ABSTRACT

A long-haul form of progressive fibrotic lung disease has emerged in the aftermath of this pandemic, i.e., *post-COVID-19 lung disease* (PCLD), for which we currently lack insights into pathogenesis, disease models, or treatment options. Using a combination of rigorous AI-guided computation and experiments, we show that COVID-19 resembles idiopathic pulmonary fibrosis (IPF) at a fundamental level; they share prognostic signatures in the circulating monocytes and the lung [Viral pandemic (*ViP*) and IPF signatures], an IL15-centric cytokine storm and the pathognomonic AT2 cytopathic changes, e.g., DNA damage, arrest in a transient, damage-induced progenitor state, and senescence-associated secretory phenotype (SASP). These changes were induced in SARS-CoV-2-challenged adult lung organoids and hamsters and reversed with effective anti-CoV-2 therapeutics in the hamsters. Mechanistically, using protein-protein interaction (PPI)-network approaches, we pinpointed ER stress as an early shared trigger for both COVID-19 and IPF. We validated the same in the lungs of deceased subjects with COVID-19 and SARS-CoV-2-challenged hamster lungs by immunohistochemistry. We confirmed that lungs from *tg*-mice, in which ER stress is induced specifically in the AT2 cells, faithfully recapitulate the host immune response and alveolar cytopathic changes that are induced by SARS-CoV-2. Thus, like IPF, COVID-19 may be driven by injury-induced ER stress that culminates into progenitor state arrest and SASP in AT2 cells. The ViP gene signatures in monocytes may help prognosticate those at highest risk of fibrosis. The insights, signatures, disease models identified here are likely to spur the development of therapies for patients with IPF and other fibrotic interstitial lung disease.

INTRODUCTION

71

As the acute phase of the COVID-19 pandemic winds down, the chronic diseases in its aftermath have begun to emerge. For example, many survivors are suffering from a mysterious long-haul form of the disease which culminates in a fibrotic form of interstitial lung disease (post-COVID-19 ILD)[1-9]. The actual prevalence of post-COVID-19 ILD (henceforth, *PCLD*) is still emerging; early analysis indicates that more than a third of the survivors develop fibrotic abnormalities. One of the important determinants for PCLD[10] is the duration of disease; ~4% of patients with a disease duration of less than 1 week, ~24% of patients with a disease duration between 1-3 weeks, and ~61% of patients with a disease duration > 3 weeks, developed fibrosis. Disability among survivors of severe COVID-19 has been primarily attributed to reduced lung capacities[11]. While COVID-19–affected lungs and post-Influenza lungs share the histologic pattern of diffuse alveolar damage (DAD)[12] with perivascular T-cell infiltration, key differences have been observed[13]. The lungs from patients with Covid-19 also showed[13]: (i) widespread thrombosis with microangiopathy; (ii) severe endothelial injury associated with the presence of intracellular virus and disrupted cell membranes; and (iii) neovascularization predominantly through a mechanism of intussusceptive angiogenesis. These findings highlight that despite being viral pandemics, COVID-19, but not influenza impacts the lungs in ways that go beyond acute DAD, a common phenomenon in progressive ILDs[12]. Although a recent study[14] implicated pathogenic subsets of respiratory CD8[+] T cells in contributing to persistent tissue microenvironment in PCLD, what remains largely unknown are some of the earliest cellular and molecular mechanisms that fuel the progression of fibrosis in COVID-19 lung (but not influenza).

90

As for how the fibrotic sequel of COVID-19 is managed at present, based on the shared pathological features of overt fibrosis in both end-stage COVID-19 and ILDs, lung transplantation remains the mainstay option for these patients[15-17]. Although corticosteroids appear to improve the risk of PCLD[2], beyond that, there is no existing therapeutic option.

95

Here we seek to unravel the fundamental molecular mechanisms underlying PCLD, identifying key disease drivers (cellular processes, immune pathways, and the signaling cascades that support those pathways). We use artificial intelligence (AI) and machine learning derived gene signatures, the *Vi*ral *P*andemic, ViP and severe(s) ViP signatures that are induced in all respiratory viral pandemics[18]. Besides the ViP signatures, we also use gene signatures induced in the lungs of patients with severe COVID-19. These approaches, in conjunction with experimental validation (in pre-clinical disease models and in human lung tissue) not only helped identify which lung pathology shares fundamental molecular features with COVID-19 lung, but also revealed key mechanistic insights into the pathogenesis of PCLD. The findings also provide clues into how to navigate, prognosticate and

104   recapitulate in pre-clinical models this emergent mysterious condition. The objectivity and precision of the AI-

105   guided unbiased approaches enhance the translational potential of our findings.

RESULTS

A study design that uses gene signatures as a computational framework to navigate COVID-19 lung disease

Because PCLD is still an emergent illness that lacks insights into disease pathophysiology, we resorted to a study design (**Figure 1**) that is geared to achieve three goals: (i) maximize rigor by using diverse transcriptomic datasets cohorts (a total of 1556 unique samples, human: 1497; mouse: 41, hamster: 18; see **Supplemental Information 1**), but (ii) minimize bias by using well characterized sets of gene signatures from independent publications (see **Supplemental Information 2**), and (iii) retain objectivity and precision by using artificial intelligence/machine learning (AI/ML) tools that are supported by precise mathematical algorithms and statistical tools (see *Methods*).

First, to ensure that the findings maintain relevance to respiratory viral pandemics and COVID-19, we used a 166-gene signature that is conserved in all *vi*ral *p*andemics (ViP), including COVID-19, and a subset of 20-genes within that signature that classifies disease severity[18] (see **Supplemental Information 2**). In the absence of a sufficiently large number of COVID-19 datasets at the onset of the COVID-19 pandemic, these ViP signatures were validated on ~45000 datasets representing the pandemics of the past (Training datasets: Influenza and avian flu; GSE47963, n = 438; GSE113211, n = 118; Validated in numerous datasets as cited before) and used without further training to prospectively analyze the samples from the current pandemic (i.e., COVID-19) (**Figure 1**, *Step 0*). The ViP signatures appeared to capture the 'invariant' host response, i.e., the shared fundamental nature of the host immune response induced by all viral pandemics, including COVID-19. Since they were discovered, these signatures have helped navigate the syndrome of multisystem inflammatory syndrome in children[30] (MIS-C; a.k.a PIMS-TS)[31]. MIS-C is still a relatively poorly understood entity, but none-the-less recognized as an immunologic response to viral exposure that shares many clinical features with the syndrome of Kawasaki disease (KD). The ViP signatures helped revealed that KD and MIS-C are on the same continuum of the host immune response as COVID-19. Here, we used the ViP signatures as a starting computational framework to navigate the syndrome of COVID-19 lung disease.

We begin first by using the ViP signatures in conjunction with an independently reported[13] COVID-19-lung derived signature to sift through diverse lung diseases and identify what pathologic condition comes closest to COVID-19 lung disease; this effort led us to pinpoint the prototypical example of interstitial lung disease that is characterized by progressive fibrosis, i.e., idiopathic pulmonary fibrosis (IPF)[32] as a computational match for COVID-19 lung disease (**Figure 1**, *Step 1*). The subsequent steps in the study use the ViP signatures alongside IPF-specific PBMC-derived prognostic signatures (**Figure 1**, *Step 2*) and signatures of alveolar cytopathic changes (**Figure 1**, *Step 3*) to systematically assess the degree of similarities between COVID-19 lung and IPF and the crossover of pathophysiologic processes in the two conditions. In the final step (**Figure 1**, *Step 4*), a set of gene signature-inspired protein-protein interaction (PPI) network analysis is used which pinpointed alveolar

6

138 ER stress as a potential early step in both IPF and PCLD, which is sufficient to recapitulate not just the ViP

139 signatures, but also the alveolar cytopathic features that are shared between the diseases. Key predictions are

140 validated in human lung tissues and plasma from COVID-19 subjects, hamster models of COVID-19 and in

141 human pre-clinical lung models (**Figure 1**, *Steps 3-4*).

142

143 **COVID-19 lung disease and IPF induce a common set of gene expression signatures**

144 We began by asking if the ViP/sViP signatures that were found to be induced in all CoV samples tested so far(*18*),

145 are induced in certain lung diseases and not in others. To avoid the overreliance on the ViP signatures, we included

146 a second set of CoV-lung disease gene signatures which were derived from a differential expression analysis on

147 lung samples from healthy controls vs. fatal COVID-19(*13*) (see **Supplemental Information 2**). As for the lung

148 diseases, we ensured that all four major pathologic conditions were represented: neoplastic (e.g., carcinoids and

149 adenocarcinoma), granulomatous (e.g., tuberculosis/TB and sarcoidosis), allergic/infectious (e.g., severe asthma

150 and community acquired pneumonia/CAP and tuberculosis) and vasculopathic (e.g., pulmonary

151 hypertension/PHT and chronic thromboembolic pulmonary hypertension/CTEPH) (**Figure 2A**). As expected,

152 ViP/sViP signatures were induced in infectious diseases (CAP and tuberculosis), and to our surprise, these

153 signatures were upregulated also in sarcoidosis, a granulomatous condition that progresses to fibrosis in ~20% of

154 the patients(*33, 34*) (**Figure 2A**). Only two diseases (tuberculosis and IPF) showed significant induction of both

155 ViP and CoV-lung signatures, of which only one condition (IPF) manifests as a diffuse disease with patchy

156 parenchymal involvement that has been reported in COVID-19 lung disease (**Figure 2A**).

157 We next analyzed a set of six signatures, each independently derived from diverse IPF-centric studies(*35-*

158 *38*), on diverse CoV samples; we also analyzed the ViP/sViP(*18*) and CoV-lung(*13*) signatures on 3 independent

159 IPF datasets. We found that most CoV samples induced the IPF signatures and *vice versa*, i.e., most IPF samples

160 induced ViP/CoV-lung signatures (**Figure 2B**). In fact, in a pooled dataset that included both CoV and IPF

161 samples the ViP (**Figure 2C**), sViP (**Figure 2D**), IPF-lung (**Figure 2E**) and CoV-lung (**Figure 2F**) were

162 indistinguishably induced in both samples compared to healthy controls. These results indicate that CoV and IPF

163 signatures have crossover utility for sample classification and indicate that IPF is the closest computational match

164 to COVID-19 lung disease (**Figure 2G**). Consistent with the fact that PCLD occurs in survivors of severe disease

165 that required hospitalization(*39*), we found that sViP signature was induced significantly higher in hospitalized

166 compared to non-hospitalized subjects (**Figure 2H**). Finally, we asked what, if any relationship exists between

167 another poorly understood feature of long-haul COVID-19, i.e., severe fatigue(*40, 41*). To improve rigor, we

168 analyzed a set of other well-defined fatigue syndromes (e.g., gulf war illness, chronic fatigue syndrome, and

169 idiopathic chronic fatigue) and for consistency, restricted the analysis to only whole blood/PBMC samples

170 (**Figure 2I**). ViP/sViP and CoV-lung immune signatures were induced only in CoV samples, but not in the

7

171 remaining fatigue-associated syndromes (**Figure 2I**), indicating that gene expression signatures in long-haul

172 COVID-19 are distinct from other fatigue-associated syndromes. Instead, fatigue in long-haul COVID-19 may be

173 of similar reasons/pathophysiology that has been observed in IPF (*42*). It is noteworthy that profound fatigue is a

174 shared phenomenon in both IPF and sarcoidosis(*42, 43*), both carry the risk of progressive fibrosis, and both

175 conditions induce the ViP/sViP response (**Figure 2A**).

176 Taken together, these results show that when it comes to gene expression patterns, long-haul PCLD is

177 closest to IPF: both are characterized by profound fatigue, diffuse and progressive lung fibrosis, and share gene

178 expression patterns. The latter suggests that these two diseases may also share molecular and cellular mechanisms

179 of disease pathogenesis.

180

181 **PBMC-derived prognostic signatures in COVID-19 and IPF show crossover utility in both diseases**.

182 Previously we showed using single cell sequencing datasets in COVID-19, as well as datasets in which bulk seq

183 was performed on sorted cells, that ViP/sViP signatures are primarily induced by lung epithelial cells and myeloid

184 cells (both alveolar macrophages and PBMCs)(*18*). When assessed in whole blood and/or PBMCs, the sViP

185 signature was prognostic in COVID-19—high expression of this 20-gene signature was associated with prolonged

186 hospital stay and mechanical ventilation(*18*). We noted that a PBMC-based 52-gene signature has previously

187 been validated in numerous IPF datasets(*44*). In the setting of IPF, the role of macrophages has been cemented

188 by several studies. Derived either from tissue-residentmacrophages or PBMCs, macrophages are first activated

189 by the secreted cytokines from senescent alveolar epithelial cells. Subsequently, they go on to activate the alveolar

190 fibroblasts via secretionof CCL18, TGFβ, IL-1β, and/or PDGF, promoting their secretion of collagen(*45-50*)

191 (**Figure 3A**). In later stages of IPF, the activated macrophages and myofibroblasts are thought toeven cross-

192 stimulate each other,resulting in a vicious cycle that assures propagation of fibrosisthroughout the lung(*45, 51*).

193 Consistent with what others have reported before(*23, 52*), we found that alveolar macrophages (marked by

194 CD-14(*53*)) in the lungs of deceased subjects contained the viral nucleocapsid protein (**Figure 3B-C**). The 20-

195 gene sViP signature was prognostic in the blood datasets from both COVID-19 (**Figure 3D**; *left*) and IPF subjects

196 (**Figure 3D**; *middle, right*); among IPF subjects, the signature was prognostic exclusively in male subjects (**Figure**

197 **3D**; *middle*). The 52-gene 'IPF-specific' prognostic signature(*47*) retained its ability to prognosticate outcome in

198 both male and female patients with IPF (as expected; **Figure 3E**; *middle, right*), but also did so in the setting of

199 COVID-19 (**Figure 3E**; *left*). By contrast, the CoV-lung tissue-derived signature that is known to distinguish

200 CoV from both healthy and influenza-affected lungs(*54*), did not prognosticate outcome in either COVID-19

201 (**Figure 3F**; *left*) or IPF subjects (**Figure 3F**; *middle vs. right*). It indicates that the PBMC-derived signatures in

202 CoV and IPF retain their prognostic relevance in both conditions, with at least one key notable difference; sViP,

203 but not the IPF signature revealed the well-established gender specific differences in the progression of IPF.

8

Taken together, these results indicate that PBMCs in both IPF and COVID-19 have similar gene induction patterns, and that these circulating immune cells may be determinants of outcome in both conditions. Our findings are in keeping with the fact that a subset of pro-fibrogenic macrophages have been detected in end-stage severe COVID-19 that progressed to fibrosis requiring lung transplantation(*15*). Others have reported that these profibrogenic macrophages express markers associated to fibrotic processes (like *TREM2* or *SPP1*) in patients with severe COVID-19(*55*); *TREM2* is suggested to prevent macrophage apoptosis and promote chronic inflammatory disease after lung viral infection(*56*). We conclude that the prognostic value of IPF- and sViP signatures induced in the PBMCs may reflect the profibrogenic immune response that is shared in both conditions.

Alveolar type II (AT2) telomere dysfunction and senescence are shared features in both COVID-19 and IPF.

Besides the contributions from PBMCs, a contemporary paradigm in IPF is that chronic injury to distal lung tissue leads to either loss or altered function of epithelial stem cells (i.e., AT2 cells), that promote dysregulated repair and pathogenic activation of fibroblasts.(*57-59*) We asked if the AT2 dysfunction states previously reported in IPF also occur in COVID-19. To this end, we analyzed a single cell dataset of bronchoalveolar lavage from COVID-19 patients (GSE145926) for the induction of ViP/sViP, CoV-lung and IPF signatures and other signatures that are indicative of three important AT2 cytopathies: (i) Damage associated transient progenitor (DATP(*60*)), a distinct *KRT8+*/*CLDN4+* AT2 lineage that has been independently shown, nearly simultaneously by 3 independent groups(*60-62*) to be associated with activated myofibroblasts during lung fibrosis in the setting of IPF(*28*). (ii) AT2-senescence signature, which was derived from another IPF-focused study(*63*) that used human and mouse models to pinpoint Doxycycline-induced program of p53-dependent cellular senescence, AT2 cell depletion, and spontaneous, progressive pulmonary fibrosis; and (iii) Aging associated telomerase dysfunction (TERC_UP) signature, which was derived from aging telomerase knockout (*Terc$^{-/-}$*) mice. We found that the entire panel of signatures analyzed were upregulated, most consistently, only in the epithelial cells (**Figure 4A**), whereas only some were induced and not others in the non-epithelial compartments.

We next confirmed that a composite score of *IL15/IL15RA*, AT2-senescence and telomerase dysfunction (TERC_UP) signatures were induced indistinguishably in both CoV and IPF samples compared to healthy controls (**Figure 4B**). A correlation matrix (**Figure 4C**) on the entire cohort showed that while both IL15 and IL15RA correlate with the ViP signature (as expected), IL15RA, but not IL15 correlate with TERC_UP and AT2-senescence signatures. Both ViP and sViP signatures correlate with AT2 senescence. Furthermore, when we tested AT2-senescence and telomere dysfunction in other CoV datasets, we found that these features were conserved in most CoV samples across diverse cohorts (**Figure 4D**). These findings are in keeping with prior IPF modeling efforts using bleomycin-challenged transgenic mice that lack the *Telomeric Repeat Binding Factor 2* in their AT2 cells (*Trf2$^{Fl/Fl}$; Sftpc-CreER*) have shown that senescent AT2 cells with telomere dysfunction

9

237 upregulate immune-signaling pathways that is IL15-centric(*64*), which is the central cytokine pathway in ViP
238 signature and COVID-19(*18*).

239 Taken together, these findings support the existence of telomere dysfunction and DNA damage in both acute
240 COVID-19 and IPF. Mutations in the two main components of the telomerase holoenzyme complex that is
241 responsible for creating new telomeric DNA, *Telomerase reverse transcriptase (TERT)* or *telomerase RNA*
242 *(TERC),* are major monogenic causes of pulmonary fibrosis(*65*). Patients with IPF have shortened telomeres; short
243 telomeres(*65, 66*) and TERT/TERC-disease associated variants were associated with specific clinical and
244 biological features and reduced transplant-free survival. Similarly, short telomeres increase the risk of severe
245 COVID-19(*67-69*), pulmonary fibrosis and poorer outcomes(*69, 70*). In the case of IL15, the presence of this
246 cytokine in the circulation has been proposed to serve as a biomarker for prognostication in both IPF(*26, 71, 72*)
247 and COVID-19(*18*).

248

249 **Hamsters, but not mice recapitulate the host immune response and AT2 cytopathic features of COVID-19**
250 Evidence suggests that there is a wide gap between COVID-19 in humans and animal models(*73*); interspecies-
251 related differences, such as host specificity and divergent immune responses can lead to misinterpretation. To
252 objectively assess which model improves the translational potential of any discovery from this study, we curated
253 all publicly available transcriptomic datasets from pre-clinical rodent models of COVID-19 and analyzed them for
254 the induction of the ViP/sViP, IL15/IL15RA composite score, CoV-lung, IPF signatures and signatures of AT2
255 senescence and transition-state arrest (DATP) (**Supplementary Figure S1A**). We saw that the golden Syrian
256 hamsters, but not the humanized transgenic mouse models (**Supplementary Figure S1A**; *bottom*) induce most, if
257 not all the key signatures upon SARS-CoV-2 challenge (**Supplementary Figure S1A**; *top*). Most importantly, all
258 signatures (**Supplementary Figure S1A**; *top*), including that of AT2-damage associated transient progenitor
259 population (**Supplementary Figure S1B**; DATP) were effectively reversed with two therapeutic approaches. The
260 first approach was the use of N-hydroxycytidine, the parent of the prodrug MK-4482 (Molnupiravir, EIDD-2801)
261 which has not only proven as a potent and selective oral antiviral nucleoside analogue in mice, guinea pigs, ferrets
262 and human airway epithelium organoids(*74-79*), but also showed promise in Phase IIa trials in the treatment of
263 COVID-19 patients (NCT04405570(*80*)). both biologic and directly acting anti-viral therapies. The second
264 approach was the use of SARS-CoV-2-neutralizing antibodies whose design was inspired by monoclonal
265 antibodies (mAbs) isolated from from convalescent donors(*28*). A specific isotype of this antibody, which binds
266 to the receptor-binding domain (RBD-A) of SARS-CoV-2 spike protein in a fashion that precludes binding to
267 host ACE2, was demonstrated as effective in preventing infection and weight loss symptoms, in cell-based and
268 *in vivo* hamster models of infection, respectively.

10

269   These findings show that hamster lungs best recapitulate the host immune response, the nature of the

270   cytokine storm (IL15-centric), and the AT2 cytopathies that are shared between COVID-19 and IPF. It is also in

271   keeping with emerging data that Syrian hamsters best emulate COVID-19(*81*); they also best emulate progressive

272   fibrosis in IPF(*82*).

273

274   **Validation of the predicted AT2 cytopathic features of COVID-19 in hamster and human lungs**

275   We next sought to determine if the SARS-CoV-2 virus can induce the AT2 cytopathic changes, and whether

276   effective therapeutics can abrogate those changes. We analyzed by RNA seq and trichrome stain the lungs from

277   SARS-CoV-2-challenged golden Syrian hamsters who were pre-treated either with EIDD-2801 or anti-Spike

278   (CoV-2) mAb or untreated controls (see study protocol in **Figure 5A**). Key genes associated with AT2 senescence

279   (*Tp53* and *Cdkn2a*), ER stress (*Hspa5/Grp78*), DATP (*Krt8* and *Cldn4*) and fibrosis (*Col1a, Col3a* and *Serpine1*)

280   were all induced in the infected lungs (compared to uninfected controls) but not in those that were treated (**Figure**

281   **5B**). Trichrome staining confirmed that compared to uninfected controls, collagen deposition was induced in the

282   infected lungs, but not in those that were treated (**Figure 5C-D**). Immunohistology studies confirmed that Cdkn2a,

283   Krt8, Cldn4 and Tp53 proteins were expressed in the injured alveoli, but not in the treated lungs (**Figure 5E-F**).

284   We next confirmed extensive deposition of eosin-positive collagenous materials in lung tissues obtained

285   at rapid autopsies on deceased subjects with COVID-19 compared to normal lung tissues (**Figure 6A**; *top*). KRT8

286   and TP53 were also induced in the COVID-19 lungs (**Figure 6A**; *middle* and *bottom*). Finally, plasma ELISA

287   studies in a cohort of symptomatic COVID-19 patients who presented to the UC San Diego Medical Center with

288   varying disease severity, ranging from mild to fatal (see **Supplemental Information 3-4**), we detected several

289   cellular senescence-associated cytokines during the acute compared to the convalescent visit (**Figure 6B;**

290   **Supplementary Figure S2**). It is noteworthy that VEGF, TNFα, IL6 and IL1β, all cytokines that have been

291   implicated in the fibrotic process post-COVID-19 (reviewed in(*83*)) were significantly elevated only in the most

292   critical form of the disease. Findings are also consistent with the fact that VEGF-targeted therapeutics

293   (Bevacizumab) in COVD-19 patients improved lung oxygenation up to day 28 during follow-up(*84*).

294   We next asked if the key aspects of the host immune response and AT2 cytopathic changes are induced

295   in the various human pre-clinical *in vitro* models of COVID-19. We assessed our published models of COVID-

296   19-in-a-dish(*27*) (**Figure 6C, 6D-***top 4 rows*) for AT2-senescence and for their ability to mimic the unique milieu

297   in COVID-19 lungs(*13*). We also analyzed CoV2-challenged primary(p)AT2 and A549 cells (**Figure 6D-***bottom*

298   *3 rows*). We found that submerged monolayers of adult lung organoids (ALO mono), which were previously

299   found to outperform fetal lung organoids(*85*) and other models in recapitulating the gene expression signatures

300   observed in human COVID-19 lungs(*27*), also outperformed here. While most models induced some signatures,

301   the submerged ALO model induced them all (**Figure 6D**).

11

302

Protein-protein network analysis predicts AT2 ER stress as an early initiating event in COVID-19

To identify some of the earliest AT2 cell processes that might be triggered as a consequence of the host immune response in acute COVID-19, which may precede the development of transient state arrest and senescence, we resorted to a PPI network analysis. To this end, we used the genes in the sViP(*18*), AT2 senescence(*63*) and DATP(*60*) and DATP(*60*) signatures as 'seed' nodes to fetch additional connecting nodes from human protein-protein interactions in STRING database(*19*) (**Figure 7A;** see **Supplemental Information 5)**. Once built, we assessed the network for degrees of connectivity (**Figure 7B**; *left*) and representation of cellular processes in the most connected nodes by using two approaches: CluGo analysis(*86*) (**Figure 7B**; *right*) and Reactome pathway analysis(*87*) (**Figure 7C**). While CluGO analysis showed an overrepresentation of proteins associated unfolded protein response, ER stress, regulation of telomerase, regulation of cell aging and regulation of G1/S phase transition (**Figure 7B**; *right*), reactome analysis showed enrichment of pathways associated with senescence (**Figure 7C**; *red*), platelet activation and degranulation (**Figure 7C**; *blue*), and Tp53-dependent DNA damage response (**Figure 7B**; *green*). That platelet activation (indicative of a prothrombotic state) is captured within the PPI network is in keeping with what appears to be a hallmark of PCLD(*13*). Numerous independent observations in diverse cohorts of patients have now confirmed that platelet dysfunction amplifies endotheliopathy in COVID-19(*88*) and that a vicious cycle of thromboinflammation, endothelial dysfunction and immunothrombosis are key pathogenic mechanisms in COVID-19(*89, 90*). It is noteworthy, that we found that levels of IL6 and platelets showed significant negative correlation (**Supplementary Figure 2**). Because IL6 has been specifically implicated in platelet hyper-reactivity and thrombosis(*91*), as well as in thrombus resolution(*92*), the strong negative correlation may suggest the presence of thromboinflammation; the latter is one of the first and most distinctive pathological feature of CoV-lung to be reported since the beginning of this pandemic(*13*). As for AT2-centric processes, the PPI network analyses suggest that ER stress, which has been shown to serve as a causal role for profibrogenic epithelial states (SASP) that is shared between aging-associated pulmonary fibrosis and IPF(*93*), may also be a common underlying factor in fibrotic PCLD.

ER stress in AT2 cells is observed in COVID-19 and is sufficient to recapitulate the host immune response in COVID-19 and IPF. We next sought to investigate if alveolar ER stress is a feature in CoV-lung. To this end, we analyzed infected human (**Figure 8A**) and hamster (**Figure 8B**) lungs for the ER chaperone *Grp78*, a key regulator of ER homeostasis expression by IHC. We found that compared to normal uninfected lungs, infected lungs showed a significant increase in Grp78 staining and that the intensity of such staining was highest in the epithelial cells lining the alveolar spaces in both species (**Figure 8A-B**).

12

334   To determine if ER stress in AT2 cells may contribute to the epithelial dysfunction and fibrosis that is

335   observed as a sequel of COVID-19, we leveraged a previously characterized *tg*-mouse model of AT2-specific

336   conditional [tamoxifen (Tmx)-inducible] deletion of Grp78 (*Sftpc$^{+/creERT2}$;Grp78$^{f/f}$*)(*93*). These mice are known to

337   lose weight and die (more pronounced in male and old mice) due to lung inflammation, and spatially

338   heterogeneous fibrosis characterized by fibroblastic foci and hyperplastic AT2 cells, all features of IPF(*93*). We

339   found that compared to their littermate controls, lungs from these mice (unlike other transgenic mouse models of

340   COVID-19; see **Figure S1A**) induced the ViP/sViP, CoV2-lung and IPF signatures, as well as the AT2 cytopathic

341   changes such as DATP and AT2 senescence (**Figure 8C**; *bottom row*). In fact, the pattern of gene expression was

342   similar to SARS-CoV-2-challenged hamster lungs (**Figure 8C**; *top row*). These findings indicate that ER stress

343   is sufficient to faithfully recapitulate the host immune response and alveolar cytopathic changes that are observed

344   in PCLD and IPF.

13

DISCUSSION

Using an integrated computational and experimental approach (see study design, **Figure 1**), the major discovery we report here is that PCLD resembles IPF, the most common form of ILD, at a fundamental level—showing similar gene expression patterns (ViP and IPF signatures), dysfunctional cell states (AT2 and monocytes), and dysfunctional AT2 processes (ER stress, telomere instability and senescence)]. Our findings support the following model (summarized as schematic in **Figure 8D**): Upon injury (viral infection/inflammatory cytokines), diffuse alveolar damage is associated with extensive loss of AT1 cells, which are duly replaced by AT2 cells serve as progenitors that are capable of self-renewal and differentiation into AT1 cells(*94-96*). But such physiologic regeneration and healing process is impaired when AT2 progenitors are also injured and begin to elicit ER stress responses, which induces telomerase activity(*97, 98*). Because severe COVID-19 has been linked to short telomere lengths(*98*) [not as a cause, i.e, SARS-CoV-2 infection does not shorten telomeres, but as a predisposition(*67*)], it is possible that patients who have short and/or dysfunctional telomeres fail to adequately respond to ER stress, and instead, become senescent (through p53 activation), accumulate DNA damage and enter a dysfunctional *KRT8+* transitional stem cell state(*99*). The latter is a phenomenon that has been independently reported by three groups, under different names: PATS, pre-alveolar type-1 transitional cell state(*62*); ADI, alveolar differentiation intermediates(*61*); DATP, damage-associated transient progenitors(*60*). All three groups reported their presence in fibrotic regions of IPF lungs; an increase of AT2 cells in the transitional state was invariably accompanied by an increase in myofibroblasts. Our PPI network analyses suggested that AT2 senescence and progenitor arrested state in the setting of a ViP/sViP-immune response (cytokine storm contributed by PBMCs) may support a SASP phenotype, which is a pathological feature of aging and IPF lung(*100, 101*). It is possible that fibroblasts/myofibroblasts also contribute to this vicious cycle of inflammation and AT2 dysfunction. These findings show that these two distinct clinical syndromes, IPF, which predates the current pandemic by many decades, and the novel COVID-19, share a similar profile of host immune response, both in the lung microenvironment (in AT2 cells, to be specific) as well as in the circulating blood/PBMCs. We not only formally define the nature of that host response and provide computational tools to measure the extent of such response, but also chart the cascade of cytopathic changes in the alveoli that are critical for the profibrogenic state. It is noteworthy that the same host immune response is seen also in MIS-C, a new disease that co-emerged with COVID-19, and in KD (which shares overlapping features with MIS-C in clinical presentation(*102*)).

There are three major impacts and/implications of the findings reported in this study. First, our finding that COVID-19 and IPF share fundamental host immune response and alveolar cytopathic features is in keeping with the fact that both diseases share epidemiologic similarities—both primarily occurs in older adults and is

14

378 characterized by progressive worsening of dyspnea and lung function(*103, 104*). Prevalence of both increases
379 with age, with most patients aged >50 years at diagnosis and a higher proportion of males than females. Risk
380 factors reported to be associated with IPF include cigarette smoking, environmental exposures, microbial
381 pathogens, and genetic risk factors(*103*). Findings also suggest that IPF may be a multi-trigger infection-driven
382 chronic inflammatory condition, as has been suggested in the past decade(*32, 105-107*). Finally, our findings are
383 in keeping with epidemiologic evidence for an increased risk of death in patients with existing ILDs from COVID-
384 19 compared with adults without ILD, even after controlling for age, sex, and comorbidities(*108-110*). At day 30
385 of COVID-19, 35% of patients with fibrotic idiopathic ILD had died compared with 19% of those with other
386 ILDs(*111*). Whether the shared molecular or pathophysiologic features we report here synergize to increase
387 fatality remains unknown.

388

389 Second, most severe COVID-19 patients develop pneumonia and hyperinflammation likely related to a
390 macrophage activation syndrome(*112*) commonly named "cytokine storm". Linked to the storm, lung fibrosis
391 emerges as a secondary event related to the progression of the pathology(*1*). Although this storm has been
392 implicated(*113*), and it is comprised of the generic mix of all the typical cytokines(*10*), which exact component
393 is the pro-fibrogenic driver remains unclear. By showing that a IL15/IL15RA-centric cytokine storm is the key
394 shared phenomenon, this study provides a link between the post-viral hyperinflammation phase and the sequelae
395 of fibrosis. The presence of IL15 in the circulation has been proposed to serve as a biomarker for prognostication
396 in IPF and other ILDs(*114-116*). As for what may be contributing to such a cytokine response, myeloid cells are
397 likely to be major culprits, but AT2 cells cannot be ruled out. Prior studies using bleomycin-challenged transgenic
398 mice that lacks the *Telomeric Repeat Binding Factor 2* in the AT2 cells (*Trf2^{Fl/Fl};Sftpc-CreER*) have shown that
399 AT2 cells with telomere dysfunction upregulate an IL15-centric pathways(*117*). It is possible that injury, DNA
400 damage and IL15 signalling are one component in the profibrogenic cascade and suggest that IL15-targeted
401 therapeutics may be beneficial in the most severe cases of COVID-19 to prevent fibrotic sequelae. Finally, our
402 findings support the rationalization of clinical trials in COVID-19 using FDA-approved drugs for IPF, nintedanib
403 (Ofev®) and pirfenidone (Esbriet®) (NCT04856111 and NCT04653831), and anecdotal case reports and case
404 series have already chronicled the benefits of their use in COVID-19 lung disease(*118-120*).

405

406 Third, our finding that shared alveolar cytopathic changes (e.g., DNA damage, progenitor state arrest,
407 SASP, and ER stress) fuel fibrogenic programs in both COVID-19 and IPF are insightful because AT2 cells are
408 known to contain an elegant quality control feedback loop to respond to intrinsic or extrinsic stress; a failure of
409 such quality control results in diverse cellular phenotypes (reviewed in (*121*)): ER stress (*122*), defective
410 autophagy, mitochondrial dysfunction, apoptosis, inflammatory cell recruitment, profibrotic signaling, and

15

411 altered progenitor function(*99, 123, 124*) that ultimately converge to drive downstream fibrotic remodeling in the

412 lung. Prior work(*63*), which led to the discovery of the AT2-senescence signature (which we used here), had

413 demonstrated that senescence of AT2 cells (not loss of AT2) is sufficient to drive progressive pulmonary fibrosis.

414 Others agree, and this is now an established pathophysiologic trigger in lung fibrosis(*57, 125-127*). Our findings

415 are in keeping with published work(*128*) that suggest that AT2 senescence may be a targetable disease driver of

416 lung injury in COVID-19. Although AT2 senescence is a shared phenomenon, our PPI network analyses --which

417 integrated AT2 processes with the immune responses (ViP signatures) -- provided valuable clues into how platelet

418 activation and thromboinflammation may be uniquely seen in the setting of COVID-19. These findings are in

419 keeping with recent publications(*129-131*) which suggest that SARS-CoV-2 could induce epithelial senescence;

420 senescencet AT2 cells would then assume a SASP phenotype, which in turn led to neutrophil and platelet

421 activation, and activation of the clotting cascade(*129*).

422

423   As for the limitations of this study, it remains unclear how to model progressive lung fibrosis *in vitro* and

424 hence, no attempt was made to do so. Our results suggest that AT2 cells alone may be insufficient for such

425 modeling because a specific host immune response that is carried in the PBMCs is a clear determinant as to who

426 progresses and who does not. Although AT2-specific modulation of ER-stress pathway and SARS-CoV-

427 challenged (treated vs untreated) hamsters were used to go beyond association and establish causation, our study

428 did not attempt to inhibit/reverse fibrosis in COVID-19 by acting on any profibrogenic cellular pathway/process.

429 Development of novel chemical matter/biologicals and validation of the therapeutic efficacy of such agents will

430 take time, but if successful, our findings show that their benefits will likely transcend beyond PCLD into IPF and

431 other fibrotic lung conditions such as IPF.

432

433   In conclusion, this transdisciplinary work provides insights into the pathogenesis of PCLD, formally

434 defines the fibrogenic processes in the lung, and rigorously validates high value gene signatures or even targets

435 (i.e., IL15, senescence pathways, etc.) to track and manipulate the same. The insights, tools, computationally

436 vetted disease models and biomarkers (prognostic gene signatures) identified here are likely to spur the

437 development of therapies for patients with fibrotic interstitial lung disease of diverse causes, including IPF, all of

438 whom have limited or no good treatment options.

DETAILED METHODS:

Computational Methods

ViP and severe (s)ViP Signatures

ViP (Viral Pandemic) signature(*18*) is derived from a list of 166 genes using Boolean Analysis of large viral infection datasets (training datasets: GSE47963, n = 438; GSE113211, n = 118). This 166-gene signature was conserved in all viral pandemics, including COVID-19, inspiring the nomenclatures ViP signature. A subset of 20-genes classified disease severity called severe-ViP signature using an additional cohort (GSE101702, n = 159)(*18*). No interstitial lung disease (ILD) datasets, or for that matter any other lung dataset was used during the process of discovery and validation of the ViP/sViP signatures. To compute the ViP signature, first the genes present in this list were normalized according to a modified Z-score approach centered around StepMiner threshold (formula = (expr -SThr)/3*stddev). The normalized expression values for every probeset for 166 genes were added together to create the final ViP signature. The severe ViP signature is computed similarly using 20 genes. The samples were ordered finally based on both the ViP and severe-ViP signature. A color-coded bar plot is combined with a violin plot to visualize the gene signature-based classification.

Protein-protein interaction network (PPIN) construction

PPIN has been constructed using the gene signatures as a set of seed nodes. The nodes between the seed nodes were fetched using the connecting shortest paths and their components from the human protein interaction dataset of the STRING database(*19*). A high cutoff of STRING interaction score has been chosen based on the proteins present in the signature list to neglect the false positive interactions.

Data analysis

Several publicly available microarrays and RNASeq databases were downloaded from the National Center for Biotechnology Information (NCBI) Gene Expression Omnibus (GEO) website.(*20-22*) Gene expression summarization was performed by normalizing Affymetrix platforms by RMA (Robust Multichip Average)[81, 82] and RNASeq platforms by computing TPM (Transcripts Per Millions) (*23, 24*) values whenever normalized data were not available in GEO. We used log2(TPM +1) as the final gene expression value for analyses. GEO accession numbers are reported in figures, and text. A catalog of all datasets analyzed in this work can be found in **Supplementary Table 1.** StepMiner analysis and methodologies for composite gene signatures, outcome analyses, and violin plots are detailed in Supplementary Online Methods.

18

Statistical Analyses

Gene signature is used to classify sample categories and the performance of the multi- class classification is measured by ROC-AUC (Receiver Operating Characteristics Area Under the Curve) values. A color-coded bar plot is combined with a density plot to visualize the gene signature-based classification.All statistical tests were performed using R version 3.2.3 (2015-12-10). Standard t-tests were performed using python scipy.stats.ttest_ind package (version 0.19.0) with Welch's Two Sample t-test (unpaired, unequalvariance (equal_var=False), and unequal sample size) parameters. Multiple hypothesis correction was performed by adjusting *p* values with statsmodels.stats.multitest.multipletests (fdr_bh: Benjamini/Hochberg principles). The results were independently validated with R statistical software (R version 3.6.1; 2019-07-05). Pathway analysis of gene lists were carried out via the Reactome database and CluGo algorithm. Reactome identifiessignaling and metabolic molecules and organizes their relations into biological pathways and processes. Kaplan- Meier analysis is performed using lifelines python package version 0.14.6. Violin, Swarm and Bubble plots are created using python seaborn package version 0.10.1. The source code for Boolean analysis framework is available at https://github.com/sahoo00/BoNE(*25*) and https://github.com/sahoo00/Hegemon(*26*).

Experimental Methods

Rapid autopsy procedure for tissue collection

The lung specimens from the COVID-19 positive human subjects were collected as described in detail previously (*18, 27*) using autopsy (study was IRB Exempt). All donations to this trial were obtained after telephone consent followed by written email confirmation with next of kin/power of attorney per California state law (no in-person visitation could be allowed into our COVID-19 ICU during the pandemic). The team member followed the CDC guidelines for COVID-19 and the autopsy procedures[8, 9]. Lung specimens were collected in 10% Zinc-formalin and stored for 72 h before processing for histology. Autopsy #2 was a standard autopsy performed by anatomical pathology in the BSL3 autopsy suite. The patient expired and his family consented for autopsy. After 48 hours, lungs were removed and immersion fixed whole in 10% formalin for 48 hours and then processed further. Lungs were only partially fixed at this time (about 50% fixed in thicker segments) and were sectioned further into small 2-4cm chunks and immersed in 10% formalin for further investigation. Autopsies #4 and #5 were collected from rapid postmortem lung biopsies. The procedure was performed in the Jacobs Medical Center ICU (all the ICU rooms have a pressure-negative environment, with air exhausted through HEPA filters [Biosafety Level 3 (BSL3)] for isolation of SARS-CoV-2 virus). Biopsies were performed 2-4 hours after patient expiration. Ventilator was shut off to reduce aerosolization of viral particles at least 1 hour after loss of pulse and before the sample collection. Every team member had personal protective equipment in accordance with the University policies for procedures on patients with COVID-19 (N95 mask + surgical mask, hairnet, full face shield, surgical gowns,

19

506 double surgical gloves, booties). Lung biopsies were obtained after L-thoracotomy in the 5th intercostal space by

507 our cardiothoracic surgery team. Samples were taken from the left upper lobe (LUL) and left lower lobe (LLL)

508 and then sectioned further.

509

510 **Collection of blood from COVID-19 patients**

511 Blood from COVID-19 donors was either obtained at a UC San Diego Health clinic under the approved IRB

512 protocols of the University of California, San Diego (UCSD; 200236X) or recruited at the La Jolla Institute under

513 IRB approved (LJI; VD-214). COVID-19 donors were California residents, who were either referred to the study

514 by a health care provider or self-referred. Blood was collected in acid citrate dextrose (ACD) tubes (UCSD) or in

515 EDTA tubes (LJI) and stored at room temperature prior to processing for plasma collection. Seropositivity against

516 SARS-CoV-2 was confirmed by ELISA. At the time of enrollment, all COVID-19 donors provided written

517 informed consent to participate in the present and future studies. Patient characteristic is listed in Supplemental

518 Information 3.

519

520 **Human serum cytokines measurement**

521 Human serum cytokines measurement was performed using the V-PLEX Custom Human Biomarkers from MSD

522 platform [MESO QuickPlex SQ 120]. Human serum samples fractionated from peripheral blood of KD and MIS-

523 C patients (all samples collected prior to the initiation of treatments) were analyzed using customized standard

524 multiplex plates as per the manufacturer's instructions using recommended software [MSD® DISCOVERY

525 WORKBENCH 4.0].

526

527 **COVID-19 lung models in-a-dish**

528 Monolayers derived from adult lung organoids (ALOs), primary airway cells, or hiPSC-derived alveolar type II

529 (AT2) pneumocytes were infected with SARS-CoV-2 to create in vitro lung models of COVID-19 as described

530 previously(27). The raw data and processed data were deposited in Gene Expression Omnibus under accession

531 no. GSE157057. These datasets were analyzed here using various gene signatures.

532

533 **COVID-19 modeling in Syrian hamsters**

534 Lung samples from 8-week-old Syrian hamsters were generated from experiments conducted exactly as in a

535 previously published study(28). Animal studies were approved and performed in accordance with Scripps

536 Research IACUC Protocol #20-0003(28). We chose three different groups of samples: uninfected control, SARS-

537 CoV-2 challenge after Den3 (antibody to dengue virus), and SARS-CoV-2 challenge after Anti-CoV2 (CC12.2;

538 a potent SARS-CoV-2 neutralizing antibodies)(28).

20

Immunohistochemistry

COVID-19 samples were inactivated by storing in 10% formalin for 2 days and then transferred to zinc-formalin solution for another 3 days. The deactivated tissues were transferred to 70% ethanol and cassettes were prepared for tissue sectioning. The slides containing hamster and human lung tissue sections were deparaffinized in xylene (Sigma-Aldrich Inc., MO, USA; catalog# 534056) and rehydrated in graded alcohols to water. For GRP78/ BIP, p53, Cytokeratin 8, and Claudin 4-specific polyclonal antigen retrieval, slides were immersed in Tris-EDTA buffer (pH 9.0) and boiled for 10 minutes at 100°C. Slides were immersed in Sodium Citrate Buffer (pH 6.0) and boiled for 10 minutes at 100°C, for p14 ARF (E3X6D) and p21 Waf1/ Cip1(12D1) antigen retrieval. Endogenous peroxidase activity was blocked by incubation with 3% H2O2 for 5-10 minutes. To block non-specific protein binding either 2.5% goat or 2.5% horse serum (Vector Laboratories, Burlingame, USA; catalog# MP-7401 or S-1012) was added. Tissues were then incubated with the following antibodies: rabbit GRP78/ BIP polyclonal antibody (1:500 dilution; proteintech®, Rosemont, IL, USA; catalog# 11587-1-AP), rabbit p53 polyclonal antibody (1:200 dilution ; proteintech®, Rosemont, IL, USA; catalog# 21891-1-AP), rabbit Cytokeratin 8 polyclonal antibody (1:2000 dilution; proteintech®, Rosemont, IL, USA; catalog# 10384-1-AP), and rabbit Claudin 4-specific polyclonal antibody (1:200 dilution, proteintech®, Rosemont, IL, USA; catalog# 16195-1-AP) for 1.5 hours at room temperature in a humidified chamber then rinsed with TBS twice for 3 minutes each. Antibodies were prepared in antibody diluent (MP Biomedicals, LLC., Catalog # 980641) for rabbit p14 ARF (E3X6D) monoclonal antibody (1:250 dilution; Cell Signaling Technology, Danvers, MA, USA; catalog# 74560S) and rabbit p21 Waf1/ Cip1 (12D1) monoclonal antibody (1:50 dilution; Cell Signaling Technology, Danvers, MA, USA; catalog# 2947S) that were then incubated in a humidified chamber overnight at 4°C, then rinsed with TBST twice for 5 minutes each. Sections were incubated with horse anti-rabbit (Vector Laboratories, Burlingame, USA; catalog# MP-7401) secondary antibodies for 30 minutes at room temperature in a humidified chamber and then washed with TBS or TBST 3x, 5 minutes each. Then incubated with DAB (BioGenex, Fremont, CA, USA; catalog # HK542-XAKE) for 5-10 minutes and counterstained with hematoxylin (BioGenex, Fremont, CA, USA; catalog# HK100-9K), dehydrated in graded alcohols, cleared in xylene, and cover slipped. All sides were visualized by Leica DM1000 LED (Leica Microsystems, Germany).

IHC Quantification

IHC images were randomly sampled at different 300x300 pixel regions of interest (ROI). The ROIs were analyzed using IHC Profiler(*29*). IHC Profiler uses a spectral deconvolution method of DAB/hematoxylin color spectra by using optimized optical density vectors of the color deconvolution plugin for proper separation of the DAB color spectra. The histogram of the DAB intensity was divided into 4 zones: high positive (0 to 60), positive (61 to 120), low positive (121 to 180) and negative (181 to 235). High positive, positive, and low positive percentages

21

572 were combined to compute the final percentage positive for each region of interest (ROI). The range of values for

573 the percent positive is compared among different experimental groups.

574

575 **Data availability**

576 Source data are provided with this paper. All data is available in the main text or the supplementary materials.

577 Publicly available datasets used are enlisted in **Supplemental Information 1**.

578

579 **Code availability**

580 The software codes are publicly available at the following links:

AUTHOR CONTRIBUTIONS

DS, SS and PG conceptualized the project; SS and DS carried out all computational modeling and analyses and DS contributed all software used in this work; GDK carried out the human serum cytokine analysis; VC and SS carried out the immunohistochemical studies and their quantitative analysis under the supervision of PG; AGF carried out the immunofluorescence studies on COVID-19 lung tissues; SS carried out the PPI network creation and analysis; JD provided access to human subjects for cytokine analyses. CT, CRE and SD were responsible for the COVID-19 lung models. SS, DS and PG prepared figures for data visualization; SS and PG wrote the original draft of the manuscript; DS, SD, GK edited and revised the manuscript. All co-authors approved the final version of the manuscript. DS, SD, and PG supervised various parts of the project and secured funding; DS and PG administered the project.

DECLARATION OF INTERESTS

The authors declare no competing interests.

899 **Figure 1. Study design: Artificial Intelligence-guided navigation of COVID-19 lung disease.**

900 (*From top to bottom*) <u>*Step 0*</u>: Over 45,000 human, mouse, and rat gene expression databases were mined using
901 machine learning tools called Boolean Equivalent Correlated Clusters (BECC(*71*)) to identify invariant host
902 response to viral pandemics (ViP). In the absence of a sufficiently large number of COVID-19 datasets at the
903 onset of the COVID-19 pandemic, these ViP signatures were trained on only two datasets from the pandemics of
904 the past (Influenza and avian flu; GSE47963, n = 438; GSE113211, n = 118) and used without further training to
905 prospectively analyze the samples from the current pandemic (i.e., COVID-19; n = 727 samples from diverse
906 datasets). A subset of 20-genes classified disease severity called severe-ViP (sViP) signature. The ViP signatures
907 appeared to capture the 'invariant' host response, i.e., the shared fundamental nature of the host immune response
908 induced by all viral pandemics, including COVID-19. <u>*Step1*</u>: The set of ViP/sViP signatures and a CoV-lung
909 specific(*13*) gene signature was analyzed on diverse transcriptomic datasets representing a plethora of lung
910 diseases; these efforts identified COVID-19 lung disease to be the closest to Idiopathic pulmonary fibrosis (IPF);
911 both conditions induced a common array of gene signatures. <u>*Step 2*</u>: Clinically useful whole-blood and PBMC-
912 derived prognostic signatures previously validated in IPF(*18*) showed crossover efficacy in COVID-19, and *vice*
913 *versa*. <u>*Step 3*</u>: Gene signatures of alveolar type II (AT2) cytopathic changes that are known to fuel IPF were
914 analyzed in COVID-19 lung, and predicted shared features were validated in human and hamster lungs and lung-
915 organoid derived models. <u>*Step 4:*</u> Protein- protein interaction (PPI) network built using sViP and AT2 cytopathy-
916 related signatures was analyzed to pinpoint ER stress as a major shared feature in COVID-19 lung disease and
917 IPF, which was subsequently validated in human and hamster lungs.

923 **A.** Bubble plots show the ROC-AUC values (radii of circles are based on the ROC-AUC) show the direction of
924 gene regulation (Up, red; Down, blue) for sample classification based on the induction of ViP/sViP(*18*) and a
925 previously published human CoV-lung signatures(*13*) in diverse datasets representing diverse lung pathologies,
926 including COVID-19. Tuberculosis, TB; community acquired pneumonia, CAPn; pulmonary hypertension, PHT;
927 chronic thromboembolic pulmonary hypertension, CTEPH; idiopathic pulmonary fibrosis, IPF; CoV, COVID-
928 19. **B.** Bubble plots in B show the ROC-AUC values for sample classification based on the induction of ViP
929 signatures and several previously published IPF signatures in COVID-19 infected lungs and IPF samples. **C-F.**
930 Violin plots display the extent of induction of ViP (E) or sViP (F), IPF (G) or CoV lung (H) signatures in a pooled
931 cohort of healthy, CoV and IPF lung samples (GSE149878; GSE122960). Welch's two sample unpaired t-test
932 is performed on the composite gene signature score (z-score of normalized tpm count) to compute the *p* values.
933 In multi-group setting each group is compared to the first control group and only significant *p* values are
934 displayed. **G.** Schematic summarizes the predicted molecular match between COVID-19 lung and IPF based on
935 the crossover validation of gene signatures showcased in B-F. **H.** Bar plots show the ability of sViP signature to
936 classify COVID-19 patients based on hospitalization status and violin plots show the degree of induction of the
937 signature within each group (H, hospitalized; NH, non-hospitalized). Welch's two sample unpaired t-test is
938 performed on the composite gene signature score (z-score of normalized tpm count) to compute the *p values*. **I.**
939 Bubble plots of ROC-AUC values (radii of circles are based on the ROC-AUC) show the direction of gene
940 regulation (Up, red; Down, blue) for the classification of healthy vs diseased samples based on the ViP/sViP and
941 the CoV-lung signatures on three well known fatigue conditions (blood/PBMC samples from GWI, gulf war
942 illness; CFS, chronic fatigue syndrome).

Figure 3. PBMC-derived prognostic signatures in IPF also prognosticate outcome in COVID-19.

34

946   **A.** Schematic showing the current understanding of the complex interplay between senescent alveolar

947   pneumocyte (AT2), reactive alveolar macrophage, and fibroblasts in the pathogenesis of pulmonary fibrosis. **B-**

948   **C**. FFPE tissues from normal lungs and from the lungs of subjects deceased due to COVID-19 were analyzed

949   for the SARS-CoV2 viral nucleocapsid protein either by IHC (B) or by confocal immunofluorescence (C). Lungs

950   were co-stained also with CD14 (a marker for activated alveolar macrophage(*53*)) in C. **D.** Kaplan-Meier plots

951   show the stratification of patients based on the degree of induction of the sViP signature in PBMCs (low and high

952   group; determined using the StepMiner algorithm(*64*) and its relationship to either the cumulative probability of

953   discharge of COVID-19 patients (D-*left*; GSE157103; derived from the hospital-free days during a 45-day follow-

954   up), or the time to lung transplant or death in male (D-*middle*) and female (D-*right*) IPF patients (GSE28221).

955   Statistical significances were estimated using the log rank test. **E.** Kaplan-Meier plots on the same cohorts as in

956   D, using a PBMC-derived 52-gene IPF-specific prognostic signature that was previously validated on numerous

957   independent IPF cohorts(*132*). **F.** Kaplan-Meier plots on the same cohorts as in D-E, using a CoV-lung derived
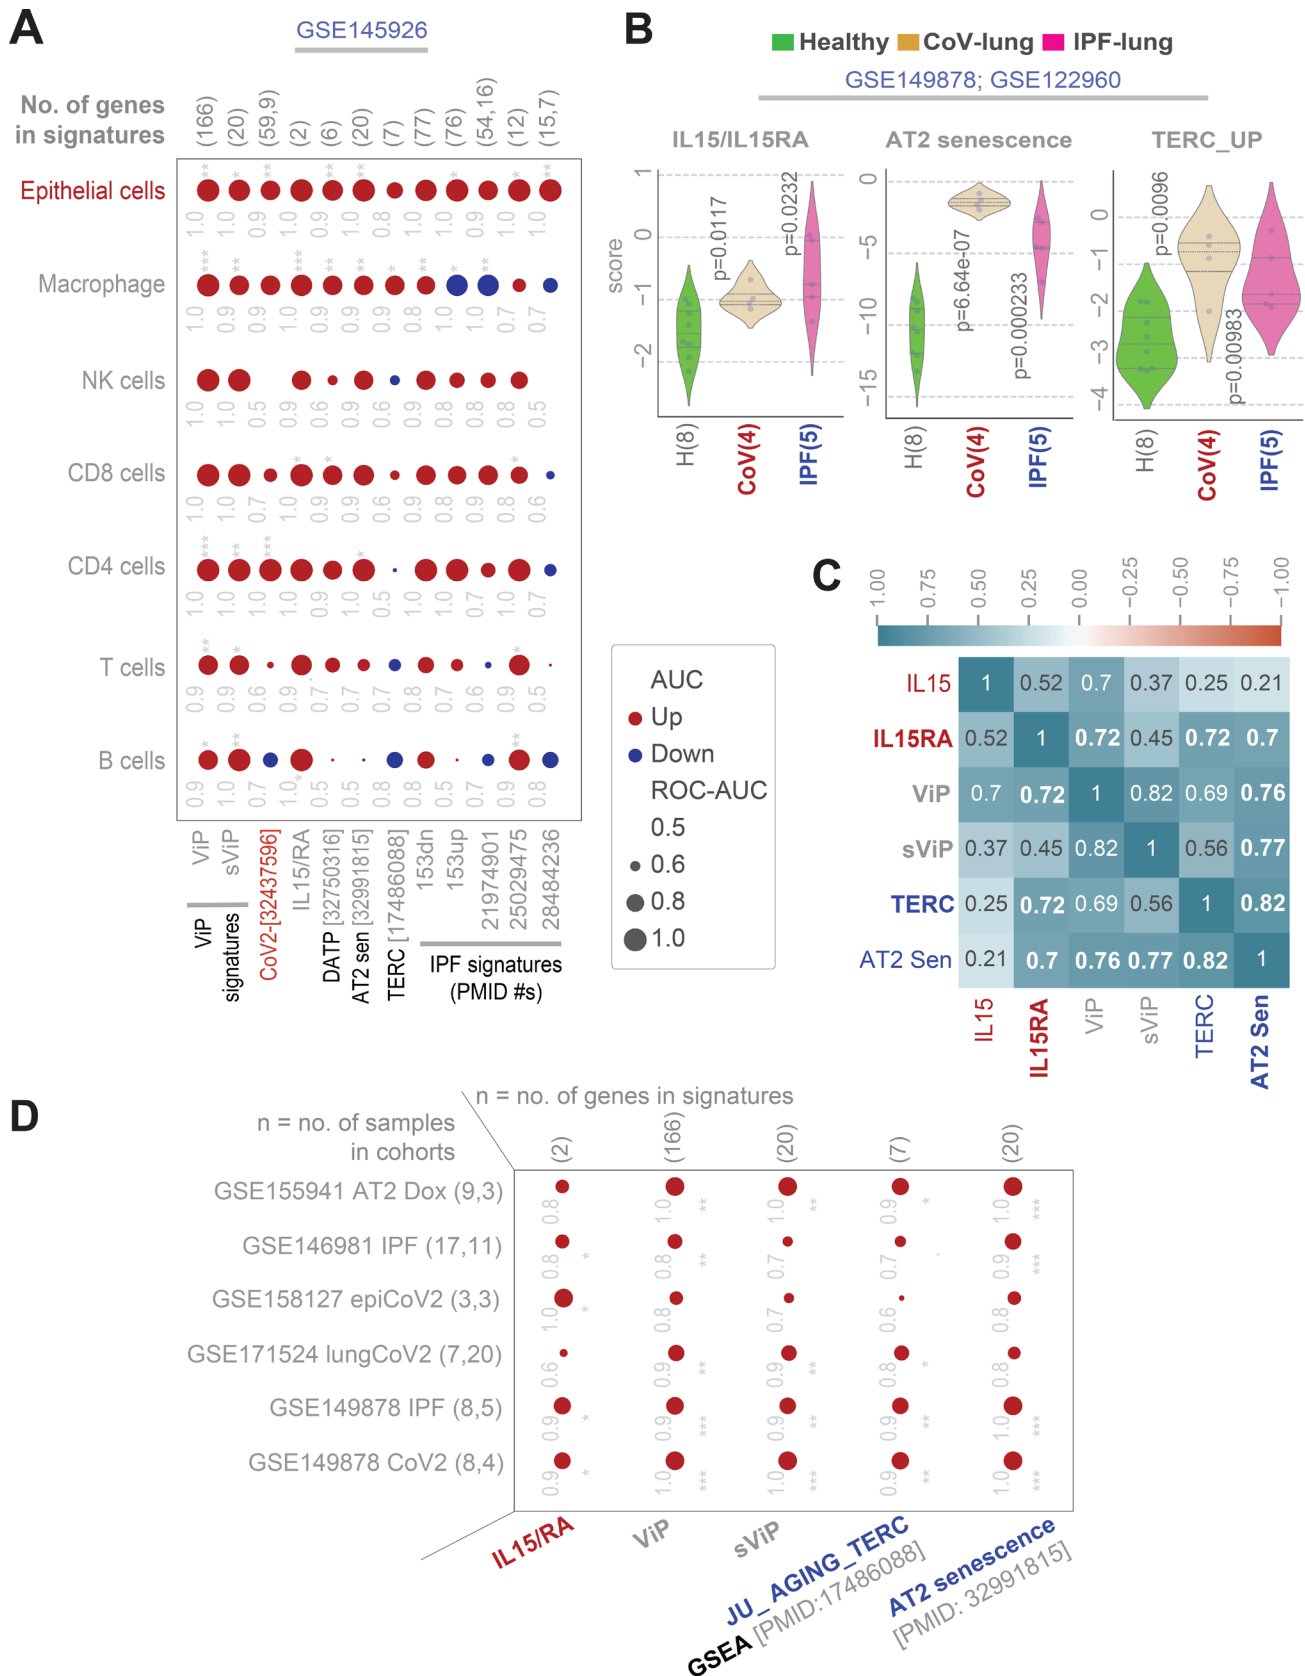

958   signature.

35

Figure 4. Identification of shared AT2 cytopathies in COVID-19 and IPF.

961 **A**. Bubble plot of ROC-AUC values (radii of circles are based on the ROC-AUC) demonstrating the direction of

962 gene regulation (Up, red; Down, blue) for the classification of various cell types between healthy and CoV lung

963 based on various ViP/sViP and IPF gene signatures in **Fig 2A-B** alongside *IL15/IL15RA* and additional signatures

964 of AT2 cytopathies that are encountered and implicated in IPF (DATP, damage associated transient progenitors;

965 Sens, senescence; TERC, *Te*lomerase *R*NA *C*omponent). Numbers in parenthesis indicate PMIDs. **B.** Violin plots

966 display the extent of induction of a *IL15/IL15RA* composite score (B-*left*), or a signature of AT2 senescence(*63*)

967 (B-*middle*), or a gene set for telomere dysfunction (JU_AGING_TERC(*133*)) in a pooled cohort of healthy, CoV

968 and IPF lung samples (GSE149878; GSE122960). Welch's two sample unpaired t-test is performed on the

969 composite gene signature score (z-score of normalized tpm count) to compute the *p* values. In multi-group setting

970 each group is compared to the first control group and only significant p values are displayed. **C.** Correlation matrix

971 showing the Pearson's correlation coefficient between different gene signatures in the pooled healthy, CoV and

972 IPF lung dataset (GSE149878; GSE122960). **D.** Bubble plots of ROC-AUC values (radii of circles are based on

973 the ROC-AUC) demonstrating the direction of gene regulation (Up, red; Down, blue) for the classification based

974 on AT2 senescence-related signatures on other publicly available CoV and IPF bulk RNA seq datasets.

Figure 5. SARS-CoV-2-challenged hamster lungs faithfully recapitulate AT2 cytopathies in COVID-19.

38

979   **A.** Schematic showing the experimental design for COVID-19 modeling in golden Syrian hamsters. *Uninf*,

980   uninfected; *Den3 and Anti-CoV-2* indicate SARS-CoV-2 challenged groups that received either a control mAb or

981   the clone CC12.2 of anti-CoV-2 IgG(*28*), respectively. PFU, plaque-forming units. **B**. Heatmap showing

982   transcripts/million (TPM)-normalized gene expression of specific genes associated with AT2 senescence

983   (*CDKN2A*, *TP53*), damage associated transition state progenitor (DATP) arrested state (*CLDN4*, *KRT8*), ER stress

984   (*HSPA5*/*GRP78*) and SASP-state (*SERPINE1*, *COL1A*, *COL3A*). **C-D**. Lungs harvested from the uninfected,

985   infected, and infected but anti-CoV-2 IgG and infected but EIDD-2801 treated hamsters have been analyzed for

986   the abundance of collagen deposition by Trichrome staining and quantified by ImageJ. Representative images are

987   shown panel C. Scale bar = 200 μm. Results of the quantification are displayed as bar plot in D. Statistical

988   significance was analyzed by one way ANOVA. Error bars represent S.E.M; n = 3. **E-F**. Lungs harvested from

989   the uninfected, infected, and infected but anti-CoV-2 IgG groups were analyzed by IHC for the indicated proteins

990   and quantified by ImageJ- IHC profiler. Representative images are shown panel E. Scale bar = 200 μm. Results

991   of the quantification are displayed as violin plots in F. Statistical significance was analyzed by one way ANOVA;
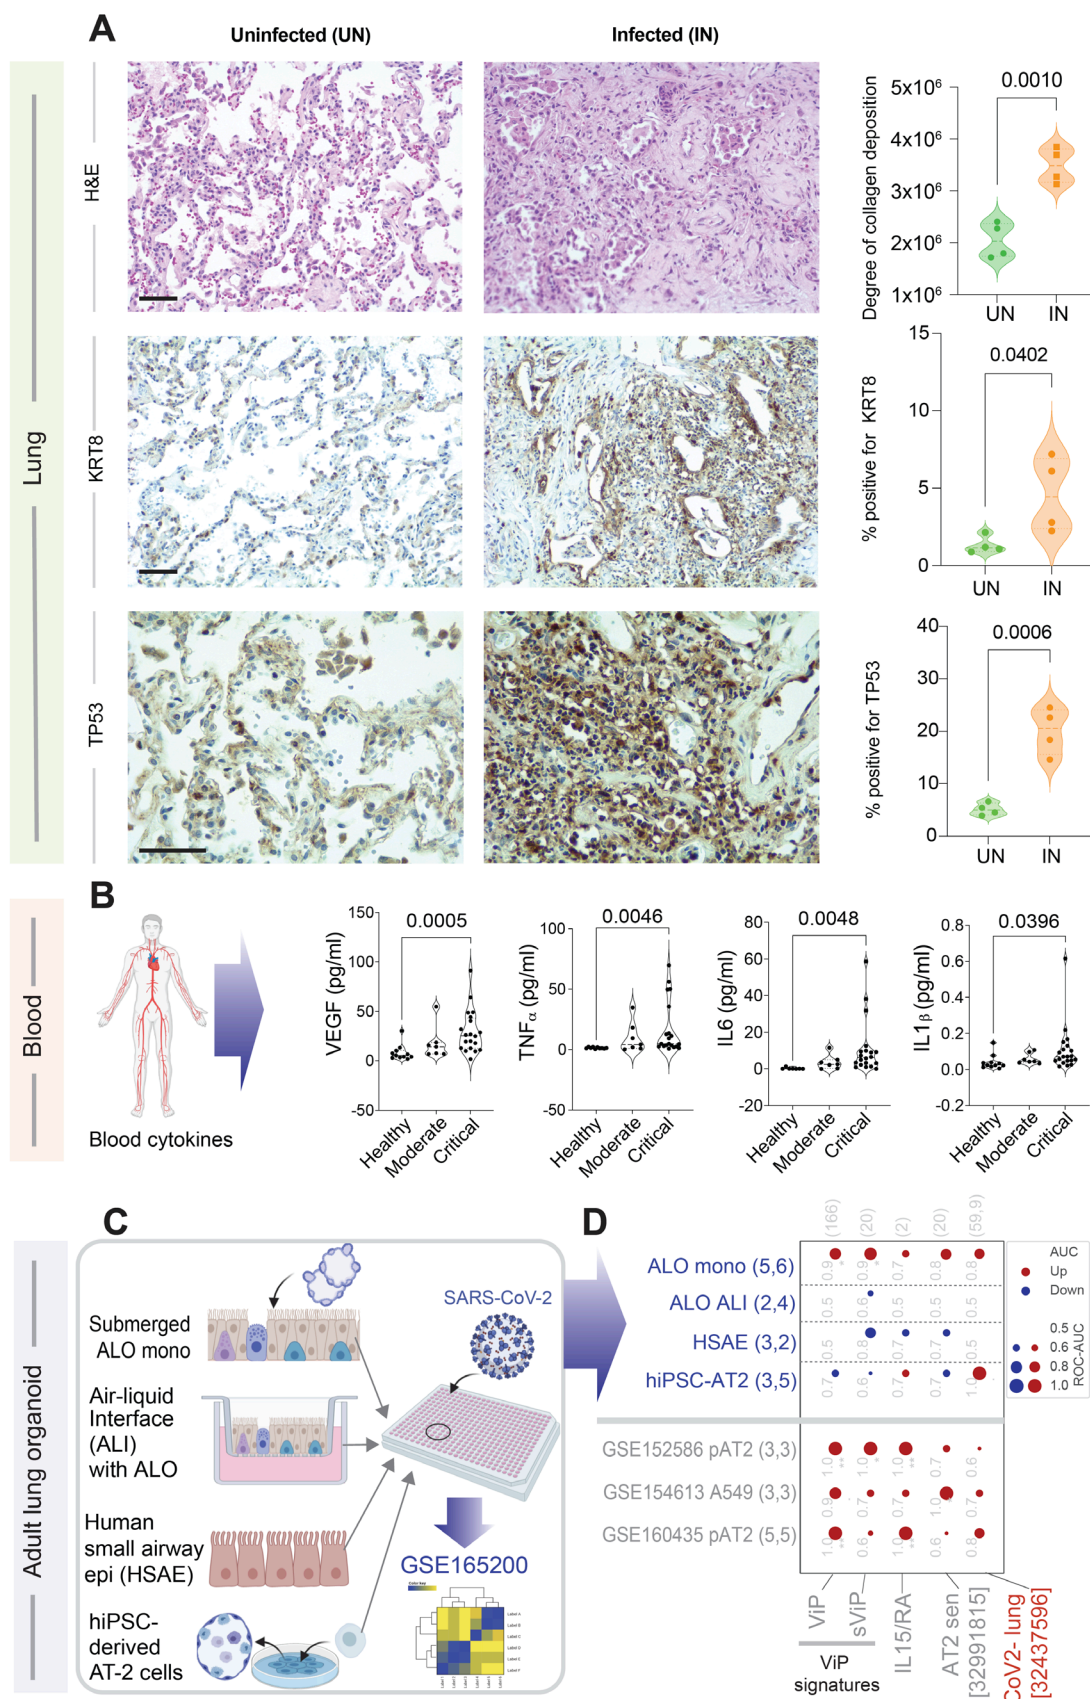

992   n = 4.

Figure 6. **AT2 cytopathic features of IPF are detected in COVID-19 lung tissues and human pre-clinical organoid models of COVID-19.**

40

996   **A**. FFPE lung tissues collected during rapid autopsy of deceased COVID-19-infected subjects and histologically

997   normal surgically resected lung tissues were analyzed by H&E staining (*top*) and for the expression of KRT8 (a

998   marker of DATP(*60*); *middle*) and TP53 (a marker of senescence; *bottom*) by IHC. Representative fields are

999   shown on the left. Scale bar = 200 μm. Images were quantified by IHC profiler (ImageJ) and displayed as violin

1000   plots on the right. **B**. Violin plots display the abundance of key senescence-associated cytokines in the plasma

1001   from adults with COVID-19 and healthy volunteers. Statistical significance was analyzed by unpaired t-test. See

1002   also **Supplemental Information 3-4** for patient demographics and cytokine concentrations. **C-D**. Schematic in

1003   C summarizes the various pre-clinical *in vitro* models of the human lung that were challenged with SARS-CoV-

1004   2, followed by RNA sequencing(*27*) (*top* rows; blue font; D). Other independent SARS-CoV-2-challenged

1005   alveolar pneumocyte datasets are listed in grey font (D). Bubble plots in D show the ROC-AUC values (radii of

1006   circles are based on the ROC-AUC) demonstrating the direction of gene regulation (Up, red; Down, blue) for the

1007   classification of uninfected vs infected samples based on the signatures (below).
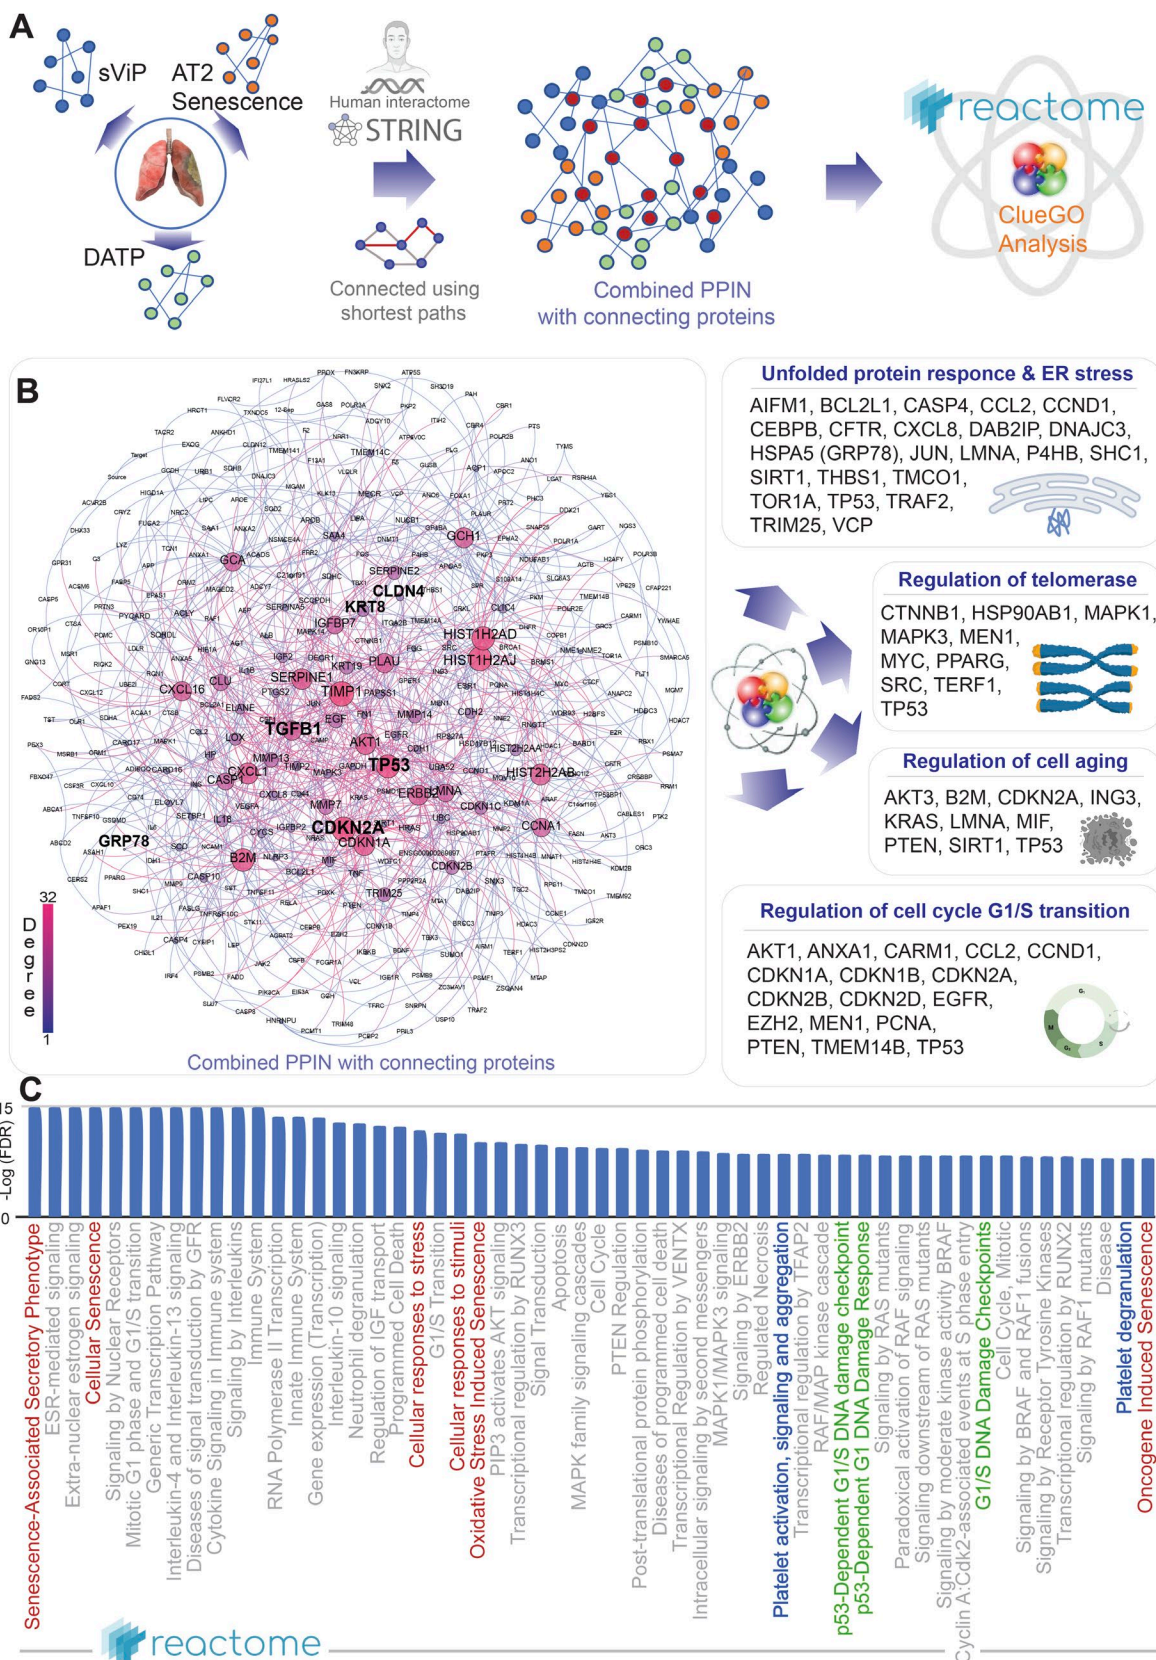

41

Figure 7. Protein-protein interaction network (PPIN) analysis predicts ER stress in AT2 cells as a driver pathophysiology in COVID-19

42

1011   **A**. Schematic summarizes the key steps in building a PPI network using as 'seeds' the genes in the sVIP, AT2

1012   senescence and transition state arrest (DATP) signatures and connecting them using shortest paths prior to

1013   carrying out network analyses. **B**. The combined PPI network is shown on the left and the degree of connectivity

1014   is indicated. See also **Supplemental Information 5** for the complete list of nodes sorted by their degrees of

1015   connectivity. Schematics on the right summarize the results of CluGo analysis, which identifies cellular processes

1016   and key genes that may perpetuate lung fibrosis. **C**. Reactome pathway analysis of the PPI network lists the most

1017   significant pathways that are associated with the node list in the network in B. Red = senescence related processes;

1018   Green = DNA damage response pathways; Blue = Platelet activation and degranulation.

Figure 8. Induction of ER stress in AT2 cells is observed in COVID-19 and is sufficient to mimic the host immune response in COVID-19 and IPF

44

1022   **A-B**. FFPE uninfected (control) and SARS-CoV-2-infected human (A) and hamster (B) lungs were analyzed for

1023   GRP78 expression by IHC. Representative fields are shown on the left. Scale bar = 200 μm. Images were

1024   quantified by IHC profiler (ImageJ) and displayed as violin plots on the right. **C**. Bubble plots show the ROC-

1025   AUC values (radii of circles are based on the ROC-AUC) demonstrating the direction of gene regulation (Up,

1026   red; Down, blue) for the classification of WT vs *GRP78*-KO murine lung (bottom row) and uninfected vs. infected

1027   hamster lung (top row) samples based on the signatures (below). **D**. Schematic summarizes the findings in this

1028   work and the proposed working model for the contributions of various alveolar cells in fueling the fibrotic

1029   progression in both IPF and COVID-19.
