ABSTRACT

There is considerable evidence that cross-talk between the Hedgehog pathway and MAPK signaling pathways occurs in several types of cancer, and contributes to the emergence of clinical resistance to Hedgehog pathway inhibitors. Here, we demonstrate that MAP kinase-mediated phosphorylation weakens the binding of the GLI1 transcription factor to its negative regulator SUFU. We show that ERK2 phosphorylates GLI1 on three evolutionarily-conserved target sites (S102, S116 and S130) located near the high-affinity binding site for the negative regulator SUFU; furthermore, these phosphorylation events cooperate to weaken the affinity of GLI1-SUFU binding by over 25 fold. Phosphorylation of any one, or even any two, of the three sites does not result in the level of SUFU release seen when all three sites are phosphorylated. Tumor-derived mutations in R100 and S105, residues bordering S102, also diminish SUFU binding, collectively defining a novel evolutionarily-conserved SUFU-affinity-modulating region. In cultured mammalian cells, mutant GLI1 variants containing phosphomimetic substitutions of S102, S116 and S130 displayed an increased ability to drive transcription. We conclude that of multisite phosphorylation of GLI1 by ERK2 or other MAP kinases weakens GLI1-SUFU binding, thereby facilitating GLI1 activation and contributing to both physiological and pathological crosstalk.

INTRODUCTION

Integration between different signaling pathways is a crucial aspect of cellular regulation, as these pathways must work together in a coordinated manner to achieve specific physiological goals. On the other hand, such crosstalk signaling can also be dysregulated in disease, contributing significantly to pathology.

Indeed, there is evidence that crosstalk between the Hedgehog (HH) pathway and mitogen-activated protein kinase (MAPK) signaling pathways may be relevant to developmental signaling and to several types of cancer [reviewed in (Aberger & Ruiz i Altaba, 2014; Pietrobono *et al*, 2019; Rovida & Stecca, 2015)]. These cancers include basal cell carcinoma, the most frequent adult cancer; medulloblastoma, the most common childhood brain cancer; and melanoma and pancreatic adenocarcinoma, some of the deadliest of cancers (Pak & Segal, 2016; Raleigh & Reiter, 2019; Teglund & Toftgard, 2010; Wu *et al*, 2017a). Additional evidence suggests that

MAPK crosstalk signaling may contribute to the emergence of clinical resistance to HH pathway inhibitors (Atwood *et al*, 2012; Boumahdi & de Sauvage, 2020).

In the developing embryo, HH signaling is widespread, and it plays a crucial role in patterning, proliferation and differentiation; in adults, HH signaling acts on stem/progenitor cells to regulate tissue homeostasis, regeneration and repair (Ingham *et al*, 2011; Kong *et al*, 2019; Lee *et al*, 2016; Robbins *et al*, 2012). HH, a secreted, cholesterol-modified ligand, binds to a transmembrane receptor designated Patched1 (PTCH1). Unliganded PTCH1 inhibits the function of the 7-transmembrane protein SMO, and this inhibition is relieved upon HH ligand binding to PTCH1. Interestingly, the initial steps of HH signaling occur in the primary cilium, an organelle that protrudes from the surface of most mammalian cells during growth arrest (Bangs & Anderson, 2017). Defective HH signaling results in birth defects, and dysregulated HH signaling is involved in a large number of cancers (Pak & Segal, 2016; Raleigh & Reiter, 2019; Teglund & Toftgard, 2010; Wu *et al*, 2017a).

The ultimate targets of activated SMO are the transcription factors GLI1, GLI2, and GLI3 (Hui & Angers, 2011). In unstimulated cells, the GLI proteins are found in cytoplasmic complexes with a 54 kDa protein designated SUFU (named after the fly ortholog *Suppressor of fused*). Upon SMO activation, GLI-SUFU complexes have been observed to move into the primary cilium, wherein GLI proteins become activated by a mechanism that is thought to involve dissociation of SUFU, coupled with changes in the post-translational modification and processing of GLI (Humke *et al*, 2010; Niewiadomski *et al*, 2014; Tukachinsky *et al*, 2010). The active GLI factors then enter the nucleus and promote transcription. GLI proteins are DNA-binding zinc finger transcription factors that bind to the consensus element GACCACCA. Active GLI1 has been shown to regulate target genes that include *CYCLIN D1 and D2*, *FOXM1*, *BCL2*, *TERT* and *GLI1* itself (Mazumdar *et al*, 2013).

SUFU is a key negative regulator of the three GLI transcription factors, and the dissociation of SUFU is considered to be a key step in GLI activation (Huang *et al*, 2018; Pak & Segal, 2016; Svard *et al*, 2006). A short, high-affinity binding site for SUFU, ¹²⁰SYGHLS¹²⁵, was identified in the N-terminal portion of GLI1 (Dunaeva *et al*, 2003). Subsequent crystallographic studies showed that peptides containing these six residues bind in a narrow channel between the N-terminal and C-terminal lobes of the bi-lobed SUFU structure (Cherry *et al*, 2013; Zhang *et al*, 2013). Germline loss-of-function mutations in *SUFU* predispose to common pediatric and adult brain cancers (Aavikko *et al*, 2012; Smith *et al*, 2014; Taylor *et al*, 2002), and are also found in patients with Gorlin syndrome and Joubert syndrome (De Mori *et al*, 2017; Pastorino *et al*, 2009; Smith *et al*, 2014). Somatic *SUFU* mutations have also been found in various cancers, including sporadic basal cell carcinomas, where they have been shown to inappropriately enable GLI1-driven transcription (Urman *et al*, 2016).

MAPK cascades are typically found embedded in signaling networks that transmit many different signals, including those initiated by growth and development factors, inflammatory stimuli, and cellular stresses (Morrison, 2012; Raman *et al*, 2007). A well-known example is the RAS/MAPK cascade, which transmits signals from growth factor receptors to effectors that promote cell division (Futran *et al*, 2013; Lavoie *et al*, 2020). Components of this pathway are frequently mutated in human cancer and developmental disorders, resulting in constitutive activation of the ERK1 and ERK2 MAPKs (Bardwell, 2020; Tidyman & Rauen, 2016). Activated MAPKs phosphorylate numerous targets, including many transcription factors (Unal *et al*, 2017; Yoon & Seger, 2006; Zeke *et al*, 2016).

The question of how MAP kinases (and other protein kinases) recognize their substrates is of considerable interest (Bardwell, 2006; Miller & Turk, 2018). The target site that MAPKs phosphorylate – a serine or threonine followed by a proline – is too degenerate to provide the requisite specificity for target recognition. Instead, MAPKs frequently tether themselves to their substrates by binding to a short linear motif designated a MAPK-docking site or ‘D-site’ (Bardwell & Bardwell, 2015; Bardwell *et al*, 2009). D-sites in substrates are typically located near a cluster

of target phosphosites, and D-site binding to MAPKs directs phosphorylation to these sites. The presence of a D-site, particularly if near a cluster of Ser-Pro or Thr-Pro (SP or TP) sites, can be used to identify putative novel substrates (Gordon *et al*, 2013; Zeke *et al*, 2015). Previously, during the course of such a bioinformatic search for novel human proteins containing predicted D-sites, we identified the GLI transcription factors as putative MAPK substrates (Whisenant *et al*, 2010).

Here, we demonstrate that MAPK-mediated phosphorylation of an N-terminal region of GLI1 near the major SUFU-binding site results in a dramatic weakening of SUFU binding to this region and a consequent release of repression. We identify three target phosphosites that are collectively necessary and sufficient for this effect, and we show that these three phosphorylated residues act cooperatively in SUFU release. In addition, we show that full-length GLI1 alleles containing phosphomimetic substitutions of these three residues are hyperactive in driving transcription in cells. Furthermore, we characterize mutations found in tumor samples that define an expanded SUFU-affinity-modulating region. Our findings suggest a mechanism that contributes to MAPK-mediated cross-activation of GLI-driven transcription.

RESULTS

ERK2 phosphorylation of GLI1 modulates GLI1-SUFU binding

In a previous study, we exploited the observation that MAPKs briefly attach to many of their substrates before phosphorylating them to develop D-finder, a computational tool that searches genome databases for MAPK-docking sites (Whisenant *et al*, 2010). Among the novel substrates predicted by D-finder were human GLI1, GLI2 and GLI3. Using *in vitro* binding and protein kinase assays, we demonstrated that both ERK and JNK-family MAPKs could bind to human GLI1 and GLI3 via the predicted D-site and phosphorylate nearby target residues. We also used mass spectrometry to determine that Ser343 in GLI3 was phosphorylated by ERK and JNK, and showed that the efficiency of this phosphorylation was dependent on the integrity of the D-site. Finally, we showed by mutagenesis that Ser130 in GLI1 (the comparable residue to Ser 343 in GLI3) was also phosphorylated by both ERK and JNK (Whisenant *et al*, 2010).

As shown in Fig 1, the D-site and S130 phosphosite of GLI1 are located near the binding site for SUFU, a key negative regulator of GLI1 function (Hui & Angers, 2011). This arrangement of functional motifs suggested that MAPK-mediated phosphorylation might regulate Gli-SUFU binding. To investigate this hypothesis, we developed an *in vitro* GLI1-SUFU binding assay. To accomplish this, we first purified GST-GLI1₆₈₋₂₃₂, a fusion of residues 68-232 of the 1106 residue human GLI1 protein to the glutathione-S-transferase affinity purification tag (Fig 2A). GLI1₆₈₋₂₃₂ contains the D-site, the SUFU binding site, and all nearby putative MAPK phosphosites, and is readily purified from bacteria. Following purification, varying amounts of GST-GLI1₆₈₋₂₃₂ protein were mixed with limiting amounts of full-length human SUFU protein that had been produced in radiolabeled form by *in vitro* transcription and translation. After a 15-minute binding incubation, glutathione-Sepharose beads were added, and protein complexes were isolated by co-sedimentation and quantified by SDS-PAGE followed by Phosphorimager analysis. In this assay, SUFU protein bound quite tightly to GLI1, with a K_d of ~4 nM (Fig 2A). These results are consistent with other published measurements of the binding affinity between GLI1 and SUFU (Cherry *et al*, 2013; Szczepny *et al*, 2014).

Having identified the appropriate range of protein concentrations at which to test the GLI1-SUFU interaction, we developed a protocol to ask if MAPK-phosphorylated GLI1 exhibited diminished binding to SUFU when compared to unphosphorylated GLI1. Purified GST-GLI1⁶⁸⁻²³² was first phosphorylated to high stoichiometry (~3 moles phosphate per mole substrate) with purified active ERK2. The kinase reaction was then halted with EDTA, and glutathione-Sepharose beads were added to capture the GLI1. Following the removal of the kinase and ATP by extensive washing of the beads, radiolabeled SUFU was added and a binding assay was performed. A parallel “mock” sample was treated identically except that the ERK2 enzyme was omitted (Fig 2A). As shown in Fig 2B, unphosphorylated GLI1 bound with high affinity to SUFU, whereas ERK2-phosphorylated GLI1 displayed substantially reduced binding affinity. Quantification of eight independent experiments revealed that the GLI1-SUFU dissociation constant was increased almost 30-fold by ERK2-mediated phosphorylation of GLI1 (Fig 2C). Note that increases in the dissociation constant (K_d) correspond to proportional decreases in affinity, as K_d is the reciprocal of the affinity constant. Similarly, increases in K_d correspond to decreases in the amount of protein complex formed. For example, a 10-fold increase in K_d can result in up to a 90% decrease in amount of heterodimer formed, and a 30-fold increase in K_d can result in up to a 97% decrease, depending on the concentrations of the interacting proteins relative to the K_d of their interaction. For convenience, we hereafter refer to the ability of ERK2-mediated phosphorylation of GLI1 to weaken the GLI1-SUFU interaction as ‘ERK2-mediated SUFU release’, or more simply, ‘SUFU release’.

Phosphorylation occurs on canonical sites and is necessary for binding modulation

MAPK's are proline-directed kinases, and thus, in the vast majority of cases, phosphorylate their substrates on serines or threonines that are immediately followed by prolines (i.e. SP or TP). GST-GLI1₆₈₋₂₃₂ contains seven SP motifs (S70, S86, S102, S116, S130, S146, and S201), and no TP motifs. To determine if phosphorylation of one or more of these seven sites was necessary for ERK2-mediated SUFU release, we constructed a mutant version of GST-GLI1₆₈₋₂₃₂, designated GLI1^{7A}, in which all 7 serines in these SP motifs were changed to alanines by site-directed mutagenesis.

Following purification, both wild-type GLI1 and GLI1^{7A} were then either treated with purified active ERK2 or mock treated, and then assessed for binding to SUFU (Fig 3A). During this process, part of each sample was removed and spiked with radioactive ATP to quantify phosphate incorporation. As shown in Fig 3B, compared to wild-type GLI1₆₈₋₂₃₂, GLI1^{7A} was only minimally phosphorylated by ERK2, indicating that the vast majority of ERK-mediated phosphorylation occurs at one or more of the seven canonical SP sites.

When assessed for SUFU binding, there was a substantial difference between phosphorylated vs. mock-treated wild-type GLI1 (Fig 3C), consistent with the findings presented in Fig 2. In contrast, there was no observable difference in the affinity of ERK2-treated vs. mock-treated GLI1^{7A} for SUFU (Fig 3C). When the results of five independent experiments were quantified, it was apparent that mock-treated GLI1^{7A} displayed a somewhat reduced affinity for SUFU compared to mock-treated wild-type GLI1 (Fig 3D). This suggested that one or more of the seven Ser-to-Ala mutations in GLI1^{7A} marginally destabilizes the GLI1-SUFU interaction, perhaps by slightly altering the conformation of the binding domain. Indeed, further experiments, reported below, indicated that the S102A substitution was the major contributor to this destabilization. Quantification of the effect on the dissociation constant is shown in Fig 3E. In this set of experiments, SUFU bound to unphosphorylated wild-type GST-GLI1 with K_d of 3 nM, and this was weakened by over 30-fold when GLI1 was phosphorylated by ERK2. In contrast, both mock-treated and ERK2-treated GLI1^{7A} bound to SUFU with a K_d of approximately 23 nM. Importantly, treatment of GLI1^{7A} with active ERK2 had no effect on SUFU binding. Furthermore, while the difference in the K_d for SUFU binding between mock-treated and ERK2-treated wild-type GLI1 was highly significant ($p < 0.0001$), the difference between mock-treated and ERK2-treated GLI1^{7A} was not statistically significant ($p = 0.57$). Based on these results, we concluded that ERK2-mediated phosphorylation at one or more of the seven SP sites present in GLI1₆₈₋₂₃₂ is required for ERK2-mediated SUFU release.

Ser102, Ser116 and Ser130 are efficiently phosphorylated by ERK2

In order to measure the phosphorylation efficiency of each of the seven SP sites individually, a series of 'single phosphosite only' mutants were constructed. In these seven mutants, only one of the seven SP phosphorylation sites remains intact, and the other six are mutated to alanine. Each of these mutant derivatives was then purified individually and tested in kinase assays. As determined by the incorporation of the gamma phosphate radioactive ATP in the presence of active ERK, the most efficient target sites in GLI1 were Ser116 and Ser 130, followed by Ser 102 and Ser 201. Phosphorylation of the other 3 sites was minimal (Fig 4).

Phosphorylation of S102, S116 and/or S130 are necessary and sufficient for SUFU release

We focused our further analysis on S102, S116 and S130, as these three residues are the closest to the SUFU-binding motif (Fig 1), and were also the three sites most efficiently phosphorylated by ERK2 (Fig 4). To ask if the integrity of these three sites was necessary for ERK-mediated SUFU release, we constructed a mutant derivative in which all three of these serines (and only these serines) were substituted with alanine (GLI1^{AAA}, Fig 5A). This mutant, when mock-treated, bound to SUFU with a K_d of 17 nM (Fig 5B,C,D). Notably, upon phosphorylation, the binding of this mutant did not appreciably change (K_d 20 nM); that is, there was no detectable release of SUFU. This result demonstrates that phosphorylation of one or more of the residues S102, S116 and/or S130 is necessary for SUFU release. In addition, since S70,

S86, S146 and S201 remained intact in this mutant, this result also demonstrates that phosphorylation of these four residues plays little or no role in promoting SUFU release.

To ask if the presence of these three MAPK phosphosites was sufficient for ERK-mediated SUFU release, we constructed a mutant derivative of GLI1₆₈₋₂₃₂ in which only S102, S116 and S130 were left intact, and the other MAPK phosphosites (S70, S86, S146 and S201) were mutated to alanine (Fig 5A). This mutant, which we designated GLI1^{SSS}, was then either phosphorylated by active ERK2 or mock treated (as shown in Fig 3A for WT vs. 7A), and then tested for binding to radiolabeled SUFU. As shown in Fig 5, mock-treated GLI1^{SSS} protein bound to SUFU with a K_d of 2.6 nM (rounded to 3 nM in Fig 5C), essentially indistinguishable from the

K_d of 4 nM observed for wild-type GLI1 tested in parallel in the same set of experiments. Likewise, ERK-phosphorylated GLI1^{SSS} protein was efficiently released from SUFU, as shown by a K_d increase from 3 to 127 nM upon phosphorylation; this magnitude was even greater than the increase to 93 nM observed for wild-type GLI1. Thus, the binding of both wild-type GLI1 and GLI1^{SSS} to SUFU was weakened by over 35-fold by ERK2-mediated phosphorylation, resulting in efficient SUFU release (Fig 5B,C,E). These results indicate that phosphorylation on one or more of the residues S102, S116 and/or S130 is sufficient for SUFU release. In addition, since serines 70, 86, 146 and 201 were mutated to alanine in this mutant, this result also demonstrates that phosphorylation of one or more of these four residues is not required for SUFU release. Statistical analysis of these results is presented further below.

Phosphorylated residues cooperate to promote SUFU release

To delineate the differential contribution of phosphorylated S102, S116 and S130 to SUFU release, we constructed a series of six additional mutant versions of GST-GLI1₆₈₋₂₃₂ containing serine to alanine substitutions of one or two of these three critical residues. In addition, each of these mutants also had serine to alanine substitutions at residues 70, 86, 146 and 201, so that in total they contained only a single MAPK-phosphorylatable serine (as in Fig 4) or two phosphorylatable serines (Fig 5A).

Analysis of the full set of 9 alleles (8 mutant alleles plus wild type) revealed that all four alleles carrying an S102A substitution (GLI1^{AAA}, GLI1^{S116}, GLI1^{S130}, and GLI1^{S116,S130}; see Fig 5A) displayed weaker binding to SUFU than the five alleles in which the native serine at position 102 was maintained. These findings are consistent with the results obtained with the 7A allele (see Fig 3), and suggest that replacing GLI1 Ser102 with alanine weakens binding to SUFU, increasing the dissociation constant by about 3.5-fold.

Despite this complication, the outcome of this set of experiments was quite clear. First, the results obtained with GLI1^{S102}, GLI1^{S116}, and GLI1^{S130}, the three mutants where 'one site only' remained intact, indicated that the phosphorylation of any single residue was not sufficient for full SUFU release. For example, mock-treated GLI1^{S102} bound to SUFU with an affinity comparable to mock-treated wild-type GLI1 and mock-treated GLI1^{SSS} (K_d ~3 nM; Fig 5C). Upon phosphorylation, however, the K_d of GLI1^{S102} increased by less than 5 fold, to 14 nM. Similarly, mock-treated GLI1^{S116} bound to SUFU with a K_d of 14 nM, and this increased by 2.6-fold upon phosphorylation. For GLI1^{S130}, there was only a 1.3-fold reduction in SUFU-binding affinity following ERK2 treatment. These modest changes in binding affinity are substantially less than the 35-fold change observed following ERK2 phosphorylation of GLI1^{SSS}, in which all three key phosphorylation sites are intact.

Three mutant constructs contained two of the three residues S102, S116 or S130 intact, with the third mutated to alanine (these are labelled 'two sites only' in Fig 5C). These mutants, when phosphorylated by ERK2, exhibited levels of SUFU release that was greater than the corresponding 'one site only' mutants, but substantially less than wild-type or GLI1^{SSS}. For the three 'one site only'-intact mutants, the K_d increased an average of 3-fold following ERK2-mediated phosphorylation (range of 1.3 - 4.7). For the three 'two sites only'-intact mutants, the K_d increased about 7-fold following ERK2-mediated phosphorylation (range 4.8 - 8.3). Only when all three sites were intact (wild-type and GLI1^{SSS}) was the dramatic 35+-fold increase in K_d observed upon phosphorylation. Statistical analysis of these results is presented in the next section.

Taken together, these results indicate that phosphorylation of all three residues, S102, S116 and S130, are required for the level of SUFU release exhibited by wild-type GLI1. Phosphorylation of any single residue is not sufficient for full SUFU release, nor is phosphorylation of any two of the three residues.

Statistical analysis of the effect of multisite phosphorylation on SUFU release

To assess the statistical significance of the results shown in Fig 5, we used Welch's T-test, which does not assume that the different populations sampled have the same variance (Ruxton, 2006). Welch's test is more conservative, that is, less likely to lead to false positives, than the standard t-test. Given that we planned to perform multiple comparisons, it was also important to apply a correction for multiple hypothesis testing. We chose to use the Bonferroni correction, which is the most conservative correction (Abdi, 2007). Applying this correction, an adjusted p-value threshold for 95% confidence of 0.0025 ($= 0.05/20$) was chosen, since we planned a total of 20 comparisons. The Bonferroni correction makes the threshold for significance more stringent by a factor equal to the number of planned comparisons; see Materials and Methods for further details.

First, we determined for each mutant allele, if the observed increase in the Kd for SUFU-binding upon phosphorylation was significant (i.e. we compared each mutant to itself, mock-treated vs. phosphorylated, for a total of 8 comparisons). For all mutants except AAA ($p = .18$) and S130-only ($p = .006$, which does not fall below the Bonferroni-corrected threshold of 0.0025) the observed Kd increase upon phosphorylation was highly significant ($p < 0.0001$).

Next, we asked if the Kd of 130 ± 20 nM that we measured for the phosphorylated GLI1^{SSS} mutant, which has all three key phosphosites intact, was significantly different from the Kds of the phosphorylated single and double-phosphosite mutants (which ranged from 14 ± 4 to 53 ± 10 nM; total of 6 comparisons). Indeed, the difference between the 130 nM Kd and any of the other 6 Kds was highly significant ($p < .0001$). Thus, when all three key phosphosites are intact, there is significantly more SUFU release than when any two of the three are present, or any single one.

The final set of 6 comparisons we performed was to compare each phosphorylated 'one site only' mutant to each of the 'two sites only' mutants of which it was part. For example, we compared the Kd of ERK2-treated GLI1^{S102} (14 ± 4 nM) to the Kd of ERK2-treated GLI1^{S102,S116} (43 ± 8 nM), as well as to the Kd of ERK2-treated GLI1^{S102,S130} (25 ± 3 nM). This analysis revealed that GLI1^{S102} was significantly different than both of the corresponding 'two sites only' mutants, as was GLI1^{S130} (all p values < 0.001). However, GLI1^{S116} was not significantly different from either GLI1^{S102,S116} ($p = 0.09$) or GLI1^{S116,S130} ($p = 0.003$, which barely misses the Bonferroni-corrected threshold of 0.0025).

Phosphomimetic substitution of GLI1 S102, S116 and S130 decrease GLI1 binding to SUFU

To assess the involvement of GLI1 residues S102, S116 and S130 in SUFU binding using a different approach than shown in Figs. 2-5, we substituted one, both, or all three of these key serine residues with the amino acid glutamate, which resembles phosphoserine in its size and negative charge. In order to keep our analysis focused on the N-terminus of GLI1, these substitutions were made in a plasmid encoding GLI1 residues 1-232 downstream of a T7 RNA polymerase promoter.

Next, full-length human SUFU protein was produced in, and purified from, *E. coli* bacteria as an N-terminal GST fusion protein. The purified GST-SUFU was then tested for binding to wild-type GLI1₁₋₂₃₂ that had been produced and radiolabeled by *in vitro* transcription/translation, as well as to the various GLI1₁₋₂₃₂ phosphomimetic substitution alleles (Fig 6).

As shown in Fig 6C and 6D, GST-SUFU bound tightly to radiolabeled wild-type GLI1₁₋₂₃₂ (Kd 8 nm \pm 2). Indeed, the affinity of this interaction was comparable to the previous experiments (Figs 2, 3, 5) assessing GST-GLI1₆₈₋₂₃₂ binding to radiolabeled full-length SUFU. Of the 3 single phosphomimetic substitutions, S102E had the largest effect, reducing GLI1-SUFU binding affinity by about 8-fold. The S102E S130E double mutant had a larger effect (38-fold). Furthermore, the S102E S116E S130E triple mutant had the largest effect (65-fold). Indeed, with one exception, every double mutant had a greater effect than either of the corresponding single mutants (the exception is that S116E, S130E was not different from S130E alone, as detailed further below). Moreover, the triple mutant had a greater effect than any of the three double mutants. Thus,

phosphomimetic substitutions in these three residues cooperated to weaken SUFU binding, and this cooperation was super-additive, or synergistic, with regard to the effect on binding affinity.

To determine statistical significance, we performed the following planned comparisons: (1) the wild type was compared to each of seven mutants; (2) each of the three double mutants was compared with the two corresponding single mutants (for instance, the 102E,116E double mutant was compared to the 102E single mutant and to the 116E single mutant); and (3) the EEE triple mutant was compared to each of the three double mutants. These 16 comparisons were performed using Welch's t-test, as was done for the analysis in Fig 5. Given that multiple comparisons were being performed, it was also important to apply a correction for multiple hypothesis testing. Again, we chose to use the Bonferroni correction, which is the most conservative correction. Applying this correction, a p-value threshold of 0.003 ($= 0.05/16$) was chosen. All but two of the 16 comparisons were significant at this level: S116E was not significantly different than wild-type ($p = 0.66$), and S116E,S130E was not significantly different than S130E ($p = 0.47$). While phosphomimetic substitution of S116 had no effect on its, own or in combination of with S130E, it did have an effect in two other contexts. First, S102E, by itself, reduced GLI1-SUFU binding affinity by about 8-fold, whereas the S102E S116E double mutant had a slightly larger effect (12-fold). Second, as mentioned above, the S102E S116E S130E triple mutant had a much larger effect on SUFU binding (65-fold increase in K_d) than the S102E S130E double mutant (38-fold).

Phosphomimetic substitutions have a reduced effect on full-length GLI1

The experiments presented in Figs 2, 4 and 5 show that ERK2-mediated phosphorylation of key residues near the MAPK-docking site and SUFU-binding motif have a dramatic effect on the ability of GLI1₆₈₋₂₃₂ to bind to full-length SUFU. Similarly, the experiments shown in Fig 6 demonstrate that phosphomimetic substitution of those same key residues in the context of GLI1₁₋₂₃₂ have a dramatic effect on the ability of GLI1₁₋₂₃₂ to bind to full-length GST-SUFU. We were unable to purify full-length, soluble, GLI1 protein from bacteria, and thus we could not biochemically assess the effect of ERK2-mediated phosphorylation on the ability of full-length GLI1 to bind to SUFU. Nevertheless, our ability to purify full-length GST-SUFU from bacteria, and to produce full-length, soluble GLI1 (and mutants thereof) by *in vitro* transcription/translation, allowed us to assess the effect of phosphomimetic substitutions on the binding affinity of full-length GLI1 to full-length SUFU (Fig 6E).

As shown in Fig 6E, full-length GLI1 protein bound to GST-SUFU with an affinity ($K_d = 14 \text{ nM} \pm 4$) comparable to the affinity that GLI1₁₋₂₃₂ protein bound to GST-SUFU ($K_d = 8 \text{ nM} \pm 2$). In contrast, the reduction in affinity caused by the S102E S116E S130E triple mutation was less dramatic in the context of full-length GLI1 ($K_d = 42 \text{ nM} \pm 8$, a 3-fold decrease in affinity) than in the context of GLI1₁₋₂₃₂, where there was a 65-fold decrease in affinity. To provide a further point of comparison, we introduced the G122A,H123A double substitution into full-length GLI1. These substitutions lie in the core of the ¹²⁰SYGHLS¹²⁵ SUFU-binding motif, and were previously shown to substantially reduce the binding of SUFU to the N-terminus of GLI1 (Dunaeva *et al.*, 2003). Full-length GLI1^{G122A,H123A} displayed about 10-fold reduced affinity for GST-SUFU ($K_d = 120 \text{ nM} \pm 35$).

Some GLI1 somatic mutations found in tumors reduce binding to SUFU

Our finding that SUFU binding was diminished by phosphorylation of, or phosphomimetic substitution of, GLI1 S102, S116 and S130, led us to ask if the region between the D-site and S130 might either (a) be a part of an extended N-terminal SUFU-binding region that was larger than the recognized minimal SUFU-binding motif (GLI1 residues 120-125), or (b) communicate allosterically with the SUFU-binding motif. Consistent with these possibilities, the region between and including the D-site and the SUFU-binding site is conserved between human GLI1, GLI2 and GLI3 (Fig 7C), and, as shown in the next section, is also conserved between GLI orthologs present in most of the major animal phyla (Fig 8).

Figure 7. Effect of tumor-derived mutations on GLI1 binding to SUFU

- A** Radiolabeled GLI1₁₋₂₃₂ alleles were assessed for binding to GST-SUFU protein.
- B** GLI1-SUFU binding isotherms of selected mutants. The data points on the graph are an average of 3 or 4 different experiments.
- C** The chart shows which single substitutions in GLI1₁₋₂₃₂ had a no effect (defined as an affinity change that was either less than 2-fold, and/or was not statistically significant), a minor effect (affinity decrease between 2 and 5-fold that was statistically significant), a major effect (greater than 10-fold, significant), or a substantial effect (greater than 35-fold, significant). An alignment of human GLI1 residues 79-131 with the corresponding regions of human GLI2 and GLI3 is also shown, with the consensus shown below. Asterisks (*) indicate chemically similar residues that are also frequently substituted for one another in homologous sequences (Pearson, 1990).

To begin to investigate these possibilities, we chose 20 tumor-derived single-amino-acid substitution mutations in the region spanning residues 80-130 of GLI1, and used site-directed mutagenesis to introduce them into GLI1₁₋₂₃₂. These mutations were chosen from those documented in the COSMIC (catalog of somatic mutations in cancer) database (Tate *et al*, 2019), as well as from mutations found from targeted sequencing of the *GLI1* gene in advanced or drug resistant basal cell carcinomas (Supplemental Data 1). Mutant derivatives were then produced by *in vitro* transcription/translation and tested for binding to GST-SUFU. The relative binding of each mutant was compared to wild type GLI1₁₋₂₃₂, which was used as a positive control in every experiment. Since this procedure resulted in 20 planned comparisons, we used a Bonferroni correction factor of 20, resulting in an adjusted cut off for 95% confidence of $0.05/20 = 0.0025$.

In this set of experiments, wild type GLI1₁₋₂₃₂ bound to GST-SUFU with a K_d of 14 ± 4 nM. Sixteen of the 20 tumor-derived point mutations had no discernable effect on the binding of GLI1₁₋₂₃₂ to full-length GST-SUFU. This set included mutations in and around the D-site, including R81W, S84P and L88M, and S89L. The R81Q mutation had a small but reproducible and

statistically significant effect on binding ($K_d = 37 \pm 10$, a ~2.5-fold decrease in affinity; $p < 0.001$). These results suggest that the MAPK-docking site is not directly involved in SUFU binding, although a more comprehensive mutational scan will be required to definitively establish this. Likewise, tumor-derived substitutions in a stretch of 12 amino acids running from V107 to G118 did not affect binding to SUFU.

We tested two tumor-derived mutations in residues that flank S102: R100C and S105F (Fig 7B). R100C mutations have been found in a basal cell carcinoma, a head/neck squamous cell carcinoma and two different lung adenocarcinomas. This mutant exhibited a substantially reduced affinity for GST-SUFU ($K_d = 498 \pm 81$, a ~35-fold decrease in affinity). S105 somatic mutations have been found in five tumors: S105F in a head/neck cancer and a B cell leukemia, S105T in a liver cancer, and S105Y in two different lung cancers. The S105F mutation had a major effect on binding SUFU ($K_d = 181 \pm 30$ nM, a ~13-fold decrease in affinity). For the purposes of comparison, the S102A single mutation decreased affinity for SUFU by 3.5-fold (Fig 5), and the S102E single mutation decreased affinity for SUFU by 8-fold (Fig 6).

One tumor-derived mutation, L124P, was within the $^{120}\text{SYGHLS}^{125}$ SUFU-binding motif. This mutation, from a drug-resistant basal cell carcinoma patient, dramatically diminished GLI1-SUFU binding ($K_d = 3800 \pm 1600$ nM, a ~250-fold decrease in affinity).

Collectively, these results affirm the critical importance of the $^{120}\text{SYGHLS}^{125}$ SUFU-binding motif (Dunaeva *et al.*, 2003), yet additionally suggest that a small region that includes S102 and nearby residues (R100, S105) is also involved in SUFU binding.

The MAPK D-site and target phosphosites are evolutionarily conserved

We examined vertebrate orthologs of GLI1 for conservation of five motifs – the D-Site, the SP102, SP116, and SP130 phosphosites, and the SUFU-binding motif (Fig 8). For convenience, we will hereafter use the term ‘SP102’ to refer to Ser102-Pro103 in human GLI1, SP130 to refer to Ser130-Pro131 in human GLI1, etc. Moreover, we will also use the term ‘SP102’ to refer to the equivalent position in all orthologs, even though the residue numbers will naturally be different in these orthologs. Examination of 149 mammalian species indicated that all placental mammals possess all five of these motifs, with zero or minimal sequence changes when compared to human GLI1. The four marsupial species we examined, however, have PP rather than SP116. We also compared 61 bird species, 18 reptilian species, 6 amphibian species, and 74 fish species. We found that birds, reptiles, amphibians and fish possess four of the five motifs, with close agreement to the mammalian consensus, but – like marsupials – do not possess a MAPK phosphorylation site equivalent to SP116. The terrestrial classes lack the proline in the SP116 site, whereas fish lack the serine as well. Hence SP116 may be an invention of placental mammals, while the other four motifs are widely conserved in vertebrates.

We looked for conservation of the five motifs in the two non-vertebrate chordate subphyla – tunicates (e.g. sea squirts) and cephalochordates (lancelets) – as well as in the eight major invertebrate phyla (Fig 8B). In most non-vertebrate animal species, there is only one *GLI* gene, as the three vertebrate paralogs arose from two gene duplication events early in vertebrate evolution (Abbasi *et al.*, 2009). Hence, we were not surprised to find that the SP116 site is not conserved in invertebrates, as it appears to have originated in placental mammals. In contrast, a very close or exact fit to the D-site is present in chordates, echinoderms (e.g. sea urchins) and one of the most ancient animal phyla, Porifera (sponges). These D-sites are predicted to be fully functional for MAPK docking, as they contain an intact basic submotif (R/K-R-K in vertebrate GLI proteins) as well as an intact hydrophobic submotif (LSI in vertebrate GLI proteins). Both of these submotifs are important for MAPK binding and docking activity (Bardwell & Bardwell, 2015; Bardwell, 2006). In the other invertebrate model organisms examined, however, the hydrophobic submotif was lacking one or both hydrophobic residues, suggesting it may no longer function as a high-efficiency MAPK docking site in these species. The SP102 site is pan-chordate, and is also present in most invertebrate phyla, including two of the most ancient – Porifera (sponges) and

Cnidaria (sea anemones) – although in the three worm phyla and mollusks the proline has been lost. The SUFU-binding motif was, as expected, widely conserved. Finally, a site that may be equivalent to the SP130 site was also present in most of the species we examined; only in lancelets did we fail to find an SP within 10 residues of the SUFU-binding motif. To summarize, a functional D-site, SP102 site and SP130 site are present in GLI orthologs in most major animal phyla, whereas the SP116 site in GLI1 appears to be an innovation of placental mammals.

Interestingly, the R100 and S105 residues that we identified as being important for SUFU binding from scanning human tumor-derived GLI1 mutations (Fig 7) were also extremely well-conserved in all chordate and all invertebrate species that we examined, as was L106 (Fig 8). This suggests that these and neighboring residues may constitute an evolutionarily conserved region that functions to modulate the affinity of SUFU binding.

Substitution of phosphorylated residues alters GLI1 transcriptional activity in cells

To begin to investigate the physiological consequences of phosphorylation of GLI1 at S102, S116 and S130, we constructed two mutant derivatives of full-length (FL) GLI1 protein. The first mutant, FL-GLI1^{AAA}, contains serine-to-alanine substitutions at those three residues, and is therefore phosphodeficient. The second mutant, FL-GLI1^{EEE}, contains phosphomimetic serine-to-glutamate substitutions at those three residues; in Fig 6E, we showed that this mutant exhibits diminished SUFU-binding *in vitro*. Both variants were subcloned into the pCMV6-XL5 mammalian expression vector, resulting in constructs which drive the expression of full-length GLI1 cDNAs from the CMV promoter. These variants were then transiently transfected into Cos-1 cells, along with a luciferase reporter gene containing 12 copies of the consensus Gli-binding site (GACCACCCA) linked to a basal promoter (Kogerman *et al*, 1999). As shown in Fig 9A, vector-driven expression of wild-type GLI1 strongly activated the luciferase reporter in this system. Furthermore, compared to wild-type, the phosphomimetic mutant GLI1^{EEE} was hyperactive, driving a more than 2-fold increase in reporter activity. Moreover, this increase was statistically significant ($p < .01$). In contrast, the GLI1^{AAA} mutant displayed a slightly reduced ability to drive reporter expression compared to wild type, although this difference was not statistically significant. Immunoblot analysis showed that expression of all three proteins was roughly equivalent (Fig 9A). To summarize, these data show that phosphomimetic mutations in S102, S116 and S130 result in an increase in GLI1-driven transcription.

To achieve stable expression of FL-GLI1 variants, we used the piggyBac transposon system to integrate the wild-type, AAA and EEE alleles into the genome of NIH 3T3 cells. In addition, as a control, the L124P allele (a substitution in the SUFU-binding site derived from a drug-resistant basal cell carcinoma tumor) was also expressed using this system. Stable transformants were then treated with a conditioned medium derived from cells expressing active Sonic Hh (Shh-N), or with a control conditioned medium lacking Shh-N. To assay Hh pathway activity, expression of the endogenous mouse *Gli1* locus was monitored by reverse-transcription PCR (Fig 9B). As mentioned in the introduction, the *Gli1* gene is a target of the Hh pathway; thus, expression of this locus is a measure of the level of activation of endogenous Hh pathway output.

The results were interesting for several reasons. First, the expression of the endogenous mouse *Gli1* locus, driven by transfected wild-type human GLI1 protein, was inducible (2.2-fold) by Shh-N, as expected. Second, the L124P allele was hyperactive (by 2.9-fold) in the absence of induction, consistent with its *in vitro* SUFU-binding defect (Fig 7). Interestingly, this allele was also inducible by Shh-N (1.5-fold), suggesting that L124P is not completely defective in SUFU binding in cells, and/or that there are additional mechanisms by which GLI1-driven transcription can be potentiated by Hh pathway stimulation that are independent of SUFU release. Notably, the phosphodeficient triple mutant S102A, S116A, S130A (GLI1^{AAA}) was slightly less active than wild-type GLI1 in the absence of Shh-N, and, importantly, was not significantly induced by ligand. This suggests that, in cells, phosphorylation of one or more of these three residues is necessary for full GLI1 activation. Finally, the phosphomimetic triple mutant S102E, S116E, S130E (GLI1^{EEE}) was not discernably different from wild-type GLI1 in the absence of Shh-N. Strikingly, however, transcription driven by GLI1^{EEE} was substantially induced by ligand. Indeed, the level of induction exhibited by GLI1^{EEE} was significantly greater than wild-type (3.8-fold for GLI1^{EEE} vs 2.2-fold for wild-type GLI1). The lack of basal induction in the presence of GLI1^{EEE} indicates that phosphorylation of S102, S116, and/or S130 is not sufficient to activate GLI1 in NIH 3T3 cells. At the same time, the hyperinduction driven by GLI1^{EEE} in the presence of Shh ligand indicates phosphorylation of S102, S116, and/or S130 can potentiate transcription driven by activated GLI1.

DISCUSSION

Given the widespread involvement of MAP kinase pathways in cancer, the more concentrated involvement of HH/GLI in many tumor types, and the substantial evidence of crosstalk between these pathways, it is important to understand the molecular mechanisms of this crosstalk. Indeed, such understanding could suggest new strategies for targeted intervention in cancer, and improve our understanding of signal crossover and network rewiring in tumor cells (Aberger & Ruiz i Altaba, 2014; Caunt *et al.*, 2015; Pietrobono *et al.*, 2019; Samatar & Poulikakos, 2014; Yesilkanal *et al.*, 2021).

GLI1, GLI2 and GLI3 are the primary transcriptional effectors of the HH pathway. Responding to HH pathway signaling, GLI proteins regulate genes that promote self-renewal, proliferation, survival, and other processes. In recent years, however, evidence has accumulated indicating that GLI transcription factors receive inputs from many other pathways in the form of protein-protein interactions and post-translational modifications (Chen & Jiang, 2013; Montagnani & Stecca, 2019). These inputs presumably function to integrate the signaling status of the HH pathway and cross-regulating pathways into a coherent response.

Previously, we used a computational approach to identify a MAPK-docking site in the N-terminal portion of human GLI1, GLI2 and GLI3, and demonstrated that this D-site both bound to ERK2, and directed ERK2 to phosphorylate nearby target residues in GLI1. We also identified one of these sites as S343 in GLI3 and S130 in GLI1, both of which sit just C-terminal to the high-affinity binding site for SUFU (Whisenant *et al.*, 2010). Here we took a biochemical approach to identify additional MAPK target sites, and to investigate the consequences of MAP kinase-mediated phosphorylation of GLI1 in this region, and presented five major findings.

First, we showed that GLI1 bound to SUFU with high affinity, and that *in vitro* phosphorylation of purified GLI1₆₈₋₂₃₂ by purified, active ERK2 weakened the affinity of GLI1-SUFU binding by over 25-fold (Fig 2), an effect that we refer to as MAPK-mediated SUFU release. Second, we identified S102, S116 and S130 as the phosphorylation sites in the N-terminus of GLI1 that underlie this release, as we showed that phosphorylation of these three sites is both necessary and sufficient for this effect (Figs. 3-5). Third, we provided evidence that multisite phosphorylation of these three sites is required for full SUFU release: phosphorylation of any one, or even any two, of the three sites did not result in the level of SUFU release seen when all three sites were able to be phosphorylated (Fig 5). These findings were corroborated when we analyzed a set alleles containing phosphomimetic substitutions of S102, S116 and/or S130 in all possible combinations (Fig 6).

Our fourth major/key finding was the identification of a region of SUFU centered around Ser102 that plays a role in SUFU binding. We identified two GLI1 variants found in multiple patient-derived tumor samples, R100C and S105F, that substantially weakened SUFU binding (Fig 7), and have been highly conserved throughout animal evolution (Fig 8). Conceivably, R100, S102 and S105 may, like ¹²⁰SYGHLS¹²⁵, make direct contact with SUFU. Alternatively, these residues may act indirectly, by stabilizing a GLI1 conformation that is accessible to SUFU. Of note, we also showed that the L124P substitution in GLI1, identified in a vismodegib-resistant basal cell carcinoma, dramatically weakened binding to SUFU and potentiated GLI1-driven transcription, suggesting that this mutation may account for the acquired drug resistance seen in the patient (Figs 7, 9).

Finally, we showed that a mutant GLI1 allele containing phosphomimetic substitutions of S102, S116 and S130 displayed an increased ability to drive transcription of both a reporter gene and an authentic *GLI1* target gene. Conversely, substitution of S102, S116 and S130 with alanine (hence rendering them unphosphorylatable) resulted in a modest reduction in GLI1-driven transcription (Fig 9). Taken together, our results suggest that phosphorylation of GLI1 on S102, S116 and/or S130, mediated by ERK2 or other kinases, weakens GLI1-SUFU binding, thereby facilitating GLI1 activation.

MAPK phosphorylation occurs in an important regulatory region

For much of this study, we focused on a small region of GLI1, approximately 60 amino acids long, that contains both the ⁷⁹KKRALSI⁸⁵ D-site and the ¹²⁰SYGHLS¹²⁵ SUFU-binding motif. In this region, we characterized three ERK2-phosphorylation sites which cooperate to regulate SUFU binding. Additionally, we found three tumor-derived mutations in this region – R100C, S105F and L124P – that also disrupted SUFU binding. Interestingly, several other important functional motifs are also found in this region, including a degradation signal that spans the entire region (Huntzicker *et al*, 2006) and a ciliary localization signal that partially overlaps with the D-site and with the S70 and S86 MAPK target sites (Han *et al*, 2017). Other kinases also phosphorylate GLI1 in this region (Li *et al*, 2015; Schneider *et al*, 2015; Wang *et al*, 2012).

This ~60-residue region is well conserved between vertebrate and invertebrate GLI orthologs, as was first described by Croker *et al.*, who noted the homology in this region between *Drosophila Cubitus interruptus* (*Ci*), the founding *GLI* gene, and mouse and human GLI proteins (Croker *et al*, 2006). Here we extended this observation to all the major animal phyla, particularly focusing on the conservation of the D-site, the SUFU-binding motif, and the SP102, SP116, and SP130 phosphosites (Fig 8). While the SP116 site was highly conserved in placental mammals but not elsewhere, the other four sites were highly conserved in all vertebrates with minimal sequence changes, suggesting that MAPK-mediated regulation of GLI-SUFU binding may be widespread in vertebrates.

In fact, there are hints that such regulation may be present in some invertebrate organisms as well: A strong D-site (with consensus basic and hydrophobic submotifs) is present in chordates, sponges and echinoderms. SP102 is present in these phyla as well as arthropods and anemones, and all invertebrate models we examined had an SP130-like site within 10 residues of the ¹²⁰SYGHLS¹²⁵ SUFU-binding motif. MAP kinase cascades are present in virtually all eukaryotic organisms, and thus predate the evolution of the hedgehog signaling pathway, which is first found in animals, and presumed to have been absent from the last unicellular ancestor of animals (Babonis & Martindale, 2017; Ingham *et al.*, 2011). Hence, MAPK regulation of GLI transcription factors could conceivably have evolved contemporaneously with the origination of the first *GLI* gene.

Three closely spaced residues – R100, S102, and S105 – are strictly conserved in all chordate and invertebrate *GLI* orthologs we examined. Mutations in these residues, which are located about 20-25 residues N-terminal to the SYGHLS SUFU-binding motif, weakened SUFU binding affinity up to 35-fold (Fig 7). We propose that these and near-neighbor residues constitute a SUFU-affinity-modulating region that either contacts SUFU directly (i.e. orthosterically), or indirectly (i.e. allosterically) influences the ability of the SYGHLS motif to optimally engage with SUFU. Phosphorylation of this region on S102, whether by MAP kinases or other kinases, may be a mechanism of regulation of the GLI-SUFU interaction that is conserved throughout the animal kingdom.

Multisite phosphorylation regulates SUFU binding

What is the mechanism by which phosphorylation of S102, S116 and S130 in GLI1 cooperate in SUFU release? Phosphorylation of these residues might sterically interfere with a GLI1-SUFU binding. Alternatively, phosphorylation of these residues might initiate a structural rearrangement that results in the ¹²⁰SYGHLS¹²⁵ SUFU-binding motif being less accessible to SUFU. To gain further insight, it is necessary to understand how GLI1 SP102, SP116 and SP130 influence binding to SUFU both when phosphorylated and when unphosphorylated. Some hints come from structural studies of complexes of SUFU with GLI1-derived peptides. These studies showed that the ¹²⁰SYGHLS¹²⁵ motif binds directly (i.e. orthosterically) to SUFU by a β -strand addition mechanism, in which it combines with β -strands from both lobes of SUFU into a merged 3-stranded β -sheet (Cherry *et al.*, 2013; Zhang *et al.*, 2013). It is straightforward to envision how

phosphorylation of the serines/tyrosine in this motif might block SUFU binding by steric clash and/or electrostatic repulsion. There is no evidence, however, that these residues are phosphorylated by any kinases, and our data show that they are not phosphorylated by ERK2. The GLI1 peptide that Zhang *et al.* co-crystallized with SUFU spanned residues 112-128, and thus included SP116, but not SP102 or SP130. The GLI1 peptide used by Cherry *et al.* spanned residues 115-131, and thus included both SP116 and SP130, but again not SP102. In both studies, however, the SP sites did not have visible electron density, suggesting that they did not make direct contact with SUFU. For this reason, we lean in favor of allosteric communication as the mechanism by which phosphorylation of S102, S116 and S130 promotes SUFU release (Nussinov & Tsai, 2013). In this regard, it should be noted that the GLI1 112-128 peptide used by Zhang *et al.* bound to SUFU with micromolar affinity in isothermal titration calorimetry assays, and they obtained substantially better binding by using longer GLI1 peptides (e.g. 97-143) that included not only SP116 but also SP102 and SP130. This observation is compatible with the idea that residues around SP102 and SP130 play a role in SUFU binding; it is also compatible with either an orthosteric or allosteric influence of the three SP sites. Neither group examined the binding of phosphorylated versions of their peptides.

How might multisite phosphorylation-mediated allosteric inhibition of GLI1-SUFU binding work? To speculate on this question, it is helpful to examine studies that tackle related questions for other proteins (Nishi *et al.*, 2014). Conformational rearrangements may be initiated when phosphorylated residues form salt bridges with basic residues elsewhere in the protein (Pearlman *et al.*, 2011); these rearrangements can propagate to nearby regions of the protein (Kumar *et al.*, 2012). In NFAT, multisite phosphorylation favors a conformation that occludes a nuclear-localization signal (Shen *et al.*, 2005). Phosphorylation can also modulate the binding of an autoinhibitory domain, thereby occluding/revealing a binding site for another protein (Ferreon *et al.*, 2009). At a more abstract level, phosphorylation results in a change in free energy that favors one conformation over others. Multiple such changes (resulting from multisite phosphorylation) are additive at the level of free energy, but multiplicative in terms of their effect on the equilibrium constant, according to standard thermodynamic principles.

Multiple mechanisms of MAPK-mediated crosstalk

There are likely to be multiple mechanisms of crosstalk between the RAS/MAPK pathway and the HH pathway (Rovida & Stecca, 2015). This is certainly true if we consider the branched signaling pathways downstream of activated receptor tyrosine kinases or RAS (Eberl *et al.*, 2012), but is true even if we only focus on effects downstream of MAP kinase activation. ERK1/2 have a large number of substrates, including many transcription factors such as Elk-1, Ets1/2, Fos and Pax6, some of which could cooperate with GLI1 proteins to regulate particular subsets of target genes (Maik-Rachline *et al.*, 2019). Active ERK1/2 also activate several downstream kinases including MSK1/2 and pp90RSK (Morrison, 2012). These kinases could in turn regulate GLI proteins directly (by phosphorylating them), or indirectly (by phosphorylating other proteins). With respect to the latter possibility, activated pp90RSK has been shown to promote GLI2 stability by phosphorylating and thereby inhibiting GSK3 β , which is a negative regulator of GLI stability (Liu *et al.*, 2014). It seems likely that different mechanisms of crosstalk will predominate to a greater or lesser extent depending on the cell type and context, including the oncogenic load (Aberger & Ruiz i Altaba, 2014).

In this study, we focused on MAPK phosphorylation events in the N-terminus of GLI1, where the MAPK-docking site and SUFU-binding motif are located. We did not attempt to assess MAPK-mediated phosphorylation of residues distal to residue 232, although this might be a productive direction for future studies. There are no canonical MAPK target sites (SP or TP) in the DNA binding domain of GLI1 (residues 233-401). There are, however, a total of 12 SP and 3 TP sites in the remainder of the molecule.

Phosphomimetic substitutions of S102, S116 and S130 in full-length GLI1 did not lead to complete dissociation of SUFU, nor did mutations in the SUFU-binding motif (Fig 6E). This suggests that additional events may be required for full release of SUFU, and is consistent with evidence for a second SUFU-binding domain in the C-terminal portion of GLI1, GLI2 and fly Ci (Han *et al*, 2015; Merchant *et al*, 2004; Oh *et al*, 2015). SUFU, like GLI1, is subject to complex levels of regulation, and some of these might cooperate with GLI1 phosphorylation in the 75-135 region to promote full SUFU dissociation. In addition to binding to GLI1, GLI2 and GLI3, SUFU binds to several other proteins (Lin *et al*, 2014; Wu *et al*, 2017b), and is itself post translationally modified by phosphorylation and ubiquitylation (Chen *et al*, 2011; Infante *et al*, 2018; Raducu *et al*, 2016). Finally, we note that there is some evidence suggesting that GLI1 activation may lead to a structural rearrangement of the GLI1-SUFU complex, but not to complete dissociation of this complex (Zhang *et al*, 2017).

Conclusion

Here we have shown that the ERK2 MAP kinase directly phosphorylates GLI1 on multiple evolutionarily-conserved target sites near the SUFU-binding motif, thereby facilitating the release of SUFU from GLI1. We suggest that this MAPK-mediated SUFU release might be an important component of the molecular mechanism by which MAP kinases activate GLI1 in cancers and other pathological scenarios. We further suggest that phosphorylation of these residues may play a widespread role in Hedgehog signaling in animals.

MATERIALS AND METHODS

Genes

The mammalian genes used in this study were human *GLI1* (NCBI accession number NM_005269) and human *SUFU* (NM_016169).

Plasmids

The vector used for generating glutathione-S-transferase (GST) fusion proteins was pGEX-LB, a derivative of pGEX-4T-1. In pGEX-LB, an encoded Pro residue is replaced with a Gly-Gly-Gly-Gly-Gly-Ser-Gly coding sequence to promote the independent functioning of the GST and fusion moieties (Bardwell *et al.*, 2001). Plasmid GST-GLI1(68-232), which encodes a fusion of GST to residues 68-232 of human GLI1, was previously described (Whisenant *et al.*, 2010). Plasmid pGEM4Z-SUFU encodes full-length (residues 1-484) human SUFU downstream of a promoter for SP6 RNA polymerase. To construct this plasmid, the SUFU open reading frame was amplified by PCR using Open Biosystems clone 3533158 as the template and primers JB-SUFU-UP1 (5'-GCGGGATCCACCATGGCGGAGCTGCGGCCT) and JB-SUFU-DN1 (5'-GCGTCTGACTTAG TGTAGCGGACTGTCTGAACA). The PCR product was digested with the *Bam*HI and *Sal*I restriction enzymes and inserted into pGEM4Z (Promega) that had been digested with the same enzymes. Plasmid GST-SUFU encodes a fusion of GST to full-length human SUFU. To construct this plasmid, the *Bam*HI-SUFU-*Sal*I cassette described above was inserted into the corresponding sites of plasmid pGEXLB (Bardwell *et al.*, 2001). Quikchange (Invitrogen) was used for site-directed mutagenesis; all mutations were confirmed by sequencing. For the experiments shown in Fig 9A, we obtained a clone expressing full-length (residues 1-1106) untagged GLI1 in the pCMV6-XL5 vector backbone from OriGene Technologies (catalog number SC125780). For Fig 9B, we obtained a PiggyBac mApple fusion cassette derived from the EF1 constitutive active expression system PB-EF1-MCS-IRES-Neo (PB533A-2; Systems Biosciences) where mApple cDNA was inserted between *Nhe*I/*Eco*RI sites and the *GLI1* gene or its variants inserted into *Eco*RI downstream of mApple using the InFusion cloning kit (Takara Bio).

Quikchange (Invitrogen) was used for site-directed mutagenesis; all mutations were confirmed by sequencing.

Protein purification

GST fusion proteins were expressed in bacteria, purified by affinity chromatography using glutathione-Sepharose (GE Healthcare), eluted from the matrix by reduced glutathione, dialyzed to remove the glutathione, quantified by Bradford assay, and flash frozen in aliquots at 80 °C, as described elsewhere (Bardwell *et al.*, 2001; Gordon *et al.*, 2013; Whisenant *et al.*, 2010).

In vitro transcription and translation

Proteins labeled with [³⁵S]-methionine were produced by coupled transcription and translation reactions (SP6 or T7, Promega). Translation products were partially purified by ammonium sulfate precipitation (Bardwell & Shah, 2006), and resuspended in 'Binding Buffer' (20 mM Tris-HCl, pH 7.5, 125 mM KOAc, 0.5 mM EDTA, 5 mM DTT, 0.1% (v/v) Tween20, 12.5% (v/v) glycerol) prior to use in binding assays.

Protein kinase assays

The protein kinase assay shown in Fig 4 was performed as described elsewhere (Bardwell & Bardwell, 2015). The buffer for kinase assays was MAP kinase buffer (50 mM Tris-HCl (pH 7.5), 10 mM MgCl₂, 1 mM EGTA, and 2 mM DTT) with 50 μM ATP and 1 μCi of [γ-³²P]-ATP.

High efficiency phosphorylation of GST-GLI1₆₈₋₂₃₂ for use in SUFU binding assays (Figs 2, 3 and 5) was accomplished by incubating 1 μM (~1.8 μg) GST-GLI1₆₈₋₂₃₂ with 100 units (~10 ng) of purified active ERK2 for 2 hours at 30 °C in MAP kinase buffer with 400 μM ATP. Reactions were

then stopped by the addition of an excess volume of ice cold 1X Binding Buffer (described above) in which the EDTA had been raised to 10 mM. Mock-treated samples were treated identically except no ERK2 was added. The phosphorylated or mock-treated GST-GLI1₆₈₋₂₃₂ was then aliquoted to tubes at the appropriate concentration for the binding isotherm (final concentration 1.25 to 80 nM). Then, glutathione-Sepharose beads (20 µl of a 50% slurry) were added, the samples were rocked for 1 hr at room temperature, and the resulting bead-bound protein complexes were isolated by sedimentation and washed thoroughly in Binding Buffer. After that, ³⁵S-radiolabeled full-length human SUFU protein was added as described below.

Protein binding assays

For the experiments shown in Figs 6 and 7, ³⁵S radiolabeled GLI1 protein was prepared by *in vitro* translation and partially purified by ammonium sulfate precipitation. Approximately 1 pmol of ³⁵S-GLI1 was added to each 200 µl binding reaction; 10% of this amount was loaded in the 'Input' lane. Purified GST-SUFU was added at concentrations that varied from 1.25 to 80 nM. The buffer for binding reactions was Binding Buffer, described above. The binding reactions were incubated for 15 min at 30 °C. Then, glutathione-Sepharose beads (20 µl of a 50% slurry) were added, the samples were rocked for 1 hr at room temperature, and the resulting bead-bound protein complexes were isolated by sedimentation and resolved by 10% SDS-PAGE on the same gel. Other details of the protein binding assays are as described elsewhere (Bardwell *et al.*, 2001; Gordon *et al.*, 2013).

For the experiments shown in Figs 2, 3 and 5, ³⁵S radiolabeled full-length human SUFU protein was prepared by *in vitro* translation and partially purified by ammonium sulfate precipitation. Approximately 1 pmol of ³⁵S-SUFU was added to each 200 µl binding reaction; 10% of this amount was loaded in the 'Input' lane. The phosphorylated and mock-treated GST-GLI1₆₈₋₂₃₂ used in these assays was prepared as described above (see 'Protein kinase assays'). The binding reactions were incubated for 15 min at 30 °C, then rocked for 1 hr at room temperature. The resulting bead-bound protein complexes were isolated by sedimentation and resolved by 10% SDS-PAGE on the same gel.

Statistical analysis and fitting

Statistical analysis of binding assay results was performed using Welch's unequal variance t-test with two tails. The Bonferroni correction factors were obtained by dividing the standard p-value threshold of 0.05 by the number of planned comparisons. The Bonferroni correction addresses the following issue: in the absence of a correction for multiple hypothesis testing, if one were to test 20 hypotheses, all of which were false, with a 95% confidence threshold, the probability that one or more of them would appear true just by chance would be 1-.95²⁰, or 0.64. With the Bonferroni correction, the probability of one or more false positives occurring in the set of 20 comparisons is reduced to 1-.9975²⁰, which is less than 0.05.

All differences that were found to be significant by the Bonferroni-corrected Welch's t-test were also found to be significant using Dunnett's T3 multiple comparison test. Graphpad Prism and Microsoft Excel software packages were used for statistical analysis.

Binding isotherms analysis was conducted as follows: Emax and Kd for the wild-type protein were determined by fitting wild-type data from each experiment to the formula

$$\% = E_{max} \frac{x}{Kd + x}$$

where '%' is the percent of the radiolabeled protein bound, and *x* is the concentration of the GST-GLI1₆₈₋₂₂₃ or GST-SUFU (i.e. 1.25, 2.5, 5, 10, 20, 40 or 80 nM). The Emax for wild-type

was then used to normalize the wild type and all mutant variants analyzed in the same experiment.

Kd values for each concentration were determined from the formula

$$Kd = x \frac{100 - \%}{\%}$$

where ‘%’ and x are as defined above. The set of Kd values so obtained was used as the input array for the t-test.

Sequencing of *GLI1* alleles from vismodegib-resistant basal cell carcinoma samples

Five to eight 10-μm sections were obtained from the formalin-fixed, paraffin-embedded (FFPE) tumor block of resistant BCC tumors, and DNA was isolated using the QIAGEN DNeasy blood and tissue kit according to manufacturer’s protocol (QIAGEN). The exonic regions of *Gli1* were amplified using the Access Array platform (Fluidigm). The samples were amplified in a multiplex format with genomic DNA (100 ng) according to the manufacturer’s recommendation (Ambry Genetics). Subsequently, the multiplexed library pools were subjected to deep sequencing using the Illumina MiSeq platform. After demultiplexing and FASTQ file generation for the raw data, 150 base pair reads were aligned to the human reference genome sequence (hg19) using the BWA aligner. Samtools mpileup was used to call variants. Calls required a minimum allele frequency of 5% at a position with a read depth of >100. Identified variants were annotated using SeattleSeq138 to exclude non-pathogenic variants reported in dbSNP138 and to identify variants that had non-synonymous consequences or affected splice sites.

Sequence homology analysis

For the analysis shown in Fig 8A, we examined over 300 sequences from the U.S. National Center for Biotechnology Information (NCBI) vertebrate orthologs for *GLI1* <https://www.ncbi.nlm.nih.gov/gene/2735/ortholog/?scope=7776>. Predicted low quality sequences were omitted. For the analysis shown in Fig 8B, we BLASTed the sequence of human *GLI1* residues 75-135 against non-redundant protein sequences from the phylum indicated, using the *Choose Search Set* section of the BLAST form to limit the search to individual phyla or subphyla (Johnson *et al*, 2008).

Cell based assays

Luciferase assays were performed essentially as described previously (Sprowl-Tanio *et al*, 2016). COS-1 cells were transfected with 0.5 μg 12GLI-RE-TKO-luc (Kogerman *et al.*, 1999), 0.5 μg pCMV6-FL-GLI1 plasmid, and 0.1 μg thymidine kinase β-galactosidase plasmid using a lipofectin-based transfection reagent. Cells were harvested 24-hr post transfection and assayed for luciferase activity and β-galactosidase activity (used for normalization). Immunoblot analysis was also as described (Sprowl-Tanio *et al.*, 2016); the antibodies used were rabbit monoclonal anti-GLI1 (Clone EPR4523, Origene Technologies) at a 1:1000 dilution and anti-Lamin A/C (Cell Signaling Technologies 2032) at 1:1000.

Stable cells lines were generated using NIH3T3 cells and piggyBacTM transposons containing coding sequences for mApple and full-length human *GLI1*. Cells were transfected with PEI (NC1038561, Fisher Scientific) per the manufacturer’s protocol and then selected for using 500 μg/mL Geneticin G-418 (50841720, Fisher Scientific) until all non-transfected cells were no longer viable. NIH3T3 cell lines were plated to confluency, serum starved, and treated with Shh-N-conditioned media (1:100) for 24 hours. RNA was isolated using the Directzol RNA MiniPrep Plus (ZYMO Research). Real-time quantitative reverse-transcription polymerase chain reaction (RT-

qPCR) was performed using the iTaq Univer SYBR Green 1-Step Kit (Bio-Rad) on a StepOnePlus Real-time PCR system (Applied BioSystems) using primers for *Gli1* (forward: 5'-GCAGGTGTGAGGCC AGGTAG TGACGA TG-3', reverse: 5'-CGCGGG CAGCAC TGAGGA CTTGTC-3') and *mApple* (forward: 5'- ACCTAC AAGGCC AAGAAG CC -3', reverse: 5'-GCGTTC GTACTG TTCCAC GA -3'). Fold change in *Gli1* mRNA expression was measured using $\Delta\Delta C_t$ analysis with *mApple* as an internal control. Experiments were repeated three times, each experiment had triplicate technical replicates.

ACKNOWLEDGEMENTS

This work was supported by National Institute of General Medical Sciences research grant P50GM76516 and National Cancer Institute (NCI) award P30CA062203. M.L.W. and B.W. were also supported by NCI grants CA096878, CA108697, and U54CA217378. S.X.A was also supported by NCI grant CA237563. K.Y.S. is the D. G. "Mitch" Mitchell Clinical Investigator, and is supported by the Damon Runyon Cancer Research Foundation (CI-104-19) and NCI grant CA211793.
