#### 37 Abstract

38 A growing body of theoretical and experimental evidence suggests that intramolecular epistasis is 39 a major determinant of rates and patterns of protein evolution and imposes a substantial constraint 40 on the evolution of novel protein functions. Here, we examine the role of intramolecular epistasis 41 in the recurrent evolution of resistance to cardiotonic steroids (CTS) across tetrapods, which occurs 42 via specific amino acid substitutions to the  $\alpha$ -subunit family of Na,K-ATPases (ATP1A). After 43 identifying a series of recurrent substitutions at two key sites of ATP1A that are predicted to confer 44 CTS resistance in diverse tetrapods, we then performed protein engineering experiments to test 45 the functional consequences of introducing these substitutions onto divergent species backgrounds. In line with previous results, we find that substitutions at these sites can have 46 47 substantial background-dependent effects on CTS resistance. Globally, however, these 48 substitutions also have pleiotropic effects that are consistent with additive rather than background-49 dependent effects. Moreover, the magnitude of a substitution's effect on activity does not depend 50 on the overall extent of ATP1A sequence divergence between species. Our results suggest that 51 epistatic constraints on the evolution of CTS-resistant forms of Na,K-ATPase likely depend on a 52 small number of sites, with little dependence on overall levels of protein divergence. We propose 53 that dependence on a limited number sites may account for the observation of convergent CTS 54 resistance substitutions observed among taxa with highly divergent Na,K-ATPases.

- 55
- 56

#### 57 Significance Statement

58 Individual amino acid residues within a protein work in concert to produce a functionally coherent 59 structure that must be maintained even as orthologous proteins in different species diverge over 60 time. Given this dependence, we expect identical mutations to have more similar effects on protein 61 function in more closely related species. We tested this hypothesis by performing protein-62 engineering experiments on ATP1A, an enzyme mediating target-site insensitivity to cardiotonic 63 steroids (CTS) in diverse animals. These experiments reveal that the phenotypic effects of 64 substitutions can sometimes be background-dependent, but also that the magnitude of these 65 phenotypic effects does not correlate with overall levels of ATP1A sequence divergence. Our 66 results suggest that epistatic constraints are determined by states at a small number of sites, 67 potentially explaining the frequent convergent CTS resistance substitutions among Na,K-ATPases 68 of highly divergent taxa.

72

#### 71 Introduction

73 Instances of parallel and convergent (hereafter "convergent") evolution represent a useful paradigm 74 to examine the factors that limit the rate of adaptation and the extent to which adaptive evolutionary 75 paths are predictable [1,2]. The evolution of resistance to cardiotonic steroids (CTS) in animals 76 represents one of the clearest examples of convergent molecular evolution. CTS are potent 77 inhibitors of Na,K-ATPase (NKA, Fig. 1A), a protein that plays a critical role in maintaining 78 membrane potential and is consequently vital for the maintenance of many physiological processes 79 and signaling pathways in animals [3]. CTS inhibit NKA function by binding to a highly conserved 80 domain of the protein's  $\alpha$ -subunit (ATP1A) and blocking the exchange of Na<sup>+</sup> and K<sup>+</sup> ions [3]. Thus, 81 NKA is often the target of convergent evolution of CTS resistance across widely divergent species, 82 including insect herbivores that feed on toxic plants [4,5] as well as predators that feed on toxic 83 prey [6-10].

84

85 Patterns of convergence in adaptive protein evolution are influenced by the mutational target size 86 (i.e. the number of potentially adaptive mutations), the degree of pleiotropy (i.e. the effect of a given 87 mutation on multiple phenotypes), and intramolecular epistasis (i.e. nonadditive interactions 88 between mutant sites in the same protein) [11–19]. If the phenotypic and fitness effects of mutations 89 depend on the protein sequence background on which they arise (i.e. there is intramolecular 90 epistasis), a given mutation is expected to have more similar phenotypic and fitness effects in 91 orthologs from closely-related species. Therefore, the probability of convergent substitution is 92 expected to decrease with increasing sequence divergence between orthologous proteins in 93 different species. Consistent with this expectation, such a decline is observed in broad-scale 94 phylogenetic comparisons of mitochondrial [20] and nuclear [21,22] proteins. While these results 95 suggest epistasis is an important global determinant of patterns of convergent protein evolution, 96 studies linking these broad-scale observations with functional data at the level of individual proteins 97 are lacking.

98

99 Functional investigations of CTS resistance-conferring substitutions at two key sites (111 and 122) 100 in ATP1A orthologs of Drosophila [23,24] and Neotropical grass frogs [25] revealed associated 101 negative pleiotropic effects on protein function and showed that evolution at other sites in the 102 protein mitigate these detrimental effects. In light of these pleiotropic and epistatic constraints, it is 103 curious that convergent CTS-resistant substitutions are often observed among ATP1A orthologs of 104 highly divergent species. Due to limited comparative functional data, the generality of pleiotropic and epistatic constraints on ATP1A-mediated CTS resistance, and specifically the predicted
 dependence on evolutionary distance, remain poorly understood.

107

108 To achieve a clearer picture of the phylogenetic distribution of CTS resistance substitutions, a more 109 complete and consistent sampling of ATP1A is needed in vertebrates. Broad phylogenetic 110 comparisons in vertebrates have primarily focused on the H1-H2 extracellular loop of ATP1A, which 111 represents only a subset of the CTS-binding domain. Further, most vertebrates possess three 112 paralogs of ATP1A that have different tissue-specific expression profiles and are associated with 113 distinct physiological roles (Fig. 1B) [3,26]. Previous studies of the ATP1A paralogs of vertebrate taxa focused on ATP1A3 in reptiles [7,8,27,28], ATP1A1 and/or ATP1A2 in birds and mammals 114 115 [10,28], and either ATP1A1 or ATP1A3 in amphibians [6,28]. We therefore lack a comprehensive 116 and systematic survey of amino acid variation in the ATP1A protein family across vertebrates.

117

118 To bridge this gap, we first surveyed variation in near full-length coding sequences of the three 119 NKA α-subunit paralogs (ATP1A1, ATP1A2, ATP1A3) that are shared across major extant tetrapod 120 groups (mammals, birds, non-avian reptiles, and amphibians), and identified substitutions that 121 occur repeatedly among divergent lineages. If the phenotypic effects of these substitutions depend 122 on states at a large number of sites throughout the protein, we expect that identical substitutions 123 should have increasingly distinct effects on more highly divergent proteins. Focusing on two key 124 sites implicated in CTS resistance across animals (111 and 122), we tested whether substitutions 125 at these sites have increasingly distinct phenotypic effects on more divergent genetic backgrounds. 126 We engineered several common substitutions at sites 111 and 122 of ATP1A1 that differ between 127 species to reveal potential 'cryptic' epistasis [16,29]. By quantifying the level of CTS resistance 128 conferred by these substitutions on different backgrounds, as well as their pleiotropic effects on 129 enzyme function, we evaluate the extent to which overall protein sequence background has 130 constrained the evolution of CTS-resistant forms of ATP1A1 across tetrapods.

#### 133 Results

134

#### 135 Patterns of ATP1A sequence evolution across species and paralogs.

136

To obtain a more comprehensive portrait of ATP1A amino acid variation among tetrapods, we created multiple sequence alignments for near full-length ATP1A proteins for the three ATP1A paralogs shared among vertebrates. In addition to publicly available data, we generated new RNAseq data for 27 non-avian reptiles (PRJNA754197) (Table S1-S2). We then *de novo* assembled 141 full-length transcripts of all ATP1A paralogs using these and generated new RNA-seq data for 18

anuran species [25] (PRJNA627222) to achieve better representation for these groups. In total, this

- 143 dataset comprises 429 species for ATP1A1, 197 species for ATP1A2 and 204 species for ATP1A3
- 144 (831 sequences total, including the newly generated data; Supplemental Dataset 1, Fig. S1).
- 145

Our survey reveals numerous substitutions at sites implicated in CTS resistance of NKA (Fig. 2; Supplementary Dataset 2; for comparison to insects, see Supplemental file 1 of ref. [23]). As anticipated from studies of full-length sequences in insects [4,5,23], most amino acid variation among species and paralogs is concentrated in the H1-H2 extracellular loop (residues 111-122; Fig 1A). Despite harboring just 28% of 43 sites previously implicated in CTS resistance [30], the H1-H2 extracellular loop contains 81.4% of all substitutions identified among the three ATP1A paralogs (Fig. S2).

153 Our survey reveals several clade- and paralog-specific patterns. Notably, ATP1A1 exhibits more 154 variation among species at sites implicated in CTS resistance (Fig. 2). Most of the variation in 155 ATP1A2 at these sites is restricted to squamate reptiles and ATP1A3 lacks substitutions at site 122 156 altogether, despite the well-known potential for substitutions at this site to confer CTS resistance 157 [25,31]. Looking across species and paralogs, the extent of convergence at sites 111 and 122 is 158 remarkable (Figs. 2-3): for example, the substitutions Q111E, Q111T, Q111H, Q111L, and Q111V 159 all occur in parallel in multiple species of both insects and vertebrates. N122H and N122D also 160 frequently occur in parallel in both of these major clades. The frequent convergence of CTS-161 sensitive (i.e. Q111 and N122) to CTS-resistant states at these sites has been interpreted as 162 evidence for adaptive significance of these substitutions [4-7], but may also reflect mutational 163 biases [32] and the nature of physico-chemico constraints [21,33].

In contrast, some convergence is restricted to specific clades: for example, Q111R occurs in parallel across tetrapods but has not been observed in insects. Similarly, the combination Q111R+N122D has evolved three times independently in ATP1A1 of tetrapods but is not observed in insects. Conversely, insects have evolved Q111V+N122H independently four times, but this combination has never been observed in tetrapods. These patterns suggest that the fitness effects of some CTS-resistant substitutions depend on genetic background (i.e. epistatic constraints), with the result that CTS-resistance evolved via different mutational pathways in different lineages.

Beyond known CTS-resistant substitutions at sites 111 and 122, some taxa have evolved other
paths to CTS resistance. For example, horned frogs of the genus *Ceratophyrs* are known to prey
on CTS-containing toads [34] and their ATP1A1 harbors a known CTS-resistant substitution at site
121 (D121N, Supplementary Dataset 2). This substitution is rare among vertebrates but has been

175 previously reported in CTS-adapted milkweed bugs [4,5]. Similarly, the known CTS resistance 176 substitution C104Y is observed in ATP1A1 among garter snakes of the genus Thamnophis 177 (Supplementary Dataset 2) and CTS-adapted milkweed weevils [5]. Histricognathi rodents, 178 including Chinchilla (Chinchilla lanigera), and yellow-throated sandgrouse (Pterocles gutturalis) 179 show distinct single-amino acid insertions in the H1-H2 extracellular loop, a characteristic that has 180 been previously associated with CTS resistance in pyrgomorphid grasshoppers [30,35]. Further, in 181 *lieu* of variation at site 122, ATP1A3 of tetrapods harbors frequent convergent substitutions at site 182 120 (G120R, see also [7]). Interestingly, this site also shows substantial convergent substitution in 183 the ATP1A1 paralog of birds (where N120K occurs eight times independently) but is mostly 184 invariant in ATP1A1 of other tetrapods.

185

#### 186 Context-dependent CTS resistance of substitutions at sites 111 and 122

187

The clade- and paralog-specific patterns of substitution among ATP1A paralogs outlined above suggest that the evolution of CTS resistance may be highly dependent on sequence context. However, the functional effects of the vast majority of these substitutions on the diverse genetic backgrounds in which they occur remain largely unknown [25,27,31]. Given the diversity and broad phylogenetic distribution of convergent substitutions at sites 111 and 122, and the documented effects of some of these substitutions on CTS resistance, we experimentally tested the extent to which functional effects of substitutions at these sites are background-dependent.

195

196 We focused functional experiments on ATP1A1, because it is the most ubiquitously expressed 197 paralog and exhibits both the most sequence diversity and the broadest phylogenetic distribution 198 of convergent substitutions. Specifically, we considered ATP1A1 orthologs from nine 199 representative tetrapod species that possess different combinations of wild-type amino acids at 200 111 and 122 (Fig. 4A). Our taxon sampling included two lizards, two snakes, two birds, two 201 mammals, and previously published data for one amphibian (Fig. S6; Fig. S7; Table S3). The 202 ancestral amino acid states of sites 111 and 122 in tetrapods are Q and N, respectively. We found 203 that the sum of the number of derived states at positions 111 and 122 is a strong predictor of the 204 level of CTS-resistance (Fig 4B, IC<sub>50</sub>, Spearman's r<sub>s</sub>=0.85, p=0.001). Nonetheless, we also found 205 greater than 10-fold variation in CTS resistance among enzymes that had identical paired states at 206 111 and 122 (e.g., compare chinchilla (CHI) versus red-necked keelback snake (KEE) or compare 207 rat (RAT) versus the resistant paralog of grass frog (GRA<sub>R</sub>)). These differences suggest that 208 substitutions at other sites also contribute to CTS resistance.

210 To test for epistatic effects of common CTS-resistant substitutions at sites 111 and 122, we used 211 site-directed mutagenesis to introduce 15 substitutions (nine at position 111 and six at position 122) 212 in the wild-type ATP1A1 backgrounds of nine species (Fig. S6). The specific substitutions chosen 213 were either phylogenetically broadly-distributed convergent substitutions and/or divergent 214 substitutions that distinguish closely related clades of species. We expressed each of these 24 215 ATP1A1 constructs with an appropriate species-specific ATP1B1 protein (Table S3). For each 216 recombinant NKA protein complex, we characterized its level of CTS resistance (IC<sub>50</sub>) and 217 estimated enzyme activity as the rate of ATP hydrolysis in the absence of CTS (Table S4).

218

219 Among the 12 cases for which IC<sub>50</sub> could be measured, substitutions had a 15-fold effect on 220 average (Fig. 4C, Table S4) and were equally likely to increase or decrease  $IC_{50}$ . To assess the 221 background dependence of specific substitutions, we examined five cases in which a given 222 substitution (e.g., E111H), or the reverse substitution (e.g., H111E), could be evaluated on two or 223 more backgrounds. In the absence of intramolecular epistasis, the effect of a substitution on 224 different backgrounds should remain unchanged and the magnitude of the effect of the reverse 225 substitution should also be the same but with opposite sign. This analysis revealed substantial 226 background dependence for  $IC_{50}$  in two of the five informative cases (Fig. 4E; Table S5). In one 227 case, the N122D substitution resulted in a 200-fold larger increase in IC<sub>50</sub> when added to the 228 chinchilla (CHI) background compared to the grass frog (GRA) background (p=1.2e-3 by ANOVA). 229 In the other case, the E111H substitution and the reverse substitution (H111E) produced effects in 230 the same direction (reducing CTS-resistance) when added to different backgrounds (false fer-de-231 lance (FER) and red-necked keelback (KEE) snakes, respectively, p=1e-7 by ANOVA). Overall, 232 these results suggest that the effect of a given substitution on  $IC_{50}$  can be strongly dependent on 233 the background on which it occurs. The remaining three substitutions (H111T, Q111R and H122D) 234 showed no significant change in the magnitude of the effect on IC<sub>50</sub> when introduced into different 235 species' backgrounds. These results suggest that, while some substitutions can have strong 236 background-dependent effects, strong intramolecular epistasis with respect to CTS resistance is 237 not universal.

238

#### 239 Pleiotropic effects on NKA activity largely depend on states at a small set of sites.

240

We next tested whether substitutions at sites 111 and 122 have pleiotropic effects on ATPase activity. Because ion transport across the membrane is a primary function of NKA and its disruption can have severe pathological effects [36], mutations that compromise this function are likely to be under strong purifying selection. As suggested by previous work [23–25], CTS-resistant substitutions at sites 111 and 122 can decrease enzyme activity. We evaluated the generality of these effects across a broader phylogenetic scale by comparing enzyme activity of the 15 mutantNKA proteins to their corresponding wild-type proteins.

248

249 Interestingly, the wild-type enzymes themselves exhibit substantial variation in activity, from 3-18 250 nmol/mg\*min (p= 6e-7 by ANOVA, Fig 4E; Table S4). On average, substitutions at sites 111 and 251 122 on divergent orthologous protein backgrounds changed enzyme activity by 60% (mean of the 252 absolute change; Fig 4D; Fig S4). In two cases, amino acid substitutions at position 122 (N122H 253 and H122D) nearly inactivated lizard NKAs and, in one case, a substitution at position 111 (Q111T) 254 resulted in low expression of the recombinant protein in the transfected cells (Fig S7; Fig. S8). A 255 test of uniformity of pairwise t-test p-values across substitutions suggests a significant enrichment 256 of low p-values (Fig 4D inset; p=2.5e-4, chi-squared test of uniformity). Thus, globally, this set of 257 substitutions has significant effects on NKA activity, but they were surprisingly not more likely to 258 decrease than increase activity (10 decrease : 5 increase, p>0.3, binomial test, Fig. 4D, Table S5). 259

260 We next asked to what extent pleiotropic effects of CTS resistant substitutions at positions 111 and 261 122 are dependent on genetic background. This guestion is motivated by recent studies in insects 262 which revealed that deleterious pleiotropic effects of some resistance-conferring substitutions at 263 sites 111 and 122 are background dependent [23,24]. Likewise, recent work on ATP1A1 of toad-264 eating grass frogs showed that effects of Q111R and N122D on NKA activity are also background 265 dependent [25]. In contrast, among the five informative cases in which we compared the same 266 substitution (or the reverse substitution) on two or more backgrounds, there is no evidence for 267 background dependence (Fig 4E; Table S5). For example, N122D has similar effects on NKA 268 activity in grass frog and chinchilla despite the substantial divergence between the species' proteins 269 (8.4% protein sequence divergence; Fig. 4D). Similarly, the effects of Q111R in ostrich or the 270 reverse substitution R111Q in sandgrouse were not significantly different from the effect of Q111R 271 in grass frog (7.5% and 8% protein sequence divergence, respectively).

272

273 To further examine the evidence for background dependence, we tested whether changes to the 274 same amino acid state (regardless of starting state) at 111 and 122 produce different changes in 275 NKA activity (e.g., R111E on the rat background versus H111E on the false fer-de-lance 276 background). If epistasis is prevalent, involving a large number of sites, we expect that the absolute 277 difference in effects of substitutions to a given amino acid state should increase with increasing 278 sequence divergence of the wild-type ATP1A1 proteins. The 11 possible comparisons reveal 279 substantial variation in the absolute difference of effects on protein activity, ranging from 8% to 280 190% (Table S7). Despite this, we found no relationship between the difference in the effect of 281 substitutions to the same state and the extent of amino acid divergence between the orthologous

proteins (Fig. 5A). This pattern suggests that, while pleiotropic effects may be pervasive and can
be background dependent [23,25], these effects do not correlate with overall sequence divergence.

- 285 We hypothesized that background-dependent effects may instead depend on states at a small 286 number of sites. If so, using total divergence may obscure a relationship between functional effects 287 and divergence at these sites. To test this hypothesis, we used an analysis of variance to ask which 288 variant sites across our functional constructs best accounted for differences in effects on different 289 backgrounds (Methods and Fig. S5). Of 24 groups of variant sites (grouped as those with Pearson's 290 r > 0.8), we discovered two groups that included 16 of 113 total variant sites. These two groups of 291 16 sites jointly accounted for 78% of the variance among construct comparisons (p<0.004 by 292 permutation). Further, in contrast to the pattern observed using all variant sites (Fig. 5A), we found 293 a strong positive correlation between the difference in the effect of substitutions and the extent of 294 divergence at these 16 sites (Fig. 5B; Pearson's r = 0.78, p=0.003 by permutation). This analysis 295 strongly supports the notion that background-dependent effects depend on a circumscribed 296 number of sites. While our resolution is limited (due to the limited number of genetic backgrounds 297 in the experiments), we can say that 16 sites or fewer explain a large proportion of the differences 298 in the effect of substitutions on different backgrounds.
- 299

# A global analysis of ATP1A sequences reveals further constraints on the evolution of CTS resistance

302

303 Since our functional experiments were necessarily limited in scope, we carried out a broad 304 phylogenetic analysis to evaluate how well our findings align with global estimates of rates of 305 convergence for the ATP1A family beyond ATP1A1 and beyond sites implicated in CTS resistance. 306 Using a multisequence alignment of 831 ATP1A protein sequences, including the three ATP1A 307 paralogs shared among tetrapods (i.e., amphibians, non-avian reptiles, birds, and mammals), we 308 inferred a maximum likelihood phylogeny of the gene family (Fig. S1). We then used ancestral 309 sequence reconstruction to infer the history of substitution events on all branches in the tree and 310 counted the number of convergent amino acid substitutions per site along the entire protein (see 311 Materials and Methods). Convergent substitutions are defined as substitutions on two branches at 312 the same site resulting in the same amino acid state. Interestingly, we did not detect a correlation 313 between the relative number of convergent substitutions with overall ATP1A divergence across the tree (Fig. S5). This result also held true when considering only substitutions to the key CTSresistance sites 111 and 122 (Fig. S7).

316

317 To gain further insights into the factors that determine convergent evolution in ATP1A, we looked 318 more closely at patterns of individual convergent substitutions at sites 111 and 122 by extracting 319 each convergent substitution and visualizing its distribution along the sequence divergence axis 320 (Fig. 6A). Under the expectation that rates of convergence should tend to decrease as a function 321 of sequence divergence due to prevalent epistasis, the distribution of pairwise convergent events 322 along the sequence divergence axis should be left-skewed, with a peak towards lower sequence 323 divergence. In contrast to this expectation, the distribution is bimodal, with one peak at 0.33 and 324 the other at 0.69 substitutions/site (Fig. 6B bottom panel). Convergent substitutions have occurred 325 almost across the full range of protein divergence estimates. For example, if X is any starting state, 326 the substitution X111R has occurred independently in 13 tetrapod lineages and X111L 327 independently in 20 lineages. Both substitutions have a broad phylogenetic distribution, suggesting 328 that their effects do not strongly depend on sequence states at a large number of sites throughout 329 the protein. Interestingly, however, the distributions for X111H and X111E substitutions are 330 relatively left-skewed, in line with epistasis for CTS resistance that we observed in experiments for 331 H111E/E111H (Fig 4E).

332

333 Using this same 831-sequence, 3-paralog alignment, we also asked which sites across all paralogs 334 have substitution patterns that are most strongly correlated with those at 111 and 122 (Methods). 335 We found 4 sites (102, 112, 527 and 676) that stand out as being in the top 5% of sites most 336 strongly correlated with substitutions at both 111 and 122 (Fig. 6B), and this amount of overlap was 337 larger than expected by chance. Further, the top 5% of sites most strongly correlated with site 111 338 also tend to be closer to 111 in atomic distance than expected (median distance to 111: 25.1 Å, p 339 < 5e-4, bootstrap; Fig. 6C). Combining the results from our phylogenetic and functional analyses 340 we identified a set of substitutions that are both strongly correlated with changes in 111 and 122 341 and account for a substantial proportion of the variance in background-dependent effects in our 342 functional experiments (overlaps are larger than expected by chance; Fig 6B). For instance, despite 343 being independently ascertained, site 102 is also among the most strongly predictive sites for 344 background-dependent effects in our functional experiments, belonging to a group of 6 sites that 345 explains 60% of variance (Fig. 5B and Fig. 6B). Together, our results suggest that proximate 346 interactions involving a small number of sites, particularly site 111, are likely to be an important 347 determinant of background-dependent effects.

348

349 Discussion

350

351 Previous work has shown that the adaptive evolution of NKA-mediated CTS resistance in animals 352 is constrained by pleiotropy and epistasis (i.e., background-dependence) [5,23–25,30]. Further, 353 based on broad phylogenetic analysis of proteomes, our a priori expectation is that epistasis should 354 represent a stronger constraint with increasing levels of divergence between species and ATP1A 355 paralogs [20]. In light of these considerations, our extensive survey of the ATP1A gene family in 356 tetrapods reveals two striking and seemingly contradictory patterns. The first is that some 357 substitutions underlying CTS resistance in tetrapods are broadly distributed phylogenetically and 358 even shared with insects (e.g., N122H is widespread among snakes and found in the monarch 359 butterfly and other insects; see Fig. 3 for more examples). Patterns like these suggest that epistatic 360 constraints have a limited role in the evolution of CTS resistance, as the same mutation can be 361 favored on highly divergent genetic backgrounds. On the other hand, there is also substantial 362 diversity in resistance-conferring states at sites 111 and 122, and some combinations of these 363 substitutions appear to be phylogenetically restricted. For example, the CTS-resistant combination 364 of Q111R+N122D has evolved multiple times in tetrapods but is absent in insects, whereas the 365 CTS-resistant combination Q111V+N122H evolved multiple times in insects but is absent in 366 tetrapods (Fig 3). Additionally, some substitutions also appear to be paralog-specific in tetrapods 367 (Fig 3). These phylogenetic signatures suggest at least some role for epistasis as a source of 368 contingency in the evolution of ATP1A-mediated CTS resistance in animals, i.e., that the fitness 369 effects of substitutions depend on the order in which they occur. How can these disparate patterns 370 be reconciled? To what extent do genetic background and contingency limit the evolution of CTS 371 resistance in animals?

372

373 In our functional analysis of diverse ATP1A1 proteins, we find that derived substitutions at sites 374 111 and 122 have largely predictable effects on CTS resistance, with salient exceptions that tend 375 to be in size rather than direction (Fig. 4). For example, Q111R contributes to CTS resistance on 376 many species' backgrounds, but not on that of sandgrouse (Fig. 4C and 4E). We also note that species with identical paired states at 111 and 122 can vary in CTS resistance by more than an 377 378 order of magnitude (Fig. 4B). Together, these patterns point to background determinants of CTS 379 resistance that may be additive rather than epistatic. Despite this, there are some substitutions that 380 are widely distributed phylogenetically, such as N122D, that nonetheless do exhibit background-381 dependent effects on CTS resistance (Fig. 4C and 4E).

382

With respect to pleiotropic effects on NKA activity, our functional analysis of substitutions at sites 111 and 122 on diverse ATP1A1 backgrounds suggest that interactions between these substitutions and those backgrounds are largely additive. Specifically, we find that the severity of 386 the effect of a particular CTS resistance substitution on NKA activity does not differ if added to 387 protein backgrounds that are in the range of 49 to 86 amino acid substitutions away from the protein 388 background on which that substitution naturally occurs (Fig. 5). In light of previous results 389 demonstrating background-dependent effects of similar substitutions on NKA activity [23-25], our 390 findings suggest that the extent of epistasis does not have a monotonic dependence on the extent 391 of ATP1A1 divergence. Our findings further support increasing evidence that while epistasis is likely 392 to be a pervasive feature of protein evolution, many mutational effects on structural and functional 393 properties of proteins nonetheless seem to be additive (e.g., [37-39]).

394

395 We propose that our observations can be reconciled with previous results demonstrating epistatic 396 constraints if epistasis with respect to protein function is confined to a small number of sites in the 397 protein. If so, we might expect that the magnitude of epistasis may have little dependence on the 398 extent of protein-wide ATP1A1 divergence but would instead be better predicted by divergence at 399 a few key sites. In support of this view, Mohammadi et al. [25] showed that decreases in ATP1A1 400 enzyme activity due to substitutions Q111R and N122D can be rescued by 10 (or fewer) of the 19 401 amino acid differences distinguishing the backgrounds of CTS-resistant and sensitive ATP1A1 402 paralogs of grass frogs. Further, studies in Drosophila melanogaster [23,24] show that severe 403 neural dysfunction associated with CTS resistance substitutions at sites 111 and 122 can largely 404 be rescued with one additional substitution (A119S). Our study lends further support to this view 405 by showing that one can identify a small group of sites (16 or fewer) that account for a large 406 proportion of the variation in background-dependent effects on enzyme activity across proteins 407 spanning the breath of the tetrapod phylogeny.

408

409 Phenotypes such as enzyme activity are not equivalent to organismal fitness and that there may 410 be a nonlinear mapping between the two. The discussion above assumes that changes in enzyme 411 activity are most likely detrimental to organismal fitness, but this need not be the case. We found 412 that the activity of wild-type NKAs varies 6-fold among the species surveyed (Fig. 4E), suggesting 413 that most species are either robust to changes in NKA activity or that changes have occurred in 414 other genes (including other ATP1A paralogs) to compensate for changes in NKA activity 415 associated with ATP1A1. Thus, either protein activity itself is not an important pleiotropic constraint 416 on the evolution of CTS resistance of NKA, or constraint depends not just on the protein background 417 but also on the broader genetic background of the organism (e.g., other interacting proteins; see 418 [23]).

419

Our work highlights the utility of comparative functional work in understanding the nature of epistaticconstraints on the evolution of novel protein functions. In this case-study of the evolution of CTS-

- resistant NKAs, we find that epistatic constraints are more likely to depend on divergence at a small
  number of key sites in the protein, likely in close proximity to site 111, rather than overall levels of
  protein divergence. The circumscribed nature of these constraints may account for the remarkable
  convergence of CTS-resistance substitutions observed among the NKAs of highly divergent
  species.

#### 430 Materials and Methods

431

#### 432 Sample collection and data sources.

433 In order to carry out a comprehensive survey of vertebrate ATP1A paralogs (ATP1A1, ATP1A2 and 434 ATP1A3), we collated a total of 831 protein sequences for this study (corresponding alignment can 435 be found in Supplementary Dataset 1). Mammals possess a fourth paralog (ATP1A4) that is 436 expressed predominantly in testes [40] that we did not consider here, although for completeness 437 the protein sequences are provided in Supplementary Dataset 1 and the alignment of variant sites 438 in Supplementary Dataset 2). The 831 sequences included RNA-seq data generated here for 27 439 species of non-avian reptiles (Table S1; PRJNA754197) to provide more information from some 440 previously underrepresented lineages. These included field-caught and museum-archived 441 specimens as well as animals purchased from commercial pet vendors. Purchased animals were 442 processed following the procedures specified in the IACUC Protocol No. 2057-16 (Princeton 443 University) and implemented by a research veterinarian at Princeton University. Wild-caught 444 animals were collected under Colombian umbrella permit resolución No. 1177 granted by the 445 Autoridad Nacional de Licencias Ambientales to the Universidad de los Andes and handled 446 according to protocols approved by the Institutional Committee on the Care and Use of Laboratory 447 Animals (abbreviated CICUAL in Spanish) of the Universidad de los Andes. In all cases, fresh 448 tissues (brain, stomach, and muscle) were taken and preserved in RNAlater (Invitrogen) and stored 449 at -80°C until used.

450

#### 451 **Reconstruction of ATP1A paralogs.**

452 RNA-seq libraries were prepared either using TruSeq RNA Library Prep Kit v2 (Illumina) and 453 sequenced on Illumina HiSeq2500 (Genomics Core Facility, Princeton, NJ, USA) or using NEBNext 454 Ultra RNA Library Preparation Lit (NEB) and sequenced on Illumina HiSeq4000 (Genewiz, South 455 Plainfield, NJ, USA) (Table S2). All raw RNA-seq data generated for this study have been deposited in the National Center for Biotechnology Information (NCBI) Sequence Read Archive (SRA) under 456 457 Bioproject PRJNA754197. Together with SRA datasets downloaded from public database, reads 458 were trimmed to Phred quality  $\geq$  20 and length  $\geq$  20 and then assembled *de novo* using Trinity 459 v2.2.0 [41]. Sequences of ATP1A paralogs 1, 2 and 3 were pulled out with BLAST searches (blast-460 v2.26), individually curated, and then aligned using ClustalW. Complete alignments of ATP1/2/3 can be found in Supplementary Dataset 1. 461

462

#### 463 Statistical phylogenetic analyses

We use the standard sheep (*Ovis aries*) numbering system to match previous literature; this number corresponds to the Uniprot:P04074 sequence minus 5 residues from the 5' end. Protein sequences from ATP1A1 (N=429), ATP1A2 (N=197) and ATP1A3 (N=205) including main tetrapod 467 classes (amphibians, non-avian reptiles, birds, and mammals) plus lungfish and coelacanth as 468 outgroups were aligned using ClustalW with default parameters. The optimal parameters for 469 phylogenetic reconstruction were taken from the best-fit amino acid substitution model based on 470 Akaike Information Criterion (AIC) as implemented in ModelTest-NG v.0.1.5 [42], and was inferred to be JTT+G4+F. An initial phylogeny was inferred using RAxML HPC v.8 [43] under the 471 472 JTT+GAMMA model with empirical amino acid frequencies. Branch lengths and node support 473 (aLRS) were further refined using PhyML v.3.1 [44] with empirical amino acid frequencies and 474 maximum likelihood estimates of rate heterogeneity parameters, I and  $\Gamma$ . Phylogeny visualization 475 and mapping of character states for each paralog was done using the R package ggtree [45].

476

#### 477 Ancestral sequence reconstruction and convergence calculations

478 Ancestral sequence reconstruction was performed in PAML using codeml [46] under the JTT+G4+F 479 substitution model. Ancestral sequences from all nodes in the ATP1A phylogeny were combined 480 with extant sequences to produce a 1040 amino-acid multiple sequence alignment of 1,660 ATP1A 481 proteins (831 extant species and 829 inferred ancestral sequences; Fig. S1). For each branch in 482 the tree, we determined the occurrence of substitutions by using the ancestral and derived amino 483 acid states at each site using only states with posterior probability (PP) > 0.8. All branch pairs were 484 compared, except sister branches and ancestor-descendent pairs [20,21]. When comparing 485 substitutions on two distinct branches at the same site, substitutions to the same amino acid state 486 were counted as convergences, while substitutions away from a common amino acid were counted as divergences. We excluded a putative 30 amino acid-long alternatively-spliced region (positions 487 488 810-840). For each pairwise comparison, we calculated the proportion of observed convergent 489 events per branch as (number of convergences +1) / (number of divergences +1). The line 490 describing the trend was calculated as a running average with a window size of 0.05 491 substitutions/site. 95% confidence intervals were estimated based on 100 random samples of 492 pairwise branch comparisons for each window. To determine whether convergence at sites 111 493 or 122 decreases with sequence divergence, we encoded convergence events as "1" and divergence events as "0" for all pairwise sequence comparisons and used a logistic regression to 494 495 test for the correlation between molecular convergence (0 or 1) and genetic distance (Fig. S4).

#### 496 Identifying correlated substitutions.

We used BayesTraits [47] to detect sites across the ATP1A phylogeny that exhibit correlated evolution with sites 111 and 122. Using the reconstructed ancestral sequences for each paralogous clade (i.e., the most recent common ancestor (MRCA) of ATP1A1, the MRCA of ATP1A2, and the MRCA of ATP1A3), we coded each amino acid state among extant sequences of the multi-species alignment into ancestral '0' and derived '1' states, and used these plus the phylogeny with 502 estimated branch lengths as inputs for BayesTraits. BayesTraits fits a continuous-time Markov 503 model to estimate transition rates between discrete, binary traits and estimates the best fitting 504 model describing their joint evolution on a phylogeny. Specifically, we tested whether the rate of 505 evolution at sites 111 and 122 was dependent on all other variant sites (see below). We excluded 506 singleton sites and sites with more than 80% gaps, as these sites would be of little information, 507 resulting in an analysis of 417 variant sites.

508 We tested two sets of models, hereafter referred as base and restricted models, each of which has 509 a null independent and an alternative dependent model. The null independent model assumes that the two sites evolve independently, and the alternative dependent model assumes that the sites 510 511 are correlated such that the change at one site is dependent on the state at the other site. Because 512 the null model is a general form of the alternative model, both models can be compared under a 513 likelihood ratio test (LRT) with degrees of freedom (df) equal to the difference in the number of 514 parameters between models. The base and restricted sets of models differ on the presence of 515 restricted parameters for certain transition rates, and consequently differ in the number of df. In the 516 base models, the null model has four rate parameters describing each possible independent 517 change of state at each site; the alternative model has eight rate parameters describing all possible 518 changes at each site dependent on the state at the other site (LRT with df=4). For the restricted 519 models, we set the rates of transition to the ancestral state to zero [23] as the median branch length 520 of the tree of 0.002351 substitutions per site makes it unlikely for a site to change twice or back to 521 the ancestral state. After these restrictions, the null independent model had four transition 522 parameters. To test for dependence, we imposed two additional restrictions to the model: one 523 forcing the transition rate at site one to be fixed regardless of the state of site 2 (q13=q24), and a 524 second forcing the transition rate at site 2 to be fixed regardless of the state of site 1 (q12=q34) 525 [23]. This effectively tests whether the transition rate is affected by the state of either site and leaves 526 the model with only two transition parameters (LRT with df=2). To run the analysis, the phylogeny 527 branch lengths were scaled using BayesTraits to have a mean length of 0.1, and to increase the 528 chance of finding the true maximum likelihood, we set MLTries to 250.

#### 529 **Protein structure analysis.**

To test for spatial clustering of sites showing statistical signatures of coevolution with site 111 or 122, we used a custom Python script (available on request) and the Bio.PDB's module. We used the crystal structure of Na,K-ATPase (PDB: 3b8e) to estimate distances (in Angstroms) between the alpha carbon of site 111 or 122 to the alpha carbon of all other variable sites in the alignment. We calculated the median distance of the top 5% of variable sites with the strongest signature of correlated evolution with each focal site, 111 or 122 (from BayesTraits output). We estimated the p-value using 1000 random samples of 5% of variable sites and calculating the proportion of timesthe median value was less than or equal to the observed value.

538

#### 539 **Construction of expression vectors**.

540 ATP1A1 and ATP1B1 wild-type sequences for the eight selected tetrapod species (Fig. 4) were synthesized by Invitrogen<sup>TM</sup> GeneArt. The  $\beta$ 1-subunit genes were inserted into pFastBac Dual 541 542 expression vectors (Life Technologies) at the p10 promoter with Xhol and Pael (FastDigest Thermo 543 Scientific<sup>™</sup>) and then control sequenced. The α1-subunit genes were inserted at the PH promoter 544 of vectors already containing the corresponding  $\beta$ 1-subunit proteins using In-Fusion® HD Cloning 545 Kit (Takara Bio, USA Inc.) and control sequenced. All resulting vectors had the α1-subunit gene 546 under the control of the PH promoter and a  $\beta$ 1-subunit gene under the p10 promoter. The resulting 547 eight vectors were then subjected to site-directed mutagenesis (QuickChange II XL Kit; Agilent 548 Technologies, La Jolla, CA, USA) to introduce the codons of interest. In total, 21 vectors were 549 produced (Table S3).

550

#### 551 Generation of recombinant viruses and transfection into Sf9 cells.

552 Escherichia coli DH10bac cells harboring the baculovirus genome (bacmid) and a transposition 553 helper vector (Life Technologies) were transformed according to the manufacturer's protocol with 554 expression vectors containing the different gene constructs. Recombinant bacmids were selected 555 through PCR screening, grown, and isolated. Subsequently, Sf9 cells (4 x 10<sup>5</sup> cells\*ml) in 2 ml of Insect-Xpress medium (Lonza, Walkersville, MD, USA) were transfected with recombinant bacmids 556 557 using Cellfectin reagent (Life Technologies). After a three-day incubation period, recombinant 558 baculoviruses were isolated (P1) and used to infect fresh Sf9 cells (1.2 x 10<sup>6</sup> cells\*ml) in 10 ml of 559 Insect-Xpress medium (Lonza, Walkersville, MD, USA) with 15 mg/ml gentamycin (Roth, Karlsruhe, 560 Germany) at a multiplicity of infection of 0.1. Five days after infection, the amplified viruses were 561 harvested (P2 stock).

562

#### 563 Preparation of Sf9 membranes.

564 For production of recombinant NKA, Sf9 cells were infected with the P2 viral stock at a multiplicity 565 of infection of 10<sup>3</sup>. The cells (1.6 x 10<sup>6</sup> cells\*ml) were grown in 50 ml of Insect-Xpress medium (Lonza, Walkersville, MD, USA) with 15 mg/ml gentamycin (Roth, Karlsruhe, Germany) at 27°C in 566 567 500 ml flasks (35). After 3 days, Sf9 cells were harvested by centrifugation at 20,000 x g for 10 min. 568 The cells were stored at -80 °C and then resuspended at 0 °C in 15 ml of homogenization buffer 569 (0.25 M sucrose, 2 mM EDTA, and 25 mM HEPES/Tris; pH 7.0). The resuspended cells were 570 sonicated at 60 W (Bandelin Electronic Company, Berlin, Germany) for three 45 s intervals at 0 °C. 571 The cell suspension was then subjected to centrifugation for 30 min at 10,000 x g (J2-21 centrifuge,

Beckmann-Coulter, Krefeld, Germany). The supernatant was collected and further centrifuged for
60 m at 100,000 x g at 4 °C (Ultra- Centrifuge L-80, Beckmann-Coulter) to pellet the cell
membranes. The pelleted membranes were washed once and resuspended in ROTIPURAN® p.a.,
ACS water (Roth) and stored at -20 °C. Protein concentrations were determined by Bradford assays
using bovine serum albumin as a standard. Three biological replicates were produced for each
NKA construct.

578

#### 579 Verification by SDS-PAGE/western blotting.

580 For each biological replicate, 10 µg of protein were solubilized in 4x SDS-polyacrylamide gel 581 electrophoresis sample buffer and separated on SDS gels containing 10% acrylamide. 582 Subsequently, they were blotted on nitrocellulose membrane (HP42.1, Roth). To block non-specific 583 binding sites after blotting, the membrane was incubated with 5% dried milk in TBS-Tween 20 for 1 h. After blocking, the membranes were incubated overnight at 4 °C with the primary monoclonal 584 585 antibody α5 (Developmental Studies Hybridoma Bank, University of Iowa, Iowa City, IA, USA). 586 Since only membrane proteins were isolated from transfected cells, detection of the  $\alpha$  subunit also 587 indicates the presence of the  $\beta$  subunit. The primary antibody was detected using a goat-anti-588 mouse secondary antibody conjugated with horseradish peroxidase (Dianova, Hamburg, 589 Germany). The staining of the precipitated polypeptide-antibody complexes was performed by 590 addition of 60 mg 4-chloro-1 naphtol (Sigma-Aldrich, Taufkirchen, Germany) in 20 ml ice-cold methanol to 100 ml phosphate buffered saline (PBS) containing 60 μl 30% H<sub>2</sub>O<sub>2</sub>. See Fig. S8. 591

592

#### 593 **Ouabain inhibition assay.**

594 To determine the sensitivity of each NKA construct against cardiotonic steroids (CTS), we used the water-soluble cardiac glycoside, ouabain (Acros Organics), as our representative CTS. 100 ug of 595 596 each protein was pipetted into each well in a nine-well row on a 96-well microplate (Fisherbrand) 597 containing stabilizing buffers (see buffer formulas in [48]). Each well in the nine-well row was exposed to exponentially decreasing concentrations of ouabain (10<sup>-3</sup> M, 10<sup>-4</sup> M, 10<sup>-5</sup> M, 10<sup>-6</sup> M, 10<sup>-5</sup> 598 599 <sup>7</sup> M, 10<sup>-8</sup> M, dissolved in distilled H<sub>2</sub>O), plus distilled water only (experimental control), and a combination of an inhibition buffer lacking KCl and 10<sup>-2</sup> M ouabain to measure background protein 600 601 activity [48]. The proteins were incubated at 37°C and 200 rpms for 10 minutes on a microplate 602 shaker (Quantifoil Instruments, Jena, Germany). Next, ATP (Sigma Aldrich) was added to each 603 well and the proteins were incubated again at 37°C and 200 rpms for 20 minutes. The activity of 604 NKA following ouabain exposure was determined by quantification of inorganic phosphate (Pi) 605 released from enzymatically hydrolyzed ATP. Reaction Pi levels were measured according to the 606 procedure described in Taussky and Shorr [49] (see Petschenka et al. [48]). All assays were run in 607 duplicate and the average of the two technical replicates was used for subsequent statistical analyses. Absorbance for each well was measured at 650 nm with a plate absorbance reader
(BioRad Model 680 spectrophotometer and software package). See Table S4.

610

#### 611 ATP hydrolysis assay.

To determine the functional efficiency of different NKA constructs, we calculated the amount of Pi hydrolyzed from ATP per mg of protein per minute. The measurements (the mean of two technical replicates) were obtained from the same assay as described above. In brief, absorbance from the experimental control reactions, in which 100  $\mu$ g of protein was incubated without any inhibiting factors (i.e., ouabain or buffer excluding KCI), were measured and translated to mM Pi from a standard curve that was run in parallel (1.2 mM Pi, 1 mM Pi, 0.8 mM Pi, 0.6 mM Pi, 0.4 mM Pi, 0.2 mM Pi, 0 mM Pi). See Table S4.

619

#### 620 Statistical analyses of functional data.

621 ATPase activity in the presence and absence of the CTS ouabain was measured following 622 Petschenka et al. [48]. Background phosphate absorbance levels from reactions with inhibiting 623 factors were used to calibrate phosphate absorbance. For ouabain sensitivity measurements, these 624 calibrated absorbance values were converted to percentage non-inhibited NKA activity based on 625 measurements from the control wells (as above). For each of the 3 biological replicates, log10 IC<sub>50</sub> 626 values were estimated using a four-parameter logistic curve, with the top asymptote set to 100 and 627 the bottom asymptote set to zero, using the nlsLM function of the minipack. Im library in R [25]. To 628 measure baseline recombinant protein activity, the calculated Pi concentrations of 100 µg of protein 629 assayed in the absence of ouabain were converted to nmol Pi/mg protein/min. We used paired t-630 tests with Bonferroni corrections to identify significant differences between constructs with and 631 without engineered substitutions. We used a two-way ANOVA to test for background dependence 632 of substitutions (i.e., interaction between background and amino acid substitution) with respect to 633 ouabain resistance (log10  $IC_{50}$ ) and protein activity. Specifically, we tested whether the effects of a 634 substitution X->Y are equal on different backgrounds (null hypothesis: X->Y (background 1) = X-635 >Y (background 2)). We further assumed that the effects of a substitution X->Y should match that 636 of Y->X. All statistical analyses were implemented in R. Data were plotted using the ggplot2 637 package in R.

638

Additionally, we evaluated the relationship between the effect of substitutions to a given amino acid state and the extent of sequence divergence between the protein backgrounds on which these

641 substitutions were tested. To do this, we first calculated the effect of introducing a derived amino

- 642 acid state as the percent change in protein activity relative to the wild-type protein. For example,
- 643 the effect of the mutation N122D in Chinchilla (CHI) is

644 
$$E_{CHI,N122D} = ([(CHI_{N122D}) - (CHI_{wt})] / (CHI_{wt})) \times 100;$$

645 We then calculated the absolute difference between effects of substitutions to the same amino acid 646 on two different backgrounds. For example, the difference ( $\Delta$ ) in the effect of 122D when introduced 647 to the Chinchilla (CHI, mammal) and false fer-de-lance (FER, snake) proteins is

648

$$\Delta_{CHI-FER,X122D} = |E_{CHI,N122D} - E_{FER,H122D}|$$

These calculations were possible for 11 pairwise comparisons (4 for site 111 and 7 for site 122; Table S7). We then evaluated the relationship between the estimated differences in the effects of substitutions to a given state versus the extent of protein sequence divergence (number of amino acid differences) between wild-type backgrounds.

653

To identify variant sites that most strongly predicted background-dependent effects in our data, we employed a site-by-site ANOVA analysis. For each of the eleven pairwise comparisons (e.g.,  $\Delta_{CHI-FER,X122D}$ ) each variant site was encoded as '0' or '1' if the wild-type sequences had the same or different amino acid state, respectively. This binarized per-site divergence (0 or 1) was used as the dependent variable in the ANOVA, with sites 111 or 122 (the mutated sites) as a covariate (Fig. S5A). For each of the 113 variant sites among the eight wild-type proteins, we then estimated that site's marginal variance explained.

661

662 Given the limited number of wild-type backgrounds (8) relative to the number of sites (113), and use of constructs in multiple comparisons, strong correlations occur some variant sites (Fig. S5B). 663 664 We thus grouped sites according to how they partition the divergence in experimental pairwise 665 sequence comparisons. Grouping sites with Pearson's r >0.8 results in 24 groups. Using one 666 representative site per group, we then fitted nested ANOVA models to determine how much of 667 variation in the  $\Delta$  is explained by adding an additional group of sites, adding groups in the order of 668 largest (group 1) to smallest (group 24) amount of variance explained. Using Likelihood Ratio Tests 669 (LRTs) and Akaike's Information Criteria (AIC), we identified the best model as the one including 670 only the first two groups, which represent a total of 16 sites (14 sites in group 1 and two sites in 671 group 2; Fig. S5C and Table S9). These 16 sites account for 78% of the variance (ANOVA R<sup>2</sup>). 672 Since groups 1 and 2 were ascertained as those accounting for the largest proportion of the 673 variance, we established the significance of this observation by permutation. Specifically, we 674 performed 10,000 permutations of the experimental pairwise  $\Delta$  across construct comparisons and 675 repeated the procedure that was applied to the observed data to obtain a null distribution of R<sup>2</sup> 676 values. The p-value is estimated as the probability of finding two groups of sites that explain  $R^2 \ge 1$ 677 0.78. We further evaluated the extent of correlation (estimated as Pearson's r) between  $\Delta$  and sequence divergence at the 16 sites identified above. Similarly, to test for the significance of our regression model between  $\Delta$  and divergence, we estimated the p-value as the probability of

- observing a Pearson's r of 0.78 (or  $R^2$  of 0.61) or larger based on 10,000 permuted samples (permuting effects, Δ, across construct comparisons). To determine the robustness of our results
- 681 (permuting effects,  $\Delta$ , across construct comparisons). To determine the robustness of our results 682 to the grouping criteria, we did the same analyses using a higher cutoff of Pearson's r > 0.99 (Table
- 683
- 684

#### 821 Figures and Tables

824

822 823

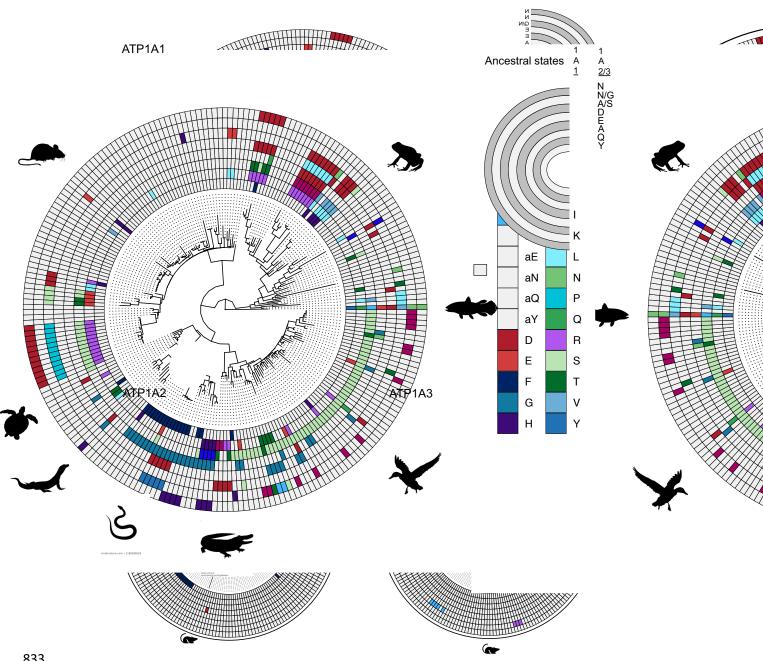

825 Figure 1. Na,K-ATPase structure and phylogenetic relationships of ATP1A paralogs among

vertebrates. (A) Crystal structure of an Na<sup>+</sup>,K<sup>+</sup>-ATPase (NKA) with a bound the representative CTS
 bufalin in blue (PDB 4RES). The zoomed-in panel shows the H1-H2 extracellular loop, highlighting

two amino acid positions (111 and 122 in red) that have been implicated repeatedly in CTS

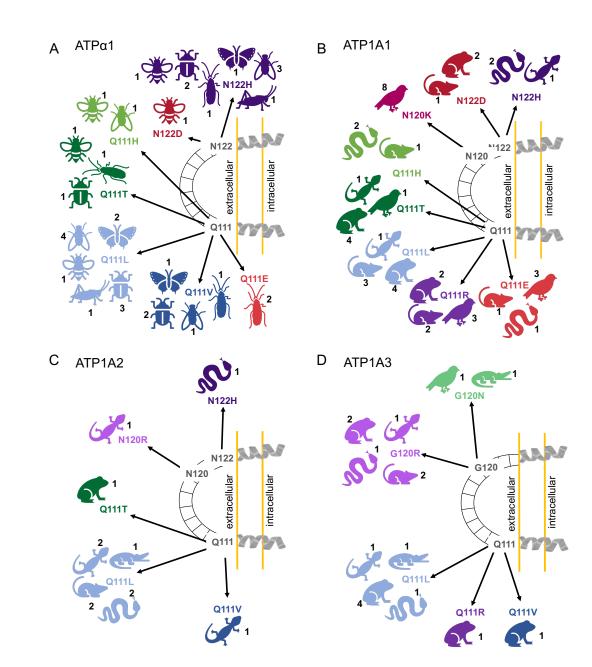

resistance. We highlight key examples of convergence in amino acid substitutions at sites in the

H1-H2 extracellular loop associated with CTS resistance in Fig. 3. (B) Phylogenetic relationships
 among ATP1A paralogs of vertebrates and ATPα of insects.

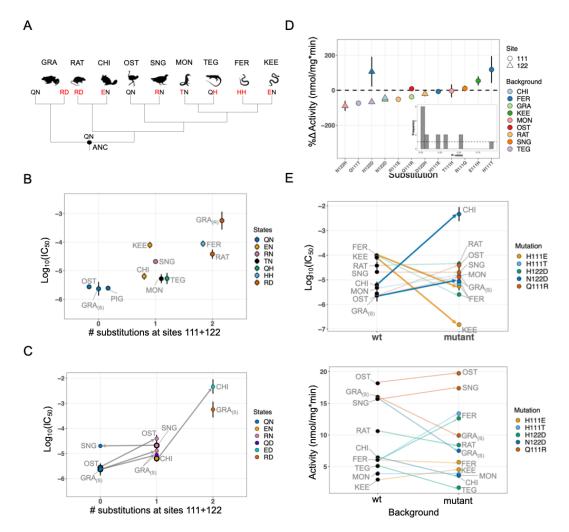

833

834 Figure 2. Patterns of molecular evolution in the  $\alpha$ (H1–H2) extracellular loop of ATP1A 835 paralogs shared among tetrapods. (A) Maximum likelihood phylogeny of tetrapod ATP1A1, (B) ATP1A2, and (C) ATP1A3. The character states for eight sites relevant to CTS resistance in and 836 near the H1-H2 loop of the NKA protein are shown at the node tips. Yellow internal nodes indicate 837 ancestral sequences reconstructed to infer derived amino acid states across clades to ease 838 839 visualization; nodes reconstructed: most recent common ancestor (MRCA) of mammals, of reptiles, 840 and of amphibians. Top right, each semi-circle indicates the site mapped in the main phylogeny 841 with the inferred ancestral amino acid state for each of the three yellow nodes (posterior probability 842 >0.8). In ATP1A1, site 119 was inferred as Q119 for amphibians and mammals, and N119 for 843 reptiles (Table S6); in ATP1A2-3 site 119 was inferred as A119 for amphibians and reptiles, and 844 S119 for mammals (Table S6). Site number corresponds to pig (Sus scrofa) reference sequence. 845 Higher number and variation of substitutions in ATP1A1 stand out in comparison to the other 846 paralogs.

848 849

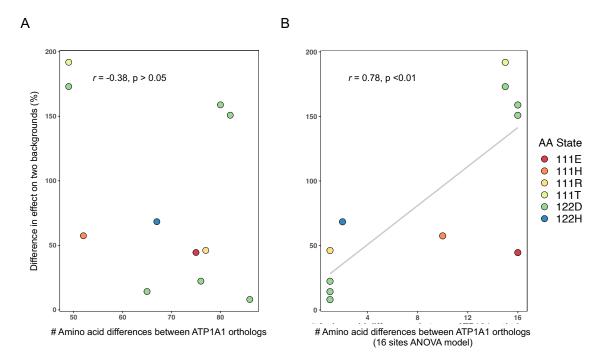

850 Figure 3. Parallel and divergent patterns of CTS-resistant substitutions across ATP $\alpha$ 1 of 851 insects and the shared ATP1A paralogs of tetrapods. Examples of convergence in ATP $\alpha$ 1 across insects (A). Convergence in the (B) ATP1A1, (C) ATP1A2, and (D) ATP1A3 paralogs, 852 respectively, across tetrapods. Numbers indicate the number of independent substitutions in each 853 major clade depicted. For ATP1A3, resistance-conferring amino acid substitutions have been 854 855 identified at site 120, and not 122. A full list of amino acid substitutions can be found in 856 Supplementary Dataset 2 for tetrapods, and Taverner et al. [23] for insects.

859 Figure 4. Functional properties of wild-type and engineered ATP1A1. (A) Cladogram relating 860 the surveyed species. GRA: Grass Frog (Leptodactylus); RAT: Rat (Rattus); CHI: Chinchilla (Chinchilla); OST: Ostrich (Struthio); SNG: Sandgrouse (Pterocles); MON: Monitor lizard 861 862 (Varanus): TEG: Tegu lizard (Tupinambis): FER: False fer-de-lance (Xenodon): KEE: Red-necked 863 keelback snake (Rhabdophis). Two-letter codes underneath each avatar indicate native amino acid 864 states at sites 111 and 122, respectively. Data for grass frog from Mohammadi et al. [25]. (B) Levels 865 of CTS resistance (IC50) among wild-type enzymes. The x-axis distinguishes among ATP1A1 with 866 0, 1 or 2 derived states at sites 111 and 122. The subscripts S and R refer to the CTS-sensitive and CTS-resistant paralogs, respectively. (C) Effects on CTS resistance ( $IC_{50}$ ) of changing the 867 868 number of substitutions at 111 or 122. Substitutions result in predictable changes to resistance 869 except in the reversal R111Q in Sandgrouse (SNG). GRAs represents Q111R+N122D on the 870 sensitive paralog background. (D) Effects of single substitutions on Na,K-ATPase (NKA) activity. 871 Each modified ATP1A1 is compared to the wild-type enzyme for that species. The inset shows the distribution of *t*-test p-values for all 15 substitutions, with the dotted line indicating the expectation. 872 873 (E) Evidence for epistasis for CTS resistance (IC50, upper panel) and lack of such effects for 874 enzyme activity (lower panel). Each line compares the same substitution (or the reverse 875 substitution) tested on at least two backgrounds. Thicker lines correspond to substitutions with 876 significant sequence-context dependent effects (Bonferroni-corrected ANOVA p-values < 0.05, 877 Table S5).

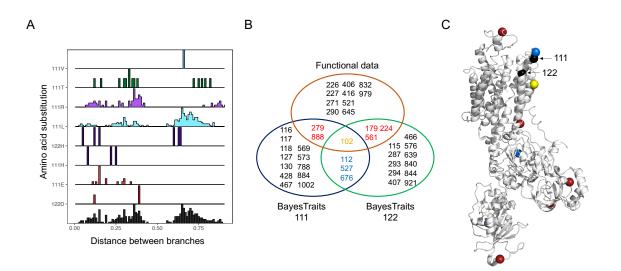

878

880

881 Figure 5. A small number of sites account for a large proportion of the differences in pleiotropic effects of the same substitution on divergent backgrounds. (A) The difference in 882 effect size of a mutation to a given state on two different backgrounds as a function of divergence 883 884 at all sites. Each point represents a comparison between the effect (% change in activity relative to 885 the wild-type enzyme) of a given amino acid state (e.g., 122D) on two different genetic backgrounds. 886 For example, the effect of 122D between chinchilla and false fer-de-lance is measured as  $|\Delta\%\rangle$ 887 [chinchilla vs. chinchilla+N122D] minus the  $\Delta$ % [false fer-de-lance vs. false fer-de-lance+H122D]]. 888 Comparisons were measured as the difference between the two effects. The x-axis represents the 889 number of amino acid differences between two wild-type ATP1A1 proteins (i.e., backgrounds) being 890 compared. Assuming intramolecular epistasis for protein function is prevalent, a positive correlation 891 is predicted. In total, 11 comparisons were possible, and no significant correlation is observed when 892 considering divergence at all sites. (B) The difference in effect size of a mutation to a given state 893 on two different backgrounds as a function of divergence at a subset of 16 sites with the largest 894 effects on the difference in activity between two backgrounds. The p-value of the correlation was 895 determined by permuting effects among constructs and generating a null distribution of correlations. 896

898 Figure 6. (A) Distribution of amino acid substitutions at sites 111 and 122 across all paralogs. For 899 each derived amino acid state at sites 111 and 122, the histograms show the distribution of pairwise 900 convergent events along the sequence divergence axis (expected number of substitutions per site). 901 Substitutions are color coded as in Fig. 2. The histogram at the bottom shows the combined 902 distribution of pairwise convergent events for both sites. (B) Intersection of 16 sites identified from 903 functional data with the sites that most strongly correlated with substitutions at sites 111 and 122 904 Sites in the "functional data" group correspond to the 16 sites from the two groups identified by the 905 ANOVA model (Tables S8 and S9). Sites in the BayesTraits analyses groups correspond to the top 906 5% sites with highest -log(P) association with 111 or 122, respectively. Overlaps between each 907 group are larger than expected by chance: Functional  $\cap$  Bayes Traits 111 = 3, P = 0.049; Functional  $\cap$ 908 BayesTraits122 = 4, P = 0.007; BayesTraits111 $\cap$  BayesTraits122 = 4, P = 0.011. (C) Crystal 909 structure of ATP1A1 (PDB 3B8E) showing sites color coded according to the intersections in panel 910 Β.
