35 Statement and Declarations

Funding statement. MB is supported by the Canadian Institutes of Health Research through the Canada
Graduate Scholarships – Master's Frederick Banting and Charles Best grant, the "Formation de maîtrise"
scholarship from the Fond de recherche en santé du Québec and an MSc scholarship from the Centre de
recherche de l'Institut universitaire de gériatrie de Montréal (CRIUGM). BP's research is supported by
the Natural Sciences and Engineering Research Council of Canada—Discovery Grants Program.

41 **Competing interests.** Maxime Bergevin, James Steele, Marie Payen de la Garanderie, Camille Féral-

Basin, Samuele Marcora, Pierre Rainville, Jeffrey Caron and Benjamin Pageaux have no conflict of
interest to disclose in respect to this manuscript.

44 Availability of data and material. All data and materials are available within the manuscript or in
 45 supplemental materials.

46 **Code availability**. Not applicable

47 Author contributions. MB, MPDLG, SM, JC and BP designed the study. MB and MPDLG performed 48 the literature search. MB, MPDLG, CFB, JC and BP designed decision flowchart to code identified 49 articles. MP and MPDLG performed risks of bias assessment. JS performed statistical analyses. MB, JS 50 and BP created the figures and tables. MB and JS wrote the first draft of this manuscript. JS, SM, PR, and 51 BP revised the first draft and final version of this manuscript. All authors approved the final manuscript.

53 Abstract

54 Background

55 The perception of effort (PE) provides information on task difficulty and influences physical 56 exercise regulation and human behavior. This perception differs from other-exercise related 57 perceptions such as pain. There is no consensus on the role of group III-IV muscle afferents 58 as a signal processed by the brain to generate PE.

59 **Objective**

60 The aim of this meta-analysis was to investigate the effect of pharmacologically blocking 61 muscle afferents on the PE.

62 Methods

63 Six databases were searched to identify studies measuring the ratings of perceived effort 64 (RPE) during physical exercise, with and without pharmacological blockade of muscle 65 afferents. Articles were coded based on the operational measurement used to distinguish 66 studies in which PE was assessed specifically (*effort dissociated*) or as a composite experience 67 including other exercise-related perceptions (*effort not dissociated*). Articles that did not 68 provide enough information for coding were assigned to the *unclear* group.

69 **Results**

The *effort dissociated* group (*n*=6) demonstrated a slight RPE increase with reduced muscle afferents feedback (standard mean change raw (SMCR), 0.39; 95%CI, 0.13 to 0.64). The group *effort not dissociated* (*n*=2) did not reveal conclusive results (SMCR, -0.29; 95%CI, -2.39 to 1.8). The group *unclear* (*n*=8) revealed a slight RPE decrease with reduced muscle afferents feedback (SMCR, -0.27; 95%CI, -0.50 to -0.04).

75 **Conclusions**

The heterogeneity in results between groups reveals that the inclusion of perceptions other than effort in its rating influences the RPE scores reported by the participants. The absence of decreased RPE in the *effort dissociated* group suggests that muscle afferents feedback is not a sensory signal of PE.

82

Key points (2-3 sentences summarizing, in non-technical language, the key findings/implications of the manuscript) 83 84 To date, there is no consensus on the neurophysiological signal processed by the brain to • 85 generate the perception of effort. 86 Following a systematic search in six databases, this meta-analysis suggests that reducing • 87 afferent feedback from the working muscles via epidural anesthesia does not reduce 88 perception of effort. This systematic review suggests that afferent feedback from the working muscles is not the 89 • 90 neurophysiological signal processed by the brain to generate the perception of effort. 91 3 sentences 92

93 **1. Introduction**

94 During physical exercise, the perception of effort provides information on how intense and difficult the 95 task being performed is perceived. The perception of effort is involved in the regulation of human behavior 96 [1] and influences how the nervous system selects a given movement amongst a myriad of possibilities 97 [2, 3]. The perception of effort is altered in the presence of fatigue [4] and various pathologies such as 98 chronic fatigue syndrome [5, 6], stroke [7] and cancer [8]. This perception is used to prescribe and monitor 99 exercise in both rehabilitation programs [9, 10] and athletic training [11-13]. Despite the growing interest 100 in this perception, to date, researchers have failed to reach a consensus on the signal(s) processed by the 101 brain leading to its generation [14-16].

102 One popular model amongst exercise physiologists, referred to as the afferent feedback model, suggests 103 that the feedback originating from the peripheral organs active during physical exercise (i.e., skeletal 104 muscles, heart, lungs) is processed by the central nervous system to generate the perception of effort [17, 105 18]. Notably, authors suggested that feedback from group III-IV muscle afferents plays an important role 106 the perception of effort [19-21]. The ratings of perceived effort intensity would then be predicted to 107 increase with higher discharge rates of the muscle afferents accompanying intense exercise [22, 23]. In 108 contrast, a popular model amongst neuroscientists and physiologists interested in the regulation of 109 cardiovascular responses during exercise and/or kinesthesia is the corollary discharge model. This model 110 proposes that the perception of effort is generated by the processing of a copy of the central motor command, named the corollary discharge [24-26]. In this model, an increase in the magnitude of the 111 112 central motor command should result in an increase in the perception of effort intensity [24, 27]. It is 113 important to note that this model does not bar peripheral contributions to the regulation of central 114 commands during voluntary movement, but states that central processing of afferent feedback does not 115 generate the perception of effort and that effort could be perceived in the absence of afferent feedback 116 [14, 15, 28, 29]. For example, any mechanisms able to alter the muscle force production capacity [24, 30] 117 or the corticospinal excitability – changes in cortical and/or spinal excitability influencing the ease with 118 which the central motor command is relayed to working muscles [31] – may modulate the perception of 119 effort by increasing or decreasing the magnitude of the central motor command needed to sustain a given 120 level of performance [32]. For instance, neuromuscular fatigue [24, 27] and pain [33, 34] have both been 121 suggested to affect muscle force production capacity and corticospinal excitability. As such, in the 122 presence of both phenomena, an increase of the central motor command might be required to recruit 123 additional motor units and keep the same level of performance, thereby increasing perceived effort.

124 A powerful technique to gain insights into the neurophysiology of the perception of effort and test the 125 existing models is by pharmacologically blocking group III-IV muscle afferent while monitoring the 126 perception of effort [e.g., 20, 28, 35, 36]. These specific muscle afferents have two important effects on 127 physiological responses to the exercise. First, their discharge ensures adequate cardiorespiratory responses 128 to physical exercise via their role in the exercise pressor reflex, also known as the mechano-metaboreflex 129 [37]. Second, while their inhibitory or excitatory effects on the corticospinal pathway seem to be muscle-130 dependent [38], recent studies suggest an overall net inhibitory effect on the corticospinal pathway during 131 endurance exercise, thus contributing to the development of neuromuscular fatigue [39]. Moreover, they 132 carry nociceptive signals and thus are involved in the perception of pain and associated discomfort [40]. 133 Since the afferent feedback model considers group III-IV muscle afferents as the signal processed by the 134 brain to generate the perception of effort, pharmacologically blocking muscle afferents should decrease 135 the ratings of perceived ratings of perceived effort. On the other hand, observing stable or increased ratings 136 of perceived effort in the presence of reduced muscle afferent feedback would support a centrally 137 generated perception of effort. Intrathecal and epidural injection of anesthetics or analgesics, such as 138 lidocaine or fentanyl, has traditionally been used to investigate the role of group III-IV muscle afferents 139 and the motor command in cardio-respiratory responses to exercises in both healthy [e.g., 35] and 140 symptomatic participants [e.g., 41] as well as in human performance during endurance exercises [39]. In 141 these studies, participants performed an exercise protocol, usually cycling or isolated knee exercises, with 142 and without intact feedback from group III-IV muscle afferents. While the primary variables of interest 143 were the cardio-respiratory responses to the tasks, these studies often measured the perception of effort as 144 a secondary or tertiary variable. Interestingly, there are conflicting results from these studies. In the 145 presence of pharmacological blockade of muscle afferents, several authors observed a decrease [e.g., 42] 146 in the ratings of perceived effort while others observed no difference [e.g., 36] or an increase [e.g., 43] 147 when compared to a sham or control intervention. This heterogeneity is also found in patients with 148 cardiovascular diseases [e.g., 41, 44]. To the best of our knowledge, only one published article has 149 narratively reviewed the use of pharmacological blockade to explore the neurophysiological mechanisms 150 underlying the perception of effort [28], and a systematic approach has vet to be conducted.

The conflicting findings on the effects of pharmacologically blocking muscle afferents on the perception of effort may be explained by differences in its operational definitions, leading to inconsistencies in the instructions provided to the participants on how to quantify the perception of effort. In his seminal work, Borg defined the perception of effort as how *heavy* and *laborious* a physical task is [45, 46]. However, he also mentioned that this perception results from the integration of various peripheral factors, including the organs of circulation and respiration, the muscles, the skin, and the joints. Since this first definition and

157 associated description provided by Borg, two lines of research have investigated the perception of effort 158 in exercise sciences (see figure 1). A first line of research considers effort as a construct encompassing a 159 mix of exercise-related perceptions [18, 47]. This approach results from the original description proposed by Borg, and later authors supplemented this definition with the notions of fatigue and discomfort: the 160 161 subjective intensity of effort, strain, discomfort, and/or fatigue that is experienced during physical exercise 162 [18]. However, while a lack of familiarization or the presence of fatigue may compromise the dissociation 163 between perceptions of effort and other exercise related perceptions [14, 48-50], experimental data 164 demonstrated that the perception of effort can be dissociated from other exercise-related perceptions, such 165 as pain [51, 52], discomfort [53-55], muscle tension [48, 56] and fatigue [57, 58]. In line with the aforementioned evidence, a second line of research considers effort as a construct dissociated from other 166 167 perceptions. This approach follows Borg's original definition conceptualizing the perception of effort as 168 one's appreciation of the difficulty of a task (how hard it is). For instance, Preston and Wegner [59] 169 described the perception of effort as the *feeling of difficulty and labor experienced during exertion*. In 170 2010. Marcora proposed that the perception of effort is the *conscious sensation of how hard, heavy and* 171 strenuous a physical task is [60]. More recently, Steele defined the perception of effort as the perception 172 of current task demands relative to the perception of capacity to meet those demands [16]. In light of the 173 disparate definitions proposed in the literature, it appears crucial to consider the definition used to 174 investigate the perception of effort when interpreting such data. However, to the best of our knowledge, 175 such consideration has not been made in the literature when discussing the signal(s) generating the 176 perception of effort.

In this context, the aim of this systematic review with meta-analysis was to explore the impact of pharmacologically blocking muscle afferents on the perception of effort during physical tasks. To explore whether the inclusion or not of other exercise-related perceptions in the definition of effort influences the quantification of perceived effort, a qualitative analysis was also used to group included studies by their theoretical approach.

183

184 **2. Methods**

The present review was conducted and is reported as per the Preferred Reporting Items for Systematic Reviews and Meta-analyses statement (PRISMA; [61]). All methods were pre-specified in a protocol registered on PROSPERO (CRD401913921) prior to the screening process and any deviations from the pre-registered methods are noted throughout.

189 **2.1 Search**

190 The following electronic databases were searched to identify studies: MEDLINE, EMBASE, CINAHL, 191 **SPORTDiscus**, Web of Science and PsycINFO. To ensure the inclusion of recently published articles, the 192 search was conducted on three separate occasions (April 2019 and March 2020 and October 2021). A 193 search strategy was developed for MEDLINE and adapted for each database. The first of the two concepts 194 included was the perception of effort and included the following terms: perception of effort, sense of effort, 195 perceived exertion, central motor command, central motor drive. Because the perception of effort has 196 been used by some in the neuroscience literature as an index of the central motor command during 197 exercise, the latter has been included in this concept. The second concept related to the pharmacological 198 blockade and included the following terms: epidural anesthesia, spinal anesthesia, neural blockade, nerve 199 block, sensory dysesthesia, fentanyl, lidocaine, bupiyacaine, muscle afferent, neural feedback, afferent 200 feedback, and group III-IV. It is noteworthy that, despite using the same search strategy in all three 201 instances, PsycINFO returned fewer articles each time the database was scanned (65 against 30 against 27 202 articles) and that 47 of the 65 original articles were not found in the subsequent searches. Additionally, no 203 limitation to the publication date was set during the search. The complete search strategy for every scanned 204 database is available in the supplementary material S1.

205 **2.2 Article inclusion**

206 Eligibility criteria were defined accordingly with the PICOS model. Articles qualified for inclusion if 207 they met the following criteria: 1) *population*: intervention was done on human participants, 2) 208 *intervention*: consisted of a blockade of spinal afferents by epidurally or intrathecally injecting a local 209 anesthetic or analgesics, 3) comparators: intervention was compared against a control or placebo 210 condition, 4) *outcome*: the perception of effort was a primary, secondary, or tertiary outcome, and 5) *study* 211 *design*: repeated-measure designs. Additionally, only articles published in peer-reviewed journals and 212 written in English were retained. We also opted not to include self-paced protocols in the quantitative 213 analyses to allow comparison between studies. This decision is based on the necessity to compare the 214 intensity of the perception of effort when the task demand (e.g., power output) is matched between

conditions [16]. The study selection process was done separately by MB and MPDLG, using the online platform Covidence (https://www.covidence.org/home). Conciliation of study selection was done after screening at the title/abstract level and after the full-text screening. Disagreements were settled through discussion and, if necessary, through consultation with BP and JS intervention.

219

220 2.3 Risks of bias

221 Risks of bias were appraised with a modified version [62] of the Effective Public Health Practice Project 222 (EPHPP) Quality Assessment Tool for Quantitative Studies [63]. By not applying the selection bias 223 component, this version was adapted to accommodate sport sciences studies where self-referral is common 224 [62]. Further adaptations were made to reflect the need of the present review following the Cochrane 225 Collaboration's guidelines [64]. The EPHPP does not provide explicit instructions on the assessment of 226 cross-over trials, which was a type of design in the included studies. Appropriately randomized cross-over 227 trials were considered equivalent to randomized controlled trials whereas cross-over trials performed in a 228 counter-balanced order or with inappropriate randomization were considered equivalent to controlled 229 clinical trials. Studies testing participants before and after opioid injection in a pre-post fashion were 230 considered cohort studies. Risks of bias may be different across several outcomes and thus warranted 231 confounders to be appraised specifically for the perception of effort. This is important because authors 232 often consider the perception of effort when interpreting their results [e.g., 65] or use their results to draw 233 conclusions on the regulation of the perception of effort [e.g, 66]. The risk of unblinding in the included 234 studies is high, owing to the side effects the epidural anesthesia may have [e.g., pruritus, dysesthesia; 67]. 235 As such, studies were considered blinded only if they detailed adequate blinding methods, such as the use 236 of a sham injection. Because correctly guessing the interventions may influence the outcomes [68], the 237 reviewers noted whether the participants were asked to guess the order of the interventions when 238 applicable. However, this had no impact on the labelling of the "blinding" component of the EPHPP. The 239 withdrawals and drop-outs component was not applied because none was reported in the included studies. 240 This is probably because the included studies were brief, usually spanning over 3 to 5 visits. Finally, all 241 the included studies were either cross-over trial or cohort studies, in which the risk of carry-over is critical. 242 This component was considered when making a judgment for the intervention integrity. As such, the 243 reviewer noted whether the risks of carry-over were minimized by allowing sufficient time in-between 244 experimental visits for the effects of both protocol and the anesthesia to dissipate (wash-out period). 245 Alternatively, risks of carry-over were considered minimal if baseline values between conditions were 246 similar.

247

248 **2.4 Coding process**

Included articles were classified into three distinct groups: 1) effort dissociated from other exercise-249 250 related perceptions (effort dissociated group), 2) effort including other exercise-related perceptions (effort 251 not-dissociated group) and 3) not enough information (unclear group). A first round attempted to code 252 articles by the reported definition of the perception of effort or the instructions provided to their 253 participants. However, this method was insufficient as none of the studies explicitly reported either of 254 those. Following this, a finer decision-making process was developed by JC, CFB, MB, MPDLG and BP 255 (see figure 2a). During a second round, the reviewers noted whether other exercise-related perceptions(s) 256 were measured (coded as *effort dissociated*) and whether the perception of effort was used interchangeably 257 with other exercise-related perception(s) (coded as *effort not dissociated*). If this information was not 258 available, studies using the perception of effort as an index of the central motor command were coded as 259 effort dissociated. Studies that could not be coded on that basis were coded as unclear. Articles were 260 separately coded by MB and MPDLG. Decisions were then conciliated, and disagreements settled through 261 discussion with BP. Notably, this process was done separately to the data extraction for meta-analysis 262 (described below). The analyst (JS) was not provided with the final coding until after extraction was 263 complete.

264

Please insert figure 2

265

266 **2.5 Data extraction**

267 Data extraction tables were prepared to map: (a) author and year of publication; (b) the test/exercise 268 conditions used; (c) the method and scale used to capture ratings of perception of effort; (d) the means and 269 standard errors or standard deviations for ratings of perception of effort including both control and 270 intervention conditions; and (e) sample sizes. It is important to note that, due to the multidimensional 271 nature of dyspnea that includes not only respiratory effort but also other physical (chest tightness) and 272 affective (unsatisfied inspiration) components [69, 70], associated ratings were not considered in the 273 present meta-analysis. Of note, we included data for all perception of effort outcomes reported in studies 274 and for all time points for which they were measured; thus, if a study reported multiple perception of effort 275 measurements were captured, these were all included but appropriately coded as either being taken during 276 submaximal tasks or maximal tasks (*i.e.*, at task failure). Some studies only reported data graphically or 277 did not report outcomes in a manner conducive to extraction for our analysis, or despite investigating

spinal blockade and capturing ratings of perception of effort did not report these outcomes as they were secondary in those studies. In these cases, authors were contacted for sharing either appropriate summary statistics or raw data to facilitate inclusion in our analysis. Three authors were contacted of which one shared the required summary statistics whereas others were either unable or unwilling to share their data. For the studies reporting only graphical data, WebPlotDigitizer (v4.3, Ankit Rohatgi; https://apps.automeris.io/wpd/) was used to extract data for inclusion in our analysis.

284

285 **2.6 Synthesis and analysis**

The meta-analysis was performed using the 'metafor' [71] package in R (v 4.0.2; R CoreTeam, https://www.r-project.org/). All analysis codes are available on the Open Science Framework website (https://osf.io/cy5n4/). As all studies relied on within-participant design, the standardized mean change using the raw values (SMCR) as described by Becker [72] was calculated between the conditions where the pooled standard deviation from both conditions was used as the denominator for standardization [73]:

Equation 1 :
$$SMCR = c(n-1)\frac{\mu_{con} - \mu_{int}}{SD_{con+int}}$$

Where μ_{con} and μ_{int} are the means for control and intervention conditions respectively, *c* is a bias correction factor [74], and $SD_{(con+int)}$ is the pooled standard deviation calculated as:

294 Equation 2 :
$$SD_{con+int} = \sqrt{\frac{(n_{con}-1)SD_{con}^2 + (n_{int}-1)SD_{int}^2}{n_{con}+n_{int}-2}}$$

As some studies reported zero variances (*e.g.*, some showing ceiling effects), a small constant (six sigma *i.e.*, $3x10^{-7}$) was added to all studies prior to calculating effect sizes. The magnitude of standardized effect sizes was interpreted with reference to Cohen [75] thresholds: *trivial* (<0.2), *small* (0.2 to <0.5), *moderate* (0.5 to <0.8), and *large* (>0.8). Standardized effects were calculated in such a manner that negative effect size values indicated the presence of an intervention effect (*i.e.*, a drop in rating of perception of effort), whereas a positive effect size values indicated an effect favoring the control conditions.

As a departure from the pre-registered analysis due to the nested structure of the effect sizes calculated from the studies included (*i.e.*, effects nested within groups nested within studies), multilevel mixed effects meta-analyses reflecting these nested random effects in the model were performed. Cluster robust point estimates and precision of those estimates using 95% compatibility (confidence) intervals (CIs) were produced, weighted by inverse sampling variance to account for the within- and between-study variance (tau-squared). Restricted maximal likelihood estimation was used in all models. A main model was

produced including all effects sizes. Several exploratory sub-group model analyses were also conducted 307 308 and detailed in the pre-registration with slight departure here because of the coding process for methods 309 to capture ratings of perception of effort. In addition to a model for all studies, we also produced models 310 for only studies where ratings of perception of effort were captured as effort dissociated, effort not 311 dissociated, and unclear separately. Further, in all models we additionally sub-grouped for tasks as 312 'maximal' (*i.e.*, ratings of perception of effort captured at the point of task failure or during a similar 313 maximal task e.g., a maximal voluntary contraction), and 'submaximal' (*i.e.*, ratings of perception of effort 314 recorded during exercise prior to the point of task failure, or during tasks not necessarily requiring 315 participants to reach task failure e.g., a fixed duration task of absolute demands). This was to separate 316 potential ceiling effects of maximal task conditions. Note, in the preregistration we initially stated we 317 would calculate a pooled effect for all submaximal values reported in any given study. However, to 318 increase the number of effect sizes for analysis, and thus statistical power, we opted to calculate each 319 separately and thus use a multilevel mixed effects meta-analysis model to account for this. We did however 320 also fit the same models as per our pre-registered intention to pool all submaximal values and have 321 included a comparison of these model estimates to those reported here in our supplementary materials 322 which suggests our inferences would not have substantially differed (see https://osf.io/qd6rt/). For each 323 sub-group analysis multilevel models were produced except for the 'effort not dissociated' 'maximal' 324 conditions where only one effect size was available.

325 In contrast to our pre-registration, and in light of the heterogeneity and poor reporting of methods to 326 capture ratings of perception of effort, dichotomizing the existence of an effect for the main results was 327 avoided. Therefore, traditional null hypothesis significance testing, which has been extensively critiqued 328 [76, 77], was not employed. Instead, the implications of all results compatible with these data, from the 329 lower limit to the upper limit of the interval estimates, was considered with the greatest interpretive 330 emphasis placed on the point estimate. During revisions however, given some of the apparently null effects 331 identified, we retrospectively refit all models using a Bayesian approach and the 'brms' package [78] and 332 produced Bayes Factors using the Savage-Dickey ratio with the 'bayestestR' package [79] to compare 333 evidence both for and against a point null of zero difference between conditions. These again did not 334 largely influence our overall inferences (typically weak evidence in favor of the null) are so also included 335 in the supplementary materials with categories of qualitative interpretations as per Kass & Rafferty [80] 336 added to aid interpretation (see https://osf.io/wrkav/).

Risk of small study bias was examined visually through contour-enhanced funnel plots. Q and I^2 statistics were also produced and reported [81]. A significant Q statistic is typically considered indicative

339 of effects likely not being drawn from a common population. I^2 values indicate the degree of heterogeneity in the effects: 0-40% were not important, 30-60% moderate heterogeneity, 50-90% substantial 340 341 heterogeneity, and 75-100% considerable heterogeneity [64]. For within participant effects pre-post 342 correlations for measures were rarely reported. Due to the repeated-measure design of included studies, 343 we explored the effect of different correlation coefficients (r = 0.5, 0.7 and 0.9) between pre-post values 344 to test its impact on the results of the models. As overall findings were relatively insensitive to this range, 345 the results for r = 0.7 are reported here. Results for inclusion of the other assumed correlation coefficients 346 are reported in the supplementary material available on OSF (r = 0.5, https://osf.io/gqby6/; r = 0.9, 347 https://osf.io/qbe2n/).

349 **3. Results**

350 The search across all databases returned 902 articles. After the removal of 319 duplicates, 583 original 351 articles remained and were screened at the title/abstract level, leaving 80 articles. A total of 20 articles 352 were retained. The screening process is shown in figure 3. None of the included articles defined the 353 perception of effort nor provided instructions for rating it. Therefore, included studies could not be coded 354 on that basis and instead, other cues have been used (see figure 2a). Based upon this, among the 20 articles, 355 only 6 could be classified in the *effort dissociated* group, while 3 were placed in the *effort not dissociated* 356 group and 11 in the unclear group. A timeline of the included studies is available in figure 2b. Three studies, 1 in the effort not dissociated group and 2 in the unclear group used a self-paced protocol and 357 358 could thus not be added to quantitative analyses. Data was not available for quantitative synthesis in 1 359 study belonging to the *unclear* group, providing a sample size on which quantitative synthesis was based of n = 164. Full details of all studies included in quantitative synthesis can be seen in the data extraction 360 361 table (https://osf.io/ku3w7/).

363

364 3.1 Risks of bias

365 A modified version of the EPHPP to accommodate sport sciences studies has been used to assess the 366 risk of bias of individual studies [62, 82]. Studies labelled "strong" are considered to have guarded themselves well against biases. Conversely, studies labelled "weak" are considered to have a high risk of 367 bias. None of the studies were labelled "strong", whereas 5 were "moderate" and 13 "weak". Most studies 368 369 used a randomized or counter-balanced within-subject design, but 7 studies were classified as cohort 370 studies (pre-test, post-test). Almost half (n = 7) of the studies were deemed to have strongly controlled for 371 known confounders of the perception of effort, but 6 of them were labelled "moderate", with the remaining 372 5 being considered "weak". None of the studies described how the assessor was blinded except for one 373 [83]. In contrast, 5 studies blinded their participants with a placebo injection. The remaining 13 studies 374 compared the epidural anaesthesia with a "no-intervention" control condition and the participants could 375 therefore not be considered blind. Furthermore, none of the included studies reported asking the 376 participants to guess the order of the intervention after completion of the protocols. All studies used either the Borg's scale (RPE 6-20) or the CR10 scale, which are known psychophysical scales in the context of 377 378 physical exercise. However, several (n = 9) articles reported to have used a modified version of the CR10 379 scale without providing any information on the modifications performed. The validity and reliability of

these modifications were therefore unclear. The table 1 shows the risk of bias within studies for every included articles. An audit trail is available in the supplementary material 2.

383

384 **3.2 Meta-Analysis**

The quantitative analysis could be performed on only 16 studies, the remaining two providing 385 386 insufficient information. The main model including all combined effects sizes (k = 49 across 16 clusters 387 [median = 2, range = 1 to 8 effects per cluster]) revealed a negative trivial point estimate with precision 388 ranging from negative small to positive trivial effects for the interval estimate (-0.05 [95% CI = -0.28 to 389 0.18]), yet with moderate to substantial heterogeneity ($Q_{(48)} = 127.22$, p < 0.0001, $I^2_{\text{between_study}} = 77\%$, $I^{2}_{\text{between group}} = 0\%$, $I^{2}_{\text{within group}} = 0\%$). When considering only submaximal conditions the model (k = 39) 390 391 across 13 clusters [median = 2, range = 1 to 8 effects per cluster]) revealed a point estimate close to zero 392 with precision ranging from negative small to positive small effects for the interval estimate (0.05 [95% 393 CI = -0.32 to 0.42]), with substantial heterogeneity ($Q_{(38)} = 103.00$, p < 0.0001, $I^2_{\text{between study}} = 77\%$, 394 $I_{\text{between group}}^2 = 0\%$, $I_{\text{within group}}^2 = 0\%$). Considering only maximal conditions the model (k = 10 across 9395 clusters [median = 1, range = 1 to 2 effects per cluster]) revealed a negative small point estimate with 396 precision ranging from negative moderate to positive trivial effects for the interval estimate (-0.17 [95% 397 CI = -0.47 to 0.13]), with moderate to substantial heterogeneity ($Q_{(9)} = 22.92$, p = 0.0064, $I^2_{\text{between study}} =$ 0%, $I^2_{\text{between}_group} = 30\%$, $I^2_{\text{within}_group} = 30\%$). Figure 4 presents the funnel plot for all studies with color 398 399 coding by method for capturing rating of perception of effort. Figures 5 and 6 present all effect sizes for 400 the submaximal models and the overall model estimates for all coding and combined.

402

403 **Ratings of perception of effort as 'effort dissociated'**. The subgroup model where the method of rating 404 of perception of effort was coded as *effort* (k = 19 across 6 clusters [median = 2.5, range = 1 to 8 effects 405 per cluster]) revealed an overall small point estimate with precision ranging from positive trivial to positive 406 moderate effects for the interval estimate (0.39 [95% CI = 0.13 to 0.64]), with relative homogeneity ($Q_{(18)}$ 407 = 36.96, p = 0.0053, $I^2_{\text{between_study}} = 77\%$, $I^2_{\text{between_group}} = 0\%$, $I^2_{\text{within_group}} = 49\%$). When considering only 408 submaximal conditions the model (k = 16 across 6 clusters [median = 2, range = 1 to 7 effects per cluster]) 409 revealed a moderate point estimate with precision ranging from positive trivial to positive large effects 410 for the interval estimate (0.54 [95% CI = 0.07 to 1.0]), with moderate to substantial heterogeneity ($Q_{(15)}$ =

411 31.44, p = 0.0077, $I^2_{\text{between_study}} = 51\%$, $I^2_{\text{between_group}} = 0\%$, $I^2_{\text{within_group}} = 8\%$). When considering only 412 maximal conditions the model (k = 3 across 3 clusters [1 effect per cluster]) revealed a negative trivial 413 point estimate with precision ranging from negative small to positive trivial effects for the interval estimate 414 (-0.05 [95% CI = -0.24 to 0.15]), with relative homogeneity ($Q_{(2)} = 0.12$, p = 0.9412, $I^2_{\text{between_study}} = 0\%$, 415 $I^2_{\text{between_group}} = 0\%$, $I^2_{\text{within_group}} = 0\%$).

416

Please insert figure 5 here

417

418 Ratings of perception of effort as 'effort not dissociated'. The subgroup model where the method of 419 rating of perception of effort capture was coded as *effort not dissociated* (k = 8 across 2 clusters [4 effects] 420 per cluster]) revealed an overall negative small point estimate with poor precision ranging from negative 421 large to positive large effects for the interval estimate (-0.29 [95% CI = -2.39 to 1.8]), with relative 422 homogeneity ($Q_{(7)} = 9.62$, p = 0.2113, $I^2_{\text{between study}} = 7\%$, $I^2_{\text{between group}} = 7\%$, $I^2_{\text{within group}} = 14\%$). When 423 considering only submaximal conditions the model (k = 7 across 2 clusters [median = 3.5, range = 3 to 4 424 effects per cluster]) revealed a negative small point estimate poor precision ranging from negative large 425 to positive large effects for the interval estimate (-0.32 [95% CI = -3.07 to 2.42]), with moderate heterogeneity ($Q_{(6)} = 9.51$, p = 0.1467, $I^2_{\text{between study}} = 12\%$, $I^2_{\text{between group}} = 12\%$, $I^2_{\text{within group}} = 20\%$). When 426 427 considering only maximal conditions only a single effect met these conditions which revealed a negative 428 small point estimate with precision ranging from negative moderate to positive small effects for the 429 interval estimate (-0.22 [95% CI = -0.76 to 0.33]).

430

431 Ratings of perception of effort as 'unclear'. The subgroup model where the method of rating of 432 perception of effort capture was coded as *unclear* (k = 22 across 8 clusters [median = 2, range = 1 to 8 433 effects per cluster]) revealed an overall negative small point estimate with precision ranging from negative 434 moderate to negative trivial effects for the interval estimate (-0.27 [95% CI = -0.50 to -0.04]), with moderate heterogeneity ($Q_{(21)} = 42.14$, p = 0.004, $I^2_{\text{between study}} = 6\%$, $I^2_{\text{between group}} = 0\%$, $I^2_{\text{within group}} = 45\%$). 435 436 When considering only submaximal conditions the model (k = 16 across 5 clusters [median = 2, range = 437 1 to 8 effects per cluster]) revealed a negative small point estimate with precision ranging from negative 438 large to positive trivial effects for the interval estimate (-0.37 [95% CI = -0.88 to 0.14]), with moderate to 439 substantial heterogeneity ($Q_{(15)} = 19.27$, p = 0.2020, $I^2_{\text{between study}} = 59\%$, $I^2_{\text{between group}} = 0\%$, $I^2_{\text{within group}} = 19.27$ 440 0%). When considering only maximal conditions the model (k = 6 across 5 clusters [median = 1, range = 441 1 to 2 effects per cluster]) revealed a negative small point estimate with poor precision ranging from

- 442negative large to positive moderate effects for the interval estimate (-0.25 [95% CI = -0.91 to 0.41]), with443considerable heterogeneity ($Q_{(5)} = 22.47$, p = 0.004, $I^2_{between_study} = 0\%$, $I^2_{between_group} = 39\%$, $I^2_{within_group} =$ 44439%).445****Please insert figure 6 here****446

448 **4. Discussion**

449 This systematic review with meta-analysis was conducted to investigate the effect of pharmacologically blocking muscle afferents on the perception of effort during physical exercise. We also sought to explore 450 451 the differences in reported ratings of perceived effort according to the approach used to investigate this 452 construct. Twenty articles were coded as *effort dissociated* (n = 6), *effort not dissociated* (n = 4) or *unclear* 453 (n = 10) according to whether the authors included other exercise-related perceptions in the investigation 454 of the perception of effort. Considering all subgroups combined, a trivial negative point estimate for 455 ratings of perceived effort reduction following pharmacological blockade of muscle afferents was 456 observed, with interval estimate ranging from negative small to positive trivial effects. The magnitude of 457 the interval estimate crossing zero as well as the trivial negative point of estimate (0.05) suggests that 458 regardless of the theoretical approach used to investigate the perception of effort, pharmacologically 459 blocking muscle afferents feedback does not reduce the perception of effort during physical exercise.

The subgroup analysis also revealed a clear influence of the theoretical approach used to investigate the perception of effort (i.e., as a construct dissociated or not from other exercise-related perceptions). To the best of our knowledge, this systematic review is the first to highlight an influence of the theoretical approach used to investigate this perception, and strongly suggests that future experimental studies should carefully report the instructions provided to the participants for rating perception of effort.

465

4.1 Effort dissociated subgroup.

466 Only considering the *effort dissociated* subgroup, pooling 6 studies yielded a small positive point 467 estimate with a positive confidence interval suggesting that in the presence of impaired group III-IV muscle afferents, participants may report higher ratings of perceived effort. Participants working at the 468 469 same absolute demands (i.e., same external workload in both conditions) reported higher perception of 470 effort with epidural anesthesia [35, 36, 43]. However, when working at similar relative workloads (i.e., 471 taking into consideration any muscle strength reduction following injection of local anesthetic [42]), the 472 same participants reported similar perception of effort. Likewise, ratings of perceived effort were also 473 similar at a given oxygen uptake during graded exercises [35, 43]. When only considering submaximal 474 tasks, the effort dissociated subgroup also showed moderate heterogeneity. Differences across studies 475 could be explained by differences in experimental designs [84], as results differed with the calibration of 476 exercise demands according to absolute or relative workloads. It is also important to note that the increased 477 perception of effort in these studies is likely due to the use of lidocaine and/or bupivacaine to block III-478 IV muscle afferent feedback. Indeed, contrary to fentanyl which acts more specifically on sensory

479 transmission [85], lidocaine and bupivacaine is known to affect sodium and potassium channels [86] and 480 reduce force production capacity [87] thereby requiring the participants to increase their motor command 481 to maintain the same absolute workload. According to the corollary discharge model, this increased motor 482 command increases the magnitude of the associated corollary discharge, which in turn increases the 483 perception of effort [24]. This subgroup analysis reveals that when effort is investigated as dissociated 484 from other exercise-related perceptions, pharmacological blockade of muscle afferents does not reduce 485 perception of effort. Therefore, as perception of effort is not reduced, muscle afferent feedback cannot be 486 considered as a sensory signal processed by the brain to generate the perception of effort. This result 487 reinforces the potential of using the perception of effort intensity as a psychophysiological index of the 488 motor command [24, 27, 88-90], as traditionally performed in the neuroscience, cardiovascular physiology 489 and kinesthesia literatures [24, 25, 27, 91].

490

4.2 Effort not-dissociated subgroup.

491 Only considering the effort not dissociated subgroup, pooling 2 studies yielded an overall small 492 negative point estimate. This negative point estimate was associated with an important imprecision based 493 upon the confidence interval range likely due to the low number of studies and small cluster sample 494 correction for robust estimates. Both studies observed lower ratings of perceived effort in epidurally 495 anaesthetized participants [20, 83]. Interestingly, Amann et al. [20] observed lower ratings of perceived 496 effort only at higher cycling power output (*i.e.*, 80% peak power output, 325 ± 19 W). According to the 497 Oxford Dictionary, discomfort can be defined as a slight pain and something that makes a person feel 498 physically uncomfortable. Because of its relation to the concept of pain, the inclusion of discomfort in the 499 definition of the perception of effort may bias the ratings of perceived effort whenever there is a change 500 in the perception of pain [14, 92]. Although there seems to exist wide interindividual variability in pain 501 threshold during cycle ergometry, muscle pain is known to increase with increased exercise demands 502 during this task [93]. Attending to these perceptions when measuring the perception of effort may attenuate 503 the perceptual differences between conditions during lower cycling demands where discomfort is already 504 low and thus, any difference with epidural anesthesia would likely be minimal. Conversely, when working 505 at 80% peak power output, participants reported substantially lower ratings of perceived effort with 506 epidural anesthesia, probably because they felt less discomfort and/or pain than they normally would have. 507 Pain and associated unpleasant sensations are transmitted through group III-IV fibres [40], and thus are 508 attenuated with epidural anesthesia. Amann et al., [20] and Gagnon et al. [83] both observed lower ratings 509 of perceived effort, suggesting that the reduction in muscle pain and associated discomfort may have 510 biased the ratings of perceived effort when other exercise-related perceptions were included in the

511 definition of effort. A study employing a self-paced protocol that could not be added to this meta-analysis 512 found similar results [42]. Participants performed a 5-km cycling time trial with and without lidocaine 513 with a mean power output similar to that of Amann et al. [20]. The authors however found a decrease in 514 ratings of perceived effort of nearly 2 unit-points on the CR10 scale (CTRL: 8.4 ± 0.4 SEM; Lidocaine: 515 6.8 ± 0.4 SEM). Given the high-power output, the fact that feedback from group III-IV is known to be the 516 signal processed by the brain to generate muscle pain [40], and that the authors reported investigating 517 "limb discomfort", the lower values likely reflect a decreased pain and discomfort when cycling with 518 lidocaine. As such, the inclusion of discomfort in the definition of effort would likely result in a decrease 519 in reported ratings of perceived effort. Interestingly, a similar protocol, with the only difference of using 520 fentanyl instead of lidocaine, observed an increase in ratings of perceived effort at the completion of the 521 5 km time-trial [66]. However, the authors also observed an excessive development of fatigue resulting in 522 an increase in central motor drive, known to exacerbate the perception of effort [4, 24, 27, 30]. Moreover, 523 when an effect of the epidural anesthesia is detected (e.g., 13% reduction in "limb discomfort" [20]), the 524 magnitude of its effect is small. Even when the theoretical approach encompasses several exercise-related 525 perceptions, the contribution of group III-IV muscle afferents appears to be limited as previously 526 suggested [92].

527

4.3 Unclear subgroup

528 Only considering the *unclear* subgroup, pooling 8 articles yielded an overall small negative point 529 estimate with a negative confidence interval. Among those articles, 2 observed lower ratings of perceived 530 effort at task failure when exercising with impaired muscle afferents with similar integrated forces between 531 conditions [19, 94]. Interestingly, 2 other studies observed similar ratings of perceived effort at task failure. 532 Amann et al. [66] found a 27% decrease in perception of effort intensity with epidural anesthesia at the 3-533 min mark (average time, placebo: 8.7 ± 0.3 , fentanyl: 6.8 ± 0.3), but not at exhaustion in trained athletes 534 cycling at 80% of their peak power output. Similarly, Sidhu et al. [95] observed a decrease in perception 535 of effort intensity with epidural anesthesia only at 25% of endurance time during a similar exercise 536 protocol. It must be noted that a 1-unit difference on the CR10 was consistently maintained throughout 537 the protocol until exhaustion where values were nearly identical (100% ET, 9.9 \pm .01 vs 10.0 \pm 0). It is 538 indicative of a tendency for ratings of perceived effort to be lower in the epidural anesthesia condition, 539 albeit not reaching statistical significance. Similar values at the end of the endurance time would also be 540 consistent with previous studies suggesting that the perception of effort attain near maximal values at 541 exhaustion [e.g., 96]. Three other studies using fentanyl in hypertensive and heart failure patients also did 542 not find different ratings of perceived effort compared to a sham or control condition [44, 97, 98]. Exercise

543 demands, determined with cycling power output, was extremely low in one of the studies (40 W; [97]). 544 Because participants reported similar ratings of perceived effort when also considering discomfort at lower 545 intensities [20] and that fentanyl does not lead to loss in muscle strength [87], it is not possible to determine 546 which was the cause of the lack of differences. However, when exercising at higher intensities (e.g., 65%547 - 80% peak power output), healthy controls and heart failure participants reported similar ratings of 548 perceived effort during both conditions [44]. Furthermore, healthy and heart failure participants did not 549 differ in ratings of perceived effort despite large differences in external workload [44], further suggesting 550 that it is the relative and not the absolute workload determining the perception of effort.

551 Although the involvement of the central motor drive in the perception of effort seems widely accepted 552 [24, 42], there is still confusion about the role of group III-IV muscle afferents as a signal processed by 553 the brain to generate the perception of effort [14, 29]. In fact, physiologists have still not reached a 554 consensus after more than 150 years of debate [99-102]. Central projections of group III-IV muscle 555 afferents to several spinal and supra-spinal sites, including sensory cortices, anatomically support the 556 afferent feedback model [103, 104]. This model also finds experimental evidence from studies involving 557 epidural anesthesia [20, 83]. However, as mentioned in the introduction, the inclusion of other exercise-558 related perceptions likely biased the ratings of perceived effort measured. Furthermore, if these muscle afferents constitute a centrally processed signal generating the perception of effort, stimulation of group 559 560 III-IV muscle afferents would generate a sense of effort even in the absence of central motor drive. 561 However, injections of physiological concentrations of metabolites known to stimulate those muscle 562 afferents do not generate perception of effort at rest [105, 106]. This manipulation however elicits 563 sensations related to discomfort (e.g., itch, tingling) and pain. It appears that the presence of the motor 564 command, and therefore the voluntary engagement of the participant in the task, is crucial for experiencing 565 the perception of effort.

4.4 Other (neuro-)physiological signals potentially processed by the brain to generate the perception of effort

As shown in figure 1, Borg's original description [45, 46] suggest that the perception of effort may also be generated by the brain processing of several peripheral inputs, including organs of circulation and respiration, skin and joints. Regarding the organs of circulation and respiration, there is evidence that heart and lung transplant recipients (i.e., denervated organs) may perceive effort normally [107, 108]. Moreover, administration of β -blockers prior to exercise does not reduce the perception of effort despite a decrease in heart rate [109]. Therefore, it seems that afferent feedback from the heart and the lungs is not processed by the brain to generate the perception of effort. Regarding skin and joint feedback, evidence from the

575 kinesthesia literature suggests that this specific feedback is involved in the perceptions of force and 576 movement rather than the perception of effort [26]. Finally, other authors have proposed that hormones 577 and cytokines may mediate the perception of effort [e.g., 110, 111]. It is important to remind that the 578 perception of effort is instantaneously experienced during the voluntary engagement in a physical task 579 and immediately disappears when an individual disengages from it. Given the relatively slow-acting 580 nature of hormones and cytokines (e.g., secretion, circulation to the brain, crossing of the blood-brain 581 barrier), it is unlikely that their signal is processed by the brain to generate the perception of effort. 582 However, it is plausible that hormones and cytokines may indirectly interact with the perception of effort, 583 for example by altering the neuronal processing of the signal generating the perception of effort.

584 There is extensive support that the neurocognitive processing of the corollary discharge generates the 585 perception of effort. Stimulation of muscle afferents, in the absence of motor command, generates various 586 perceptions (e.g., pain, movement, force), but not effort [105, 106, 112, 113]. Moreover, significant 587 correlations between the ratings of perceived effort and the amplitude of movement-related cortical 588 potential (MRCP), an index of the motor command, have previously been observed [24, 27, 88, 114, 115]. 589 For example, a reduction in force production capacity is associated with an increased MRCP amplitude 590 and an increased perception of effort intensity to maintain the same absolute force [24]. When caffeine is 591 ingested, perception of effort intensity to maintain the same absolute force is reduced in association with 592 a decreased MRCP amplitude [27]. This positive effect of caffeine on the perception of effort is most 593 likely due to the increased excitability of the corticospinal pathway induced by its ingestion [116-120], 594 leading to a lower motor command required to activate the working muscles as revealed by the decreased 595 MRCP amplitude. Second, support in favor of the role of the corollary discharge as an internal signal 596 generating the perception of effort can be found in various neuroscience or psychophysiological studies. 597 For example, Zenon et al. [121] demonstrated that disrupting the supplementary motor area via continuous 598 theta burst transcranial magnetic stimulation decreases perception of effort. Other studies demonstrated a 599 close relationship between perception of effort and physiological variables known to be strongly 600 influenced by the motor command, such as the respiratory frequency [122] or the electromyographic signal 601 [90].

602 **4.5 Strengths and limitations**

603 One strength of this systematic review is that our search was not restrained by publication date, despite 604 the articles spanning three decades. Rather, the shift from muscle weakness-inducing lidocaine and 605 bupivacaine to the highly selective μ -opioid receptor agonist fentanyl demonstrated the importance of the

606 magnitude of the central motor drive in generating the perception of effort. In the presence of muscle 607 weakness (induced by some opioids binding to spinal motoneurons), exercisers must increase the 608 magnitude of their motor command to maintain the same absolute level of performance [32]. This was 609 observed in older studies via the higher ratings of perceived effort reported when participants were 610 working at similar external workload [e.g., 43, 123]. Furthermore, a shift in the usage of the perception of 611 effort, from *effort dissociated* to *effort not dissociated* and *unclear* is observed (figure 2b). Another 612 strength of this meta-analysis is that we opted to pool the data per time-point, instead of averaging the 613 ratings of perceived effort within studies. This allows us to avoid any potential ceiling effects from 614 maximal conditions, where ratings of perceived effort are expected to attain near maximal values. 615 Moreover, this approach offered a view of the effect of pharmacologically blocking group III/IV muscle 616 afferents at different exercise demands, as several authors employed incremental protocols. This proved 617 particularly useful to interpret data from the effort not dissociated subgroup, as discomfort and pain, often 618 included in the definition of effort, are more predominant at higher workloads.

619 One limitation of this systematic review is that none of the included studies explicitly provided the 620 definition of the perception of effort, or the instructions given to the participants to report their ratings of 621 perceived effort. Therefore, to overcome this limitation, a unique coding was created to be able to classify 622 the included articles based on cues leading to the assumption or not of the inclusion of other exercise-623 related perceptions in the definition of effort. While some may argue that such approach opens the door 624 for interpretation, we would like to emphasize that the coding process was clear and objective, and could 625 be reproduced by other research groups, as presented in figure 2a. We are therefore confident that our 626 coding process was successful at separating studies according to the theoretical approach used by the 627 researcher (dissociated perception or not). Importantly, this limitation strongly emphasizes the need for 628 better reporting of the definition of the perception of effort and associated instructions provided to the 629 participants directly in the manuscript, or in supplementary materials. Indeed, in some manuscript, 630 information concerning the perception of effort solely appeared in the results without any further detail 631 [e.g., 124]. Another important point is that 9 out of 20 studies included in the qualitative analysis (~ 50%) 632 reported the use of modified scales to measure the perception of effort, without providing these 633 modifications. Explicitly reporting definition and instructions, as well as the psychophysical scale used, 634 is fundamental for study reproducibility. Such rigor should decrease the heterogeneity in the results, 635 regardless of the theoretical approach chosen by the research groups.

Because of the contrasting effects of group III/IV muscle afferents on different spinal and supra-spinal networks [38, 39], it can be difficult to make clear conclusion on their role in the regulation of the motor

638 command and the perception of effort. Importantly, we would like to emphasize that our systematic review 639 and meta-analysis investigated the role of group III-IV muscle afferent as a potential signal processed by 640 the brain to generate the perception of effort (i.e., required for perception of effort to be experienced). 641 According to this, blocking this signal (i.e., generator) should abolish, or at least considerably reduce the 642 perception of effort. By combining our results with existing evidence that stimulation of these afferents in 643 the absence of motor command does not generate a perception of effort [105, 106], it seems clear that 644 feedback from group III-IV muscle afferents is not processed by the brain to generate this perception. 645 Stimulation of these muscle afferents generates other perceptions, and particularly pain [40, 105]. To 646 reinforce this point, we could draw a comparison with the perception of movement. Movement perception 647 is well known to be generated by the brain processing of both the copy of the motor command and muscle 648 afferent feedback [26, 125, 126]. In the absence of motor command, stimulation of muscle afferents via 649 tendon vibration creates an illusion of movement [e.g., 112, 113]. As previously mentioned, stimulation 650 of muscle afferents in the absence of motor command, according to the existing literature, does not create 651 an illusion of effort when effort is defined as a perception dissociated from other exercise related 652 perceptions. While our results and the literature exclude the possibility that feedback from group III-IV 653 muscle afferents is a signal processed by the brain to generate the perception of effort, we would like to 654 emphasize that these afferents can play an indirect role in the regulation of this perception. Indeed, as 655 previously mentioned, feedback from group III-IV muscle afferent interacts with the regulation of 656 cardiorespiratory responses to the exercise and the regulation of the motor command sent to the working 657 muscles [37, 39]. Consequently, it is important for future research to further investigate how this feedback 658 modulate (as opposed to "generate") the perception of effort in healthy and clinical populations. An 659 interesting approach could consist of increasing feedback from group III-IV muscle afferents 660 concomitantly of the presence of the perception of effort. This is possible for example with the use of 661 intramuscular metabolites or saline injection [e.g., 127, 128, 129] or cuff-induced muscle ischemia [e.g., 662 130, 131, 132]. Due to the overall inhibitory effect of group III/IV muscle afferents on the corticospinal 663 pathway and the generation of the motor command, thus contributing to the development of 664 neuromuscular fatigue [38, 39], we would expect an increase in the perception of effort.

Finally, recent literature questions the inclusion of *heaviness* in the definition of effort [16, 133]. This debate is in part related to the link between the word *heavy* and the weight of an object to lift. However, the word *heavy*, as defined by the Oxford dictionary, refers to "the quality of having great weight" (i.e., weight of an object) as well as "a state of being greater in amount in force, or intensity than usual" (i.e., perceived task demand). Because this debate is fairly recent and the word *heaviness* is included in Borg's 670 original definition, separating *heaviness* from effort would have been too restrictive. Thus, this was not 671 considered for the present meta-analysis. Considering this interesting debate on the influence of the 672 inclusion of the word "heaviness" in the perception of effort, we propose two avenues. First, future 673 research should investigate the effect of including or not the word *heaviness* or *heavy* in the rating of 674 perceived effort in various exercise types, including lifting weight (e.g., resistance exercise) or not (e.g., 675 endurance exercise). Second, future research using current definitions and including the word heaviness 676 should carefully instruct their participants that this word refers to the "quality of the sensation" rather than 677 "a weight judgement".

678 **5. Conclusion and perspectives**

679 Our results indicate that the group III-IV muscle afferents does not contribute as a signal processed by 680 the brain to generate the perception of effort. However, they may induce changes in the neuromuscular 681 system, primarily by regulating the development of neuromuscular fatigue [38, 39], leading to changes in 682 the perception of effort via their influence on the central motor command. The *effort dissociated* subgroup 683 offers support to the corollary discharge model. Studies assigned to this group employed anaesthetics 684 known to reduce maximal force production capacity. Consequently, participants had to increase the 685 magnitude of their central motor command to maintain similar absolute workload, leading to an increased 686 perception of effort. This is not seen when participants had to maintain similar relative workload (i.e., 687 similar magnitude of the central motor command). So where does the signal(s) generating perception of 688 effort come from? As presented in the section 4.4, various lines of evidence from exercise physiology, 689 neuroscience and psychophysiology suggest that the perception of effort is generated by brain processing 690 of corollary discharges. Corollary discharges are neural signals generated by premotor/motor areas of the 691 cortex when they generate central motor commands to initiate and sustain voluntary skeletal muscle 692 contractions [134, 135].

693 This meta-analysis also underscores the importance to provide clear and standardized instructions to the 694 participants to avoid the confounding effect of other exercise-related perceptions in the ratings of 695 perceived effort. We therefore recommend, similarly to others [14, 29, 133], that researchers and clinicians 696 instruct and familiarize their participants to rate their perception of effort specifically by excluding other 697 exercise-related perception(s) from their sense of effort. This is also crucial for researchers investigating 698 the perception of effort as a psychophysiological marker of the magnitude of the motor command [e.g., 699 88, 90] and using muscle pain as a psychophysiological marker of feedback from group III-IV muscle 700 afferents [e.g., 136, 137].

701 Investigating effort as a unique and dissociated perception is also crucial to better understand how 702 perception of effort interacts with other exercise-related perceptions, such as pain, and influence 703 performance and the regulation of human behavior. The dissociation between the sensory signal generating 704 the perception of effort from other neurophysiological signals modulating this perception could help 705 researchers and clinicians to better understand how various neurophysiological pathways [e.g., 138] or 706 psychological factors [e.g., 1, 139] could influence this perception. It could unravel underlying 707 mechanisms generating and regulating the perception of effort, and lead to the development of unique 708 multidisciplinary interventions aimed at decreasing perception of effort to improve the adherence to an 709 exercise training program [e.g., 140].

1064

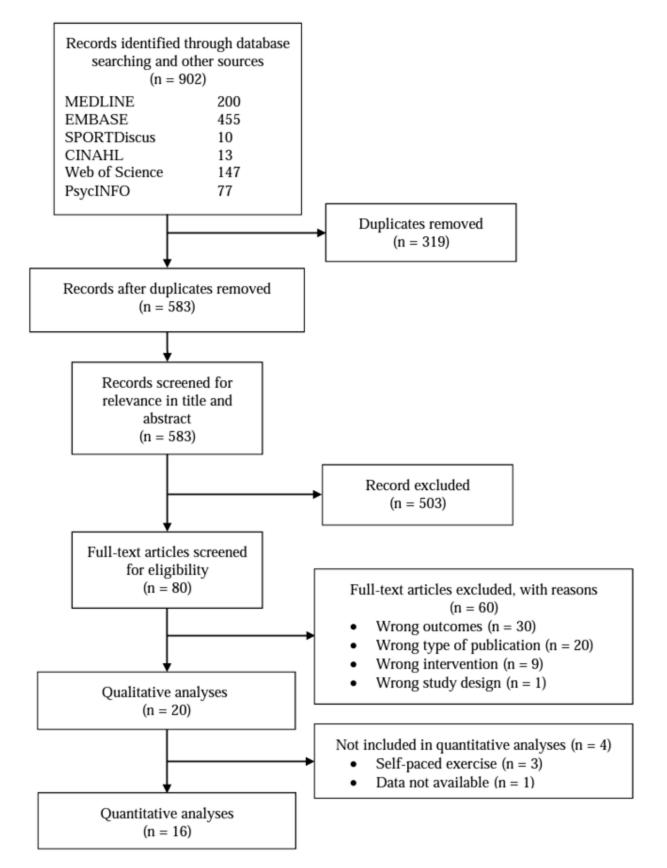

1068 Fig. 1: Overview of the two lines of research investigating the perception of effort in exercise sciences and the primary definitions used in the literature. In blue, the perception of effort does not include other 1069 1070 exercise-related perceptions and is investigated as a construct dissociated from other perceptions. This 1071 approach follows Borg's original definition conceptualizing the perception of effort as one's appreciation 1072 of the difficulty of a task (how hard it is). In green, the perception of effort includes other exercise-related 1073 perceptions and is investigated as a construct encompassing a mix of exercise-related perceptions. This ss 1074 approach results from the original description proposed by Borg.

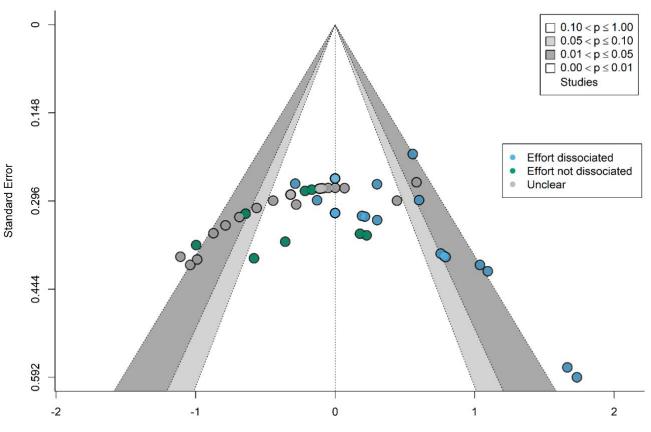

1075

1076 Fig 2: (a) coding process used for the classification of the articles included in the systematic review.
1077 (b) changes overtime in the use of the perception of effort construct in the included studies.

1078
