning and memory capacity to youthful levels.

321

### 322 3. DISCUSSION

323 Our findings reveal the involvement of necroptosis in the progression of AxD in the hippocampus  
324 during normal aging, uncovering relevant implications of necroptosis activation in age-associated  
325 cognitive impairment, which might undermine healthy aging. Of note, most detrimental consequences  
326 of brain aging, including neuroinflammation, synaptic failure and hippocampal-dependent behavioral  
327 impairment were prevented through inhibition of necroptosis by genetic or pharmacological means.  
328 In our mouse model of aging, neurodegeneration appears to be restricted to axonal-enriched brain  
329 regions, such as the corpus striatum, the cerebellum, and white matter regions of the spinal cord (**Fig**  
330 **1** and **S1**). Corresponding with this observation, neurodegeneration was also noted in hippocampal  
331 subfields recognized as the richest axonal projection regions, including DG-CA3-CA1 axonal  
332 pathways<sup>54</sup>. Importantly, necroptosis activation was also confined to these axonal-enriched areas of  
333 the hippocampus, particularly in the DG (**Fig 1**), which is the only subfield that has been shown to  
334 present neuronal loss as a consequence of aging in humans<sup>55</sup>. The DG is a crucial area in the  
335 hippocampus supporting neuronal connectivity. It receives entorhinal cortex information which is  
336 transmitted to the CA3-CA1 neurons to complete the hippocampal circuitry. DG neurons, particularly  
337 mossy cells of the hilus, are extremely vulnerable to degenerative insults and injury, whereas DG  
338 granule cells are more resistant<sup>56,57</sup>. This evidence is aligned with our results showing increased  
339 necroptosis in hilar cells, and an early activation in the hilar fibers of the DG along with aging (**Fig 2**).  
340 Moreover, it has been shown that this confined subdivision of the hippocampus where mossy cells  
341 reside is also highly vulnerable to the effects of aging<sup>55</sup>, compromising DG connectivity with other  
342 subfields of the hippocampus, and increasing susceptibility to memory failure in aged individuals<sup>58,59</sup>.  
343 These observations suggest that the restricted activation of necroptosis in DG hilar cells and axons  
344 may contribute to the vulnerability of this area to degenerate along with aging, to adversely impact  
345 synaptic function and hippocampal-dependent behavioral performance.

346 The functional role of necroptosis as a crucial pathogenic determinant in experimental models of  
347 human diseases has been of increasing interest in the field, focusing on the central effectors of  
348 necroptosis, RIPK3 and MLKL, as possible markers of disease progression and severity in humans<sup>60</sup>.  
349 Increased pMLKL levels in aged mice suggests that necroptosis could be considered as a biomarker  
350 of aging progression. Of note, aged *Mkl1*-KO mice presented a youthful phenotype in the  
351 hippocampus, reaching levels of AxD comparable with those observed in younger mice (**Fig 3a, b**).  
352 According to the survival curve comparison between mice and humans<sup>61</sup>, old mice (12-15 months  
353 old) are equivalent to humans between 38 to 47 years old, a life stage in which basal levels of pMLKL  
354 were only slightly detected in the hippocampus (**Fig 2**). Interestingly, there is no incidence of dementia  
355 and cognitive impairment at this stage of life in humans going through a normal aging process (without  
356 inherited conditions and/or associated pathologies)<sup>62</sup>, suggesting that maintaining necroptosis at  
357 lower activation levels could prevent age-associated pathological conditions.

358 As a chronic inflammatory condition, aging also influences the inflammatory status of the brain<sup>23</sup>,  
359 mainly through microglia activation and increase of pro-inflammatory cytokines<sup>63</sup>. Among the pro-  
360 inflammatory cytokines analyzed in the hippocampus of aged *Mlkl*-KO mice only IL-12 decreased,  
361 reaching levels comparable with adult mice (Fig 3f). IL-12 is produced in the brain by microglia and  
362 required for IFN- $\gamma$  and TNF- $\alpha$  production, two master inflammatory cytokines. The increased  
363 expression of IL-12 in the brain has been associated with spontaneous neurological disorders in aged  
364 mice<sup>64</sup>. By contrast, the IL12-KO mouse exhibits lower levels of microglia activation and reduced  
365 neurodegeneration in an excitotoxicity-mediated injury model<sup>65</sup>. Additionally, increased levels of the  
366 anti-inflammatory cytokines, IL-2 and IL-10, were specifically detected in aged *Mlkl*-KO mice (**Fig 3f**),  
367 suggesting that MLKL could also act as a repressor of anti-inflammatory cytokine expression under  
368 necroptosis activated conditions. Interestingly, IL-10 inhibits the production of IL-12<sup>66</sup>, which  
369 accompanied with the IL-12 decrease observed in the aged *Mlkl*-KO mice generates a positive anti-  
370 inflammatory feedback loop in conditions of *Mlkl* deficiency, limiting neuroinflammation.

371 It is well documented that neurodegeneration contributes to cognitive decline during normal aging  
372 <sup>67</sup>. Hippocampal-dependent functions are determined by accurate electrophysiological signals. Loss  
373 of *Mlkl* in aged mice produces changes in the hippocampal circuit that prevent the loss of synaptic  
374 strength observed in normal aging (**Fig 4d**). The increased facilitation index observed in aged WT  
375 mice (**Fig 4f**) is an indicator of a decreased neurotransmitter release probability from the presynaptic  
376 compartment, which suggests hippocampal axonal failure in aged mice. Remarkably, the decreased  
377 paired-pulse facilitation index in aged *Mlkl*-KO mice indicates that necroptosis is in fact contributing  
378 to these axonal defects in aged mice. Electrophysiological results were supported by improved  
379 learning and memory performance in aged *Mlkl*-KO mice, demonstrating that altogether axonal  
380 protection, controlled inflammatory status, as well as synaptic transmission restoration in *Mlkl*  
381 deficiency favor youthful-like behavior in aged mice. These observations support the notion that lower  
382 levels of necroptosis activation improves key cognitive functions that might positively impact the  
383 quality of life, favoring healthy aging.

384 Multiple efforts have been made in the field of geroscience to understand the aging process and  
385 to consider it as a therapeutical target to improve healthspan<sup>2,23,68</sup>. The brain and peripheral organs  
386 share common biological mechanisms of aging<sup>25</sup>. Thus, the development of anti-aging drugs that  
387 improve cognitive function and hence the quality of life in old age could have a significant potential at  
388 improving healthspan. Our pharmacological strategy to systemically inhibit RIPK3 with GSK'872 in  
389 aged mice demonstrated to be extraordinarily effective on reverting AxD, neuroinflammation and  
390 hippocampus-dependent functional impairment (**Fig 5** and **Fig 6**). Interestingly, GSK'872 treatment  
391 reduced the levels of most of the pro-inflammatory cytokines analyzed in the hippocampus of aged  
392 mice, indicating that systemic inhibition of necroptosis impacts the inflammatory status of the brain,  
393 thereby diminishing neuroinflammation. Moreover, the analysis of serum cytokines showed the same

394 regulatory profile as the brain, demonstrating that systemically, the inflammatory condition of aged  
395 mice is maintained in a youthful-like state under necroptotic inhibitory terms.

396 Our quantitative proteomic analysis allowed us to generate a correlative necroptotic proteomic  
397 profile and to evaluate whether necroptosis inhibition influences key networks involved in brain aging.  
398 The analysis demonstrated that about 7,000 proteins changed their expression profile as a  
399 consequence of aging (**Fig 7** and **Fig S9**), of which 2,516 shown to be upregulated and 2,307 were  
400 downregulated under necroptosis inhibitory conditions in the hippocampus of aged mice (**Fig S9**).  
401 From these clustered profiles we were capable to contextualize these proteomic changes by  
402 associated them with related canonical pathways and biological function annotations. The pathways  
403 analysis unveiled key biological processes with opposed directionality between “normal” and  
404 necroptosis-targeted aging, showing that key hallmarks of aging, including synaptic function,  
405 mitochondrial dysfunction, stress response, cellular senescence, deficient nutrient sensing, altered  
406 metabolism, and others<sup>23,25</sup>, are positively regulated under necroptosis inhibitory conditions (**Fig S8**),  
407 which may have potential impact in life quality by promoting healthy aging. Interestingly, our  
408 pharmacological approach demonstrated a similar trend in effect over the proteome as the genetic  
409 model, suggesting that necroptosis inhibition could be an attractive therapeutic strategy to develop  
410 geroprotector agents to slow aging. In fact, results obtained from our proteomic analysis indicated  
411 that GSK’872 treatment influences most of the different hallmarks of aging, an inclusion criteria that  
412 is currently recognized to accept novel molecule candidates as geroprotectors<sup>69</sup>. Furthermore,  
413 inhibition of necroptosis demonstrated ability to modulate several brain functions implicated in brain  
414 rejuvenation<sup>5</sup> (**Fig 7** and **Fig S10**), including those elucidated from the proteomic analysis and  
415 experimentally evaluated, such as synaptic plasticity and neuronal senescence (**Fig 8** and **Fig S11**),  
416 which added to the behavioral results on learning and memory, reinforced the potential of GSK’872  
417 as a candidate drug to protect against age-associated brain dysfunction, including memory decline.  
418 Moreover, other interesting pathways were also demonstrated to be positively modulated by  
419 necroptosis inhibition (see **Fig S12-S15** for individual molecular changes and proteomic profiles).  
420 These pathways include *synaptogenesis signaling*, *calcium signaling*, *CREB signaling in neurons*,  
421 and others; most of them highly implicated in the maintenance of neuronal homeostasis and  
422 functioning, and consequently in brain-dependent functions, including cognitive and behavioral  
423 processes<sup>70</sup>.

424 Overall, our study demonstrates that necroptosis contributes to the age-associated deterioration of  
425 axonal integrity and function, affecting hippocampal neuronal connectivity, and consequently the  
426 cognitive function of aged mice. Our results from the pharmacological intervention propose  
427 necroptosis inhibition as an interesting and novel therapeutic target to counteract the deleterious  
428 effects of aging, thus increasing healthspan and potentially delaying the onset of a range of age-  
429 related disabilities.

430

## 431 **4. METHODS**

### 432 **4.1. Animals**

433 Wild-type (WT) C57BL/6J mice of different ages were purchase from the Jackson Laboratory and  
434 maintained in the Universidad Mayor animal facility. Aging groups were established as follow: adult  
435 (3-6 month), old (12-15 month) and aged mice (more than 20 month). *Mkl* knockout mice (*Mkl*-KO)  
436 were kindly provided by Dr Douglas Green (St. Jude Children's Research Hospital, Memphis, TN,  
437 USA) and have been previously produced and described<sup>71</sup>. The age range was selected in  
438 equivalence with the human life phases<sup>61,72</sup>. Animals were kept under standard conditions of light and  
439 temperature and were feed with food and water ad libitum in the Animal Facility of the Sciences  
440 Faculty of the Mayor University. The research protocol no. 22-2017 was approved by the Animal  
441 Care and Use Scientific Ethic Committee of the Mayor University.

442

### 443 **4.2. Osmotic pump implantation**

444 Micro-osmotic pumps (Alzet, model 1004) containing the RIPK3 inhibitor GSK'872 (Tocris) (2 mg/kg)  
445 were surgically implanted in the peritoneal cavity of 23-moth-old. The pump allows a constant flux of  
446 the drug at 0.11  $\mu$ l/hr for 28 days. One-month post-surgery, mice (24-month-old) were subjected to  
447 behavioral test to evaluate memory and then tissue was extracted for further analyses.

### 448 **4.3. Quantification of GSK'872 in brain and plasma**

449 Brain and plasma samples were obtained from aged mice treated for 1h with GSK'872 (10mg/kg i.p.).  
450 The bioanalysis of plasma and brain samples was conducted by LC-MS/MS with a QTRAP 4500 triple  
451 quadrupole mass spectrometer (Applied Biosystems SCIEX) in the negative ion mode and interfaced  
452 with an Ekspert ultraLC 100-XL UHPLC System (Eksigent). Calibration standards (0.003 to 10  $\mu$ M)  
453 and quality controls (0.02, 0.2 and 2.0  $\mu$ M) were prepared from naïve mouse plasma in parallel with  
454 mouse plasma study samples (60  $\mu$ L) by precipitation with three volumes of ice-cold acetonitrile  
455 containing 20  $\mu$ M of theophylline. The precipitated samples were centrifuged at 6,100 g for 30 min at  
456 4°C. Following centrifugation, an aliquot of each supernatant was transferred to an autosampler vial  
457 and diluted with two volumes of aqueous mobile phase (0.2% formic acid in water). Samples were  
458 injected onto a reverse phase analytical column (YMC Triart C18; 2.0 x 50 mm; 1.9  $\mu$ m; YMC CO)  
459 and eluted with a gradient of 0.2% formic acid in Acetonitrile. GSK'872 was monitored by a multiple  
460 reaction monitoring (MRM) experiment using an Analyst software (v1.6.2, Applied Biosystems  
461 SCIEX). Quantitation was conducted using a MultiQuant software (v2.1, Applied Biosystems SCIEX)  
462 and the resulting calibration curve was fitted with a linear regression and 1/x weighting. The lower  
463 limit of quantitation (LLOQ) was 0.010  $\mu$ M.

464

### 465 **4.4. Immunohistochemistry**

466 Mice were deeply anesthetized with isoflurane and intracardially perfused with isotonic saline followed  
467 by 4% paraformaldehyde. Brains were dissected, postfixed overnight in 4% paraformaldehyde at  
468 4 °C, and then incubated in 30% sucrose. Tissue was cryoprotected in optimal cutting temperature  
469 compound (OCT, Tissue-Tek) at -20 °C and serial sagittal sections of 20 µm thickness were obtained  
470 using a cryostat (Leica, CM1860). Brain sections were pre-mounted on positively charged slides and  
471 washed in TBS. After antigen retrieval (80 °C, 30 min, 10 mM citrate buffer, pH 6.0), sections were  
472 blocked in TBSB (TBS, 5% BSA and 0.25% Triton X-100), and then incubated overnight at 4 °C with  
473 the following primary antibodies: pMLKL (1:200, phospho S345, Abcam, ab196436), neurofilament  
474 pan-axonal cocktail (1:250, SMI312 clone, Biolegend), non-phosphorylated neurofilament (1:250,  
475 SMI32 clone, Biolegend), and Iba1 (1:500, Wako Chemicals, 016-26721). Sections were washed to  
476 remove the excess of primary antibody and incubated with the appropriate Alexa-Fluor secondary  
477 antibodies for 2 h at 25 °C (1:1000, Thermo Fisher Scientific). The excess of secondary antibody was  
478 washed, and the sections were coverslipped with Fluoromount-G antifade mounting medium (EMS,  
479 17984-25) containing DAPI staining for nuclei detection (Thermo Fisher Scientific). For Fluoro-Jade  
480 C staining, brain tissue was mounted on positively charged slides and rehydrated on decreasing  
481 concentrations of ethanol. After rehydration, the tissue was pre-treated for 10 min in potassium  
482 permanganate and then incubated for 10 min in the dark at 25 °C in Fluoro-Jade C and DAPI  
483 (Biosensis, TR-100-FJ). The tissue was then washed with water and let dry overnight. The next day  
484 the slides were cleared in xylene and coverslipped with DPX-new mounting solution (Merck Millipore).  
485 The anti-pMLKL antibody purchase from Abcam (ab196436) was KO-validated by comparison of the  
486 immunodetected signal in aged WT mice with the *Mkl1*-KO mice in the hippocampus (**Fig S7**).  
487 Immunostained sections were scanned in a Leica DMI8 Fluorescence Microscope fully automatized.

#### 488 **4.5. Histological Analysis**

489 Free-floating sections were processed for immunohistochemistry as previously described<sup>31</sup>. Briefly,  
490 slices were quenched with 0.3% H<sub>2</sub>O<sub>2</sub> for 30 min, blocked with 5% BSA and 0.2% triton X-100 for 2 h  
491 and incubated with primary antibody (rabbit anti-pMLKL, 1:200 Abcam) overnight at 4 °C. Then,  
492 sections were washed with 0.1 M PBS and incubated with secondary biotinylated antibody (goat anti-  
493 rabbit, 1:500 Vector Laboratories) for 2 h at RT. After washing, slices were incubated with avidin-  
494 biotin-peroxidase complex (Vector Laboratories) for 1 h at RT followed by 0.1 M PBS washes and  
495 developed with 3,3-diaminobenzidine (DAB, Sigma-Aldrich). Finally, sections were co-stained with  
496 Nissl (cresyl-violet staining) to detect nuclei and with Eriochrome-C staining for myelinated-axons  
497 detection, and finally mounted on glass slides with Entellan medium (Merck).

#### 498 **4.6. Image Analysis**

499 Fluorescent images were analyzed using the Image J software from the NIH, USA. Axonal  
500 degeneration index (DI) was measured in pan-axonal immunostained images as the ratio of the area  
501 of fragmented axons against the total axonal area (intact + fragmented particles) in the hilus using

502 the particle analyzer algorithm of ImageJ. Fragmented and intact axonal particles were estimated by  
503 defining area and circularity of the particles (fragmented:  $<20 \mu\text{m}^2$  and  $0.3 \leq 1$  circularity; intact:  $\geq 20$   
504  $\mu\text{m}^2$  and  $0 < 0.3$  circularity)<sup>15</sup>.

505

#### 506 **4.7. Luminex Assay**

507 Cytokines levels were analyzed by Luminex Mouse Discovery Assay (R&D Systems, MN, USA) using  
508 a self-designed panel of 12 selected cytokines (plate code: LXSAMSM-12), based on color-coded  
509 beads, pre-coated with analyte-specific capture antibodies that permits simultaneous analysis of the  
510 analytes. Table S1 detailed cytokines and chemokines of the panel, bead region, sensitivity, and the  
511 main functions. Analysis and detection were performed in a Dual-laser flow-based detection  
512 instrument, Luminex 200 analyzer by Proyecto Luminex, Programa de Virología, Redeca, ICBM,  
513 Facultad de Medicina, Universidad de Chile.

#### 514 **4.8. Electrophysiology**

515 Electrophysiological recordings were performed as described before<sup>73</sup>. Briefly, transverse slices  
516 (400  $\mu\text{m}$ ) from the dorsal hippocampus were cut under cold artificial cerebrospinal fluid (ACSF, in  
517 mM: 124 NaCl, 2.6 NaHCO<sub>3</sub>, 10 D-glucose, 2.69 KCl, 1.25 KH<sub>2</sub>PO<sub>4</sub>, 2.5 CaCl<sub>2</sub>, 1.3 MgSO<sub>4</sub>, and 2.60  
518 NaHPO<sub>4</sub>) using a Vibratome (BSK microslicer DTK-1500E, Ted Pella, Redding, CA, USA) and  
519 incubated in ACSF for 1 hour at room temperature. In all experiments, 10  $\mu\text{M}$  PTX was added to  
520 suppress inhibitory GABAA transmission. Slices were transferred to an experimental chamber (2 ml),  
521 superfused (3 ml/min, at room temperature) with gassed ACSF (using 95% O<sub>2</sub>/5% CO<sub>2</sub>) and  
522 visualized by trans-illumination with a binocular microscope (Amscope, Irvine, CA, USA). To evoke  
523 field excitatory post synaptic potentials (fEPSPs), Schaffer collaterals were stimulated with bipolar  
524 concentric electrodes (Tungsten, 125  $\mu\text{m}$  OD diameter, Microprobes) connected to an isolation unit  
525 (Isoflex, AMPI, Jerusalem, Israel). The stimulation was performed in the *stratum radiatum* within 100–  
526 200  $\mu\text{m}$  from the recording site. Recordings were filtered at 2.0–3.0 kHz, sampled at 4.0 kHz using an  
527 A/D converter (National Instrument, Austin, TX, USA), and stored with the WinLTP program. The  
528 basal excitatory synaptic transmission was measured using an input/output curve protocol with 10 s  
529 of interval between stimuli. Data were collected and analyzed offline with pClamp 10 software  
530 (Molecular Devices, San Jose, CA, USA). To generate LTP, we used high-frequency stimulation  
531 (HFS) protocol, which consisted of 3 trains at 100 Hz of stimuli with an inter-train interval of 10 s. Data  
532 were collected and analyzed offline with pClamp 10 software (Molecular Devices, San Jose, CA,  
533 USA).

#### 534 **4.9. Learning and memory test**

535 Morris water maze (MWM) navigation task was performed to evaluate spatial memory and learning  
536 in adult vs aged WT, *Mikl*-KO and GSK'872-treated mice. Animals were trained in a 1.2-m-diameter

537 circular pool (opaque water, 50 cm deep) filled with 19-21°C water. A submerged 11.5-cm platform  
538 (1 cm below the surface of water, invisible to the animal) was used for training, with a maximum trial  
539 duration of 60 s; the mice remained on the platform for 10s at the end of each trial. Each animal was  
540 trained to locate the platform for 4 consecutive days following external cues (learning curve), 4 times  
541 per day. The test was performed on the fifth day by removing the platform, and swimming was  
542 monitored to measure the latency time required to reach the platform and the time spent in each  
543 quadrant and in the target quadrant (Q4), and the travelled distance within Q4. Both the learning  
544 curve and the test were tracked using an automatic tracking system (ANY-maze video tracking  
545 software, Stoelting Co, Wood Dale, IL, USA) to obtain the parameters measured. After testing, the  
546 mouse was gently removed from the pool and returned to its cage. Mean heatmaps were generated  
547 by the Anymaze software to represent the time spent by different cohorts of mice in a particular  
548 location of pool.

#### 549 **4.10. Senescence-associated beta-galactosidase (SA-βgal) activity**

550 Histochemical detection of SA-βgal activity were performed as was described before<sup>74</sup>. Briefly, SA-  
551 βgal activity was determined by incubation with 1 mg/mL of solution of 5-bromo-4-chloro-3-indolyl β-  
552 d-galactopyranoside in 0.04M citric acid/sodium, 0.005M K<sub>3</sub>FeCN<sub>6</sub>, 0.005M K<sub>4</sub>FeCN<sub>6</sub>, 0.15 M NaCl,  
553 and 0.002M MgCl<sub>2</sub> diluted in phosphate-buffered saline (pH 6) for 16h. After the incubation,  
554 hippocampal slices were washed with TBS and mounted in superfrost microscope slides  
555 (TermoFisher, 6776214) using Fluoromount-G (TermoFisher, 00-4958-02). Images were taken with  
556 Nikon Eclipse E200 optic microscope with 4X and 10X objective magnification. ImageJ software was  
557 used to process the images. Positive area for SA-βgal activity was measured and representative  
558 images are shown.

#### 559 **4.11. Statistical Analysis**

560 Statistical significance was established at p<0.01 by one-way ANOVA with Tukey's post-test or two-  
561 way ANOVA for multiple comparisons. The analysis was performed using GraphPad Prism Software  
562 v8.0 and performed with data obtained from ≥ 3 independent experiments for image analyses and n  
563 ≥ 8 animals for behavioral test.

#### 564 **4.12. Label-free proteomics**

##### 565 *S-Trap processing of samples*

566 Samples were processed using S-trap mini protocol (Protifi) (for 310 ug and 110 ug samples) and S-  
567 trap micro protocol (for low conc samples) as recommended by the manufacturer with little  
568 modification. After, application of the samples on the S-trap mini spin column, trapped proteins were  
569 washed 5 times with S-TRAP binding buffer. A double digestion with trypsin (1:40) was carried out  
570 first overnight at 37°C in TEAB at a final concentration of 50 mM, and then for another 4 hrs (1:40) in  
571 50mM TEAB. Elution of peptides from S-trap mini spin column was achieved by centrifugation at 1000

572 x g for 1 min by adding 50 mM TEAB, then 0.2% aqueous formic acid and finally 50% acetonitrile/0.2%  
573 formic acid. Resulting tryptic peptides were pooled, dried, and quantified using Pierce Quantitative  
574 fluorometric Peptide Assay (Thermo Scientific).

#### 575 *LC-MS methods*

576 1.5 µg peptide was analysed per sample. Samples were injected onto a nanoscale C18 reverse-  
577 phase chromatography system (UltiMate 3000 RSLC nano, Thermo Scientific) then electrosprayed  
578 into an Q Exactive Plus Mass Spectrometer (Thermo Scientific). For liquid chromatography buffers  
579 were as follows: buffer A (0.1% formic acid in Milli-Q water (v/v)) and buffer B (80% acetonitrile and  
580 0.1% formic acid in Milli-Q water (v/v)). Sample were loaded at 10 µL/min onto a trap column (100 µm  
581 × 2 cm, PepMap nanoViper C18 column, 5 µm, 100 Å, Thermo Scientific) equilibrated in 0.1%  
582 trifluoroacetic acid (TFA). The trap column was washed for 5 min at the same flow rate with 0.1%  
583 TFA then switched in-line with a µPAC C18 nano-LC column (200 cm, inter-pillar distance- 2.5 µm,  
584 pore size- 100-200 Å, PharmaFluidics). The peptides were eluted from the column at a constant flow  
585 rate of 300 nL/min with a linear gradient from 3.8% buffer B to 12.5% buffer B in 22 mins, then from  
586 12.5% buffer B to 41.3% buffer B in 95 mins, then from 41.3% buffer B to 61.5% in 23 mins and finally  
587 to 100% buffer B in 10 mins. The column was then washed with 100% buffer B for 10 min and re-  
588 equilibrated in 1% buffer B for 38 mins. Two blanks were run between each sample to reduce carry-  
589 over. The column was kept at a constant temperature of 50°C. The data was acquired using a uPAC-  
590 compatible easy spray emitter source operated in positive mode with spray voltage at 2.2 kV, and the  
591 ion transfer tube temperature at 275°C. The MS was operated in DIA mode. A scan cycle comprised  
592 a full MS scan (m/z range from 345-1155), with RF lens at 60%, AGC target 3E6, orbitrap resolution  
593 70,000, maximum injection time at 200 ms and source fragmentation disabled. The MS survey scan  
594 was followed by MS/MS DIA scan events using the following parameters: collision energy mode set  
595 to linear with a normalized HCD collision energy set to 25, orbitrap resolution 17500, first fixed mass  
596 200 m/z, AGC target 3E6, maximum injection time 55 ms, isolation windows were variable from 5-66  
597 m/z. The inclusion list (DIA windows) and windows widths are shown in **Table S2**. Data for both MS  
598 and MS/MS scans were acquired in profile mode. Mass accuracy was checked before the start of  
599 samples analysis.

#### 600 **4.13. Analysis of proteomic data**

##### 601 *Data filtering and generation of expression ratios*

602 Raw data files from single-shot label-free experiments were converted into Microsoft Excel workbooks  
603 and utilised to generate ratios of protein expression within each animal relative to mean expression  
604 of n=4 control animals within each comparison (ie. adult: adult (expression ratio=1), aged: adult, *Mikl*-  
605 KO: aged-WT; aged GSK'872: aged vehicle). Proteins identified by fewer than 2 unique peptides  
606 were excluded from subsequent analyses (**Figure S8**) in order to ensure maximum identification  
607 confidence. Relative expression ratios per study (ie. aged vs. adult, *Mikl*-KO vs. aged WT, and aged

608 GSK'872 vs. aged vehicle) were used for subsequent expression profile clustering analyses. UniProt  
609 Accession numbers of proteins identified by 2 or more unique peptides with accompanying expression  
610 ratios generated as described above were subjected to expression profile clustering in *BioLayout*  
611 *Express*<sup>3D</sup>. *BioLayout* utilises a user-determined Pearson correlation and the Markov Clustering  
612 Algorithm to cluster input data based on user-determined parameter(s)<sup>75,76</sup>. Pearson correlation was  
613 set to 0.97 to cluster datasets into distinct subsets based on similarity in expression profile. Discrete  
614 clusters exhibiting biologically relevant expression profiles- ie. opposing directionality between aged  
615 versus both MLKL-KO and GSK'872 expression ratios (**Fig S8 and Fig S9**) were identified and  
616 exported as .txt files containing and identifier column and expression ratios, for subsequent analyses  
617 in IPA.

618

#### 619 *Ingenuity Pathway Analysis (IPA)*

620 The Ingenuity Pathway Analysis (IPA) application (Ingenuity Systems, Silicon Valley, CA) was used  
621 to visualise and explore the cellular and molecular pathways that may have been altered as result of  
622 genetic (*Mkl-KO*) or pharmacological (GSK'872) inhibition of necroptosis. Without user-directed  
623 manipulation, IPA's statistical predictions and annotations are approximately 90% based off on peer-  
624 reviewed publications; the remaining 10% of stored interactions have been identified by other in silico  
625 techniques. The analyses were performed only using experimentally reported interactions published  
626 in peer-reviewed publications stored within the "hand-curated" and continually updated Ingenuity  
627 Knowledge database (Ingenuity Systems, Silicon Valley, CA). For more information on the  
628 computational methodology underpinning IPA, please refer to <http://www.ingenuity.com/>.

629 Prior to all analyses within IPA, input datasets comprising, as described above, mean expression  
630 ratios of  $n=4$  animals per experimental group, were converted to fold-change values, and a  $\pm 20\%$  cut-  
631 off in expression change respective to control was applied within each respective study. Individual  
632 analyses of aged vs. adult, *Mkl-KO* vs. WT, and GSK'872 vs. vehicle were performed prior to a  
633 comparative analysis in order to gain insight into potential biological networks distinguishing "normal"  
634 versus "necroptosis-inhibited" aging processes.

635 For canonical pathway analysis, p-values of canonical pathway scores and subsequent ranking for  
636 all analyses performed in this study were derived from a Fisher's Exact Test calculating overlap  
637 between molecules in each respective input dataset and number of molecules comprising canonical  
638 pathway as defined by the Ingenuity Systems Database. Predicted activation z-scores were  
639 calculated by weighing the predicted expression change of target molecules as defined by Ingenuity  
640 Knowledge Database against the actual expression change of target molecules reported in input  
641 dataset. An activation z-score  $>2$  or  $<-2$  is considered statistically significant (Ingenuity Systems,  
642 Silicon Valley, CA). Constituent molecules within pathway were colourized with intensity of colour  
643 corresponding to magnitude of change.

644 For diseases and functions analysis, predicted activation z-scores of associated downstream  
645 diseases and functions were calculated by weighing the predicted expression change of target

646 molecules associated with specific “diseases or functions” annotation as defined by Ingenuity  
647 Knowledge Database against the actual expression change of target molecules reported in input  
648 datasets. An activation z-score  $>2$  or  $<-2$  is considered statistically significant. *P*-values of overlap is  
649 derived from a Fisher's exact test were derived from a Fisher's Exact Test calculating overlap between  
650 molecules in each respective input dataset and number of molecules comprising the known  
651 interactome of each regulator as defined by Ingenuity Systems Database. In graphical format, target  
652 molecules present within each proteomic dataset predicted to be activated or inhibited to mediate the  
653 associated “diseases or functions” annotation were visualised in relation to their associated predicted  
654 regulator and were colourised with intensity of colour corresponding to magnitude of change.

655

### 656 **Funding and acknowledgement**

657 This work was supported by grants from the Geroscience Center for Brain Health and Metabolism,

666 Científico y Tecnológico (FONDECYT) N° 1200255 to CC, and a PhD fellowship by ANID (to ML).

### 667 **Data availability statement**

668 Raw data from Fig 1,2,3,4,5,6 and 8 are available as an extended excel file named "Figures Raw  
669 Data".Raw data from Supplementary Figures S1, S2, S3, S4, S5, S6 and S11 are available as an  
670 extended excel file named "Suppl Figures Raw Data". The datasets generated from the proteomic  
671 analysis are available in the data repository of Edinburgh University with an assigned DOI. All the  
672 data that support the findings of this study are also available from the corresponding author upon  
673 request.

**Fig 1. Increased axonal degeneration in the hippocampus during aging.** Representative images of hippocampal sections from adult (3-6 month), old (12-25 month) and aged mice (more than 24 month) stained with Fluoro Jade C (FJC, green), non-phosphorylated neurofilament (non-pNF) and pan-axonal NF (**a,c,e**). Nuclear staining with DAPI (blue) was used to identify the granular layer. (**b,d**) The mean fluorescence intensity was evaluated in FJC and non-pNF staining to determine levels of neurodegeneration in the hilus according to age. (**f**) Axonal degeneration was assessed in the DG hilus using the axonal integrity index in hippocampal sections immunostained with the pan-axonal NF antibody. Calibration bars, 250  $\mu$ m (entire DG) and 50  $\mu$ m for magnified hippocampal images. Values are the result of the analysis of n=3-4 mice per group. One-way ANOVA with Tukey analysis for multiple comparisons, \*p<0.05; \*\*p<0.01; \*\*\*p<0.005; \*\*\*\*p<0.001.

**Fig 2. Progressive increase of phosphorylated MLKL levels in the hippocampal hilus along aging.** (a) MLKL phosphorylation at serine 345 (green) was evaluated in adult (3-6 month), old (12-25 month) and aged mice (more than 24 month) (bar=25  $\mu$ m and 10  $\mu$ m for magnification). (b) Mosaic reconstruction of the hippocampal dentate gyrus (DG) illustrates each subfield: the granular cell layer (GCL), and the hilus, showing pMLKL in green (bar=100  $\mu$ m). (c) Quantification of pMLKL signal in hilar cells is plotted as the percentage of pMLKL positive cells normalized against the total cell number in the hilar area (upper graph), and as pMLKL mean intensity (lower graph). (d) Axonal pMLKL was detected in NF-positive axons in the hilus, dotted boxes illustrate magnified areas shown in the bottom panel. Calibration bars, 25  $\mu$ m and 5  $\mu$ m for inset. (e) pMLKL mean intensity was analyzed in hilar fibers along aging. Error bars, mean  $\pm$  SEM, \* $p$ :<0.05; \*\* $p$ :<0.01. Statistical significance was determined by one-way ANOVA with Tukey analysis for multiple comparisons. (f) Immunohistochemistry against pMLKL (brown) and Eriochrome-C staining (myelinated axons, blue). Calibration bar 40  $\mu$ m. Red dotted boxes showed image magnification of each condition. Calibration bar, 15  $\mu$ m. Necroptosis activation in DG axons and in Schaffer collateral projections of the hippocampus are shown with red arrowheads. Increased pMLKL was also observed in neuronal somas (dark brown/+Nissl, violet).

**Fig 3. *Mikl* deficiency protects the brain from age-associated axonal degeneration and neuroinflammation.** Axonal degeneration and neuroinflammation were evaluated in the DG hilus of aged WT and *Mikl*-KO mice and compared with the values of the normal aging curve (N= 3-5 mice per group). **(a)** Axonal degeneration was detected by immunostaining of axons with the pan-axonal-NF marker (red) and evaluated by calculating the axonal degeneration index (DI). Calibration bars, 25  $\mu$ m and 5 $\mu$ m for insets. **(b)** Increased non-pNF signal was also used as a positive marker of axonal degeneration. Calibration, bar, 50  $\mu$ m. **(c)** Quantification of non-pNF signal plotted as the percentage of stained area in the hilus. **(d)** Microglia activation was measured by Iba1 immunodetection. Calibration bar, 50  $\mu$ m. **(e)** Microglia activation quantified through Iba1 mean intensity. **(f)** Cytokines levels in the hippocampus of adult versus aged WT and *Mikl*-KO mice were assessed by Luminex High Performance Assay. Plots represent absolute cytokine levels (pg/ml), including IL-12, IL-2 and IL-10 in aged WT and *Mikl*-KO hippocampus, (N=4-7 mice per group). Error bars, mean  $\pm$  SEM, \*p:<0.05; \*\*p<0.01; \*\*\*p<0.005; \*\*\*\*p<0.001. Statistical significance was determined by one-way ANOVA with Tukey analysis for multiple comparisons.

**Fig 4. Hippocampal function and memory are improved in aged *Mikl-KO* mice.** (a) Field excitatory post synaptic potential (fEPSP) was measured in hippocampal slices in the CA3-CA1 circuit as described in the scheme. (b,c) Average traces of the evoked potentials recorded in each condition were used to plot the fEPSP slope upon several stimulus intensity. (d) The average fEPSP slope at the highest stimulus (gray bar in c) was plotted as bar graphs, showing significant differences between groups. (e,f) Paired pulse facilitation was measured as the facilitation index (fEPSP<sub>2</sub>/fEPSP<sub>1</sub>). Values are the result of the analysis of N=3 mice per group (n=3 slices per mice). Error bars, mean ± SEM, \*\*p<0.01. Statistical significance was determined by one-way ANOVA. Hippocampal-dependent behavioral function was evaluated using the standard Morris water maze (MWM) navigation task. (g) Escape latency was measured as the time to reach the hidden platform during the learning curve in aged and adult WT vs *Mikl-KO* mice. (h) Mean heatmaps specify location each mice cohort along time in pseudo-color during memory testing (day 5). The quadrant Q4 designates the initial location of the hidden platform during training. (i,j) Travelled distance and time spent in Q4, respectively. Values are the result of the analysis of n=7-10 mice per group. One-way ANOVA with Tukey correction for multiple comparison, \*p:<0.01; Two-way ANOVA plus Sidak's multiple comparison test was applied for the learning curve data analysis. Significance between curves was determined with a \*p=0.0209 for aged WT and *Mikl-KO* comparison, and \*\*p=0.0015 for differences between adult and aged WT mice. Differences observed at day 3 between aged WT vs *Mikl-KO* correspond to ##p=0.0043.

**Fig 5. Short-term and systemic RIPK3 inhibition reverts age-associated axonal degeneration and neuroinflammation.** Aged mice (23-month-old) treated with vehicle or GSK'872, intraperitoneally delivered through an osmotic pump, diffusion rate = 0.11  $\mu$ l/hr/28 days. **(a,b)** Axonal degeneration detected by non-pNF (calibration bar, 50  $\mu$ m) was quantified and plotted as the percentage of stained area in the DG hilus. **(c,d)** Microglia activation assessed as Iba1 immunodetection (calibration bar, 50 $\mu$ m) and quantified as Iba1 mean intensity in the hilus. **(e)** The heatmap shows fold change levels of cytokines and chemokines analyzed in the hippocampus of adult versus aged-vehicle and aged-GSK'872 treated mice (n =4, separated in each column). **(f)** Absolute levels (pg/ml) of TNF- $\alpha$ , IL-6, IL-12p70 and IFN- $\gamma$  in the hippocampus of adult (white bar), aged-vehicle (gray) and aged-GSK'872 (light blue) treated mice. (N=3-4 mice per group). Error bars, mean  $\pm$  SEM, \*p:<0.05; \*\*p<0.01; \*\*\*p<0.005. Statistical significance was determined by one-way ANOVA with Tukey analysis for multiple comparisons.

Figure 6

**Fig 6. Pharmacological necroptosis inhibition restores hippocampal function and memory in aged mice.** (a) Average traces of the evoked potentials recorded in each condition were used to plot the fEPSP slope upon several stimulus intensity in b. (c) The average fEPSP slope at the highest stimulus (gray bar in a) was plotted. Significant differences were detected between groups. (d,e) Paired pulse facilitation was measured as the facilitation index (fEPSP<sub>2</sub>/fEPSP<sub>1</sub>). Values are the result of the analysis of N=3 mice per group (n=3 slices per mice). Error bars, mean ± SEM, \*\*p<0.01. Statistical significance was determined by one-way ANOVA. Hippocampal-dependent memory was evaluated with the MWM test. (f) Escape latency of vehicle-treated vs GSK'872-treated aged mice measured during the learning curve. (g) The swimming heatmaps indicating the average mice location along time (pseudo-color) during memory testing (day 5) show increased preference of aged mice treated with GSK'872 to the original location of the platform (Q4) compared with aged-vehicle mice. (h, i) Travelled distance and the time spent in the target quadrant Q4 were plotted. Values are the result of the analysis of n=8-10 mice. T-test with Welch's correction, \*p<0.01. Two-way ANOVA with Sidak's multiple comparison test was applied for the learning curve data. Significance between both curves was determined with a \*p=0.0259. Differences between vehicle vs GSK'872 at day 2 and 3 correspond to #p=0.0210 and p=0.0328, respectively.

**Fig 7. Proteomic analysis reveals opposing directionality in protein expression and aging-associated biofunctions between normal aging and necroptosis-targeted inhibition. (a)** Heat map illustrating proteins exhibiting opposing directionality in expression between “normal” aging (aged vs. adult) and necroptosis-inhibited processes in aged mice (*Mkl*-KO and GSK’872), as identified through unbiased expression profile clustering (**Fig S8** and **Fig S9**). Heat map depicts mean expression ratio (log 2) of  $n=4$  mice per experimental group versus their respective controls. Red represents upregulation compared to control within each respective analysis, while green represents downregulation. **(b)** Selection of canonical pathways classified as aging hallmarks (**Supplementary Fig S10**) were identified through comparative analyses of proteins correlating with necroptosis-targeted inhibition of aging phenotypes. Opposing directionality was observed in predicted activation or inhibition scores between “normal” aging cohort, and both *Mkl*-KO or GSK’872-treated mice. A predicted z-score >2 or <-2 (indicated by dotted lines) is considered statistically significant. For description of statistical tests utilized to generate predictive z-score see Methods. **(c)** Selected diseases and biofunctions implicated in brain rejuvenation and derived through comparative analyses of proteins correlating with necroptosis-targeted inhibition of aging phenotypes. Heatmaps shows the opposing directionality in predicted activation or inhibition scores between “normal” aging, and both *Mkl*-KO or GSK’872-treated mice. For description of statistical tests utilized to generate predictive z-scores, see Methods.

**Fig 8. Increased synaptic long-term potentiation in the necroptosis-inhibited aging process.**

Schematic illustrating the canonical pathway annotation of “Synaptic long-term potentiation signaling”. Top canonical pathway annotations were defined by ranking of absolute z-score between “normal” aging, *Mikl*-KO and GSK'872 analyses. Intensity of colour represents magnitude of change; red corresponds to upregulation compared to control within each respective analysis, while green represents downregulation. Molecules in grey were identified to be necroptosis-correlative alterations present within input dataset, but fell below the 20% cut-off, while molecules in white were not present within input dataset (See Supplementary Figures S8, S9) but changed less than 20% in analysis. Solid connecting lines represent a direct interaction, while dashed connecting lines indicate an indirect interaction. **(b)** Heat map of individual proteins assigned to the canonical pathway “Synaptic long-term potentiation signaling”. Changes between normal aging and *Mikl*-KO or GSK'872 treated mice were expressed as fold change. **(c)** Canonical pathway annotation “Synaptic long-term potentiation signaling”. Synaptic plasticity was evaluated by LTP magnitude measurement, generated by high-frequency stimulation (HFS) in the hippocampal CA1 area of WT and *Mikl*-KO mice from adult and aged groups. fEPSP slope was plotted as individual values considering the last 10 minutes of the recording. **(d)** “Synaptic LTP signaling” in aged mice treated with GSK'872 vs vehicle. LTP was generated by HFS in the CA1-CA3 hippocampal transmission and registered for 1h. The last 10 minutes of fEPSP slope were plotted as boxes to evaluate statistical differences. Values are the result of the analysis of N=4 mice per group (n=8-10 slices per mice). Error bars, mean  $\pm$  SEM, \*\*\*p<0.005. Statistical significance was determined by one-way ANOVA.
