34 Tumor heterogeneity, cancer drug sensitivity screening, precision medicine, statistical de-
35 convolution, mathematical models of tumor growth, multiple myeloma.

36 **Significance statement**

37 Tumors are typically comprised of heterogeneous cell populations exhibiting diverse phe-
38 notypes. This heterogeneity, which is correlated with tumor aggressiveness and treatment-
39 failure, confounds current drug screening efforts to identify effective candidate therapies
40 for individual tumors. Here we present a method that enables the deconvolution of tumor
41 samples into individual subcomponents exhibiting differential drug-response. This method
42 relies on standard bulk drug-screen measurements and outputs the frequencies and drug-
43 sensitivities of tumor subpopulations. Our method was validated in cell-line experiments
44 and applied to characterize multiple myeloma patient samples. This method can be used
45 for personalized predictions of tumor response to future treatments, and also applied more
46 broadly to perform phenotypic deconvolution of heterogeneous populations in a variety of
47 biological settings.

48 **Abstract**

49 Tumor heterogeneity is an important driver of treatment failure in cancer since therapies
50 often select for drug-tolerant or drug-resistant cellular subpopulations that drive tumor
51 growth and recurrence. Profiling the drug-response heterogeneity of tumor samples using
52 traditional genomic deconvolution methods has yielded limited results, due in part to the
53 imperfect mapping between genomic variation and functional characteristics. Here, we
54 leverage mechanistic population modeling to develop a statistical framework for profiling
55 phenotypic heterogeneity from standard drug screen data on bulk tumor samples. This
56 method, called PhenoPop, reliably identifies tumor subpopulations exhibiting differential
57 drug responses, and estimates their drug-sensitivities and frequencies within the bulk. We
58 apply PhenoPop to synthetically-generated cell populations, mixed cell-line experiments,
59 and multiple myeloma patient samples, and demonstrate how it can be leveraged to perform
60 individualized predictions of tumor growth under candidate therapies. This methodology
61 can also be applied to deconvolve phenotypic responses to environmental stimuli in a variety
62 of biological settings beyond cancer drug response.

Introduction

Most human tumors display a striking amount of phenotypic heterogeneity in features such as gene expression, morphology, metabolism, and drug response. This diversity fuels tumor evolution and adaptation, and it has been correlated with higher risks of treatment failure and tumor progression [1, 2, 3, 4, 5, 6, 7, 8]. Indeed, treatments that initially elicit clinical response can select for drug-tolerant tumor subpopulations, leading to outgrowth of resistant clones and tumor recurrence. Additionally, the heterogeneity and composition of tumors is known to vary widely between patients, underscoring the need for more personalized approaches to cancer therapy that profile and address intra-tumor heterogeneity and its evolutionary consequences. Towards this goal, recent advances in single-cell genomic profiling of tumor samples have enabled the assessment of the genetic variability within tumor cell populations. However, single-cell technologies are often limited by large measurement errors, incomplete coverage, and small sample availability, which leads to challenges in capturing the temporal dynamics crucial for understanding response to therapies. Furthermore, the mapping between genotypic and phenotypic variation is far from perfect: not all variation in cellular drug response can be explained by genetic mechanisms, and divergent genetic profiles can lead to similar treatment responses [9, 10].

Another important approach to designing individualized treatment strategies is personalized drug sensitivity screening, a procedure in which patient tumor samples are tested for functional responsiveness to a library of drugs using high throughput *in vitro* drug sensitivity assays. In these assays, cells are treated with various concentrations of a drug and the number of viable cells is measured at one or more fixed time points. The resulting data are normalized and fitted to produce viability curves, whose summary characteristics (e.g. IC_{50} , EC_{50} , AUC) are used to compare drug sensitivity across multiple drugs and/or cell populations [11, 12, 13, 14, 15]. Increasingly, such drug screens are used as a tool in personalized medicine to evaluate and rank the potential efficacy of therapeutic agents on a patient’s disease cell population. However, the interpretation of these cell viability curves and associated metrics are confounded by the presence of cellular heterogeneity within the population. In particular, the presence of multiple subpopulation with divergent drug response characteristics may result in an intermediate drug sensitivity profile that does not accurately represent any individual cell type within the population [16]. Developing techniques to detect the presence of subpopulations with distinct drug sensitivity profiles is crucial for achieving effective treatment strategies.

In this work, we develop a novel methodology for detecting the presence of cellular subpopulations with differential drug responses, using standard bulk cell viability assessment data from drug screens. Our method, PhenoPop, detects the presence and composition fractions of distinct phenotypic components in the tumor sample and quantifies the sensitivity of each subpopulation to a specific mono-therapy. It utilizes statistical tools in combination with a novel underlying population dynamic model describing the evolution of a heterogeneous mixture of tumor cells with differential drug sensitivity over time. We

validate PhenoPop using simulated tumor drug screening data as well as measurements of drug response in known mixture experiments of cancer cell lines. We then use this method to profile the population drug response heterogeneity in multiple myeloma patient samples, and we demonstrate how these results can be used to produce personalized predictions of tumor response to therapy. This methodology can be applied across cancer types and therapies to characterize the drug-response heterogeneity within tumors.

Results

Figure 1: The PhenoPop workflow: 1) A cancer sample is taken from a patient. 2) Drug screening is performed on the bulk sample. 3) Population deconvolution is performed using PhenoPop. 4) Resulting identification of population subcomponents, their mixture fractions and drug-sensitivity.

Figure 1 provides an overview of the PhenoPop workflow. First, a tumor sample is extracted, divided, and exposed to a panel of therapeutic compounds at a range of concentrations. For each drug, the population size counts are measured at a series of time points for each concentration and replicate. This data is then used as the input to PhenoPop, which estimates the parameters of the underlying population dynamic model for each candidate number of subpopulations. Then, a model selection process is performed to identify the number of subpopulations present and to estimate the mixture fractions and drug

117 sensitivities of each subpopulation. Details are provided in the Materials and methods
118 section.

119 Validation in synthetic populations

120 To quantify the performance of PhenoPop in mixtures of 1, 2, and 3 populations, three
121 synthetic populations were designed to have drug-response properties similar to cell lines
122 observed in in-vitro experiments. Using the model for data generation described in the
123 Materials and methods section (subsection *Generation of synthetic population data*), syn-
124 thetic data was generated for 9 different mixture compositions of the three populations.
125 The synthetic mixtures were exposed to 17 concentrations of the simulated drug, and the
126 bulk cell populations were measured at 9 equidistant points in time. The simulated drug
127 concentrations were chosen to cover the range where population growth rates were affected
128 by changes in the drug concentration. To simulate measurement error, random noise was
129 added to each bulk cell count. Data from 4 replicates of the experiment were used to
130 perform the inference.

131 To measure drug sensitivity, PhenoPop uses the growth rate-associated metric GR_{50} ,
132 introduced in [17] and defined as the concentration at which the population growth rate
133 is reduced by half of the maximum observed effect, as it provides a robust metric for
134 comparing drug-response across cellular subpopulations (Materials and methods, section
135 *Calculation of GR_{50} values*). To assess the accuracy of the PhenoPop deconvolution anal-
136 ysis, (i) the estimated mixture fractions from the deconvolution were compared with the
137 true mixture fractions, and (ii) the GR_{50} obtained from the deconvolution was compared
138 with the true GR_{50} region. The use of a region, or range of values, for the true GR_{50} re-
139 flects the inherent limitation from sampling discrete concentrations in experimental data;
140 it is only possible to ascertain that the GR_{50} is somewhere between the closest two sam-
141 pled concentration levels, and the finer the sampling resolution, the smaller the range of
142 uncertainty.

143 Figure 2a shows true mixture compositions and GR_{50} values compared to PhenoPop’s
144 estimates for the 9 cases, in an experiment where the noise terms were sampled indepen-
145 dently from a Gaussian distribution with mean 0 and base noise level of 5 %, meaning
146 that the standard deviation of the noise terms equaled 5 % of the noiseless cell count at
147 time 0. Additional sensitivity tests evaluating PhenoPop performance on synthetic data
148 with varying noise levels (up to 50 %) are discussed in the section *PhenoPop-recommended*
149 *experimental design and limitations* and data are provided in the Supplementary Informa-
150 tion. To place these noise levels in the context of expected noise levels from experimental
151 drug screen data, the standard deviation to mean ratio reported from several common
152 automated or semi-automated cell counting techniques ranges from 1-15 % [18, 19]. For
153 example, counts obtained via a trypan blue exclusion-based Vi-CELL® XR Cell Viability
154 Analyzer (Beckman Coulter) had noise levels consistently less than 5.3 % across several
155 cell lines [18], while those obtained via a Countess® Automated Cell Counter (Invitrogen)

156 fell in the range 11-14.3 %. Cells counts obtained using the Cellomics ArrayScan high
157 content screening platform in another set of experiments (used in this work) had standard
158 deviation to mean ratios of 1-5.6 % [19].

159 Figure 2a demonstrates that PhenoPop inferred the mixture fractions within 2 percent-
160 age points for mixtures of 1, 2, and 3 populations at the 5 % noise level. The GR50 values
161 were inferred precisely within the true GR50 region for all mixtures of 1 and 2 populations,
162 and also for an equal mixture of 3 populations. In the case with 3 populations in a 40:30:30
163 mixture, one of the estimated GR50 values is off by 1 GR50 region, and in the 3-population
164 mixture with a 60:20:20 mixture, all three estimated GR50 values are off by 1 GR50 region.

165 Validation with cell line experiments

166 Next, to investigate the performance of our method in the experimental setting, mixtures
167 of cell populations with differential drug sensitivity were constructed and subjected to
168 drug screen experiments. The resulting bulk cell population readings at varying drug
169 concentrations, time points, and replicates were used as inputs to PhenoPop.

170 *Imatinib-sensitive and -resistant Ba/F3 cells.* We tested monoclonal and mixture pop-
171 ulations of isogenic Ba/F3 murine cell lines that were stably transformed with either the
172 wild-type BCR-ABL fusion oncogene or with BCR-ABL-T315I, which contains a point
173 mutation that confers increased resistance to the Abl tyrosine kinase inhibitor imatinib.
174 Note that expression of these oncogenes renders cells addicted to BCR-ABL activity [20].
175 Monopopulations and mixtures of these two cell lines were treated with 11 different concen-
176 trations of imatinib, and the bulk cell population sizes were quantified at 14 time points.
177 Using this bulk population data, PhenoPop was able to correctly assess the number of com-
178 ponent subpopulations (see Supplementary Figure S17). As shown in Figure 2b, PhenoPop
179 also estimated the fraction of the population belonging to each subcomponent at the start of
180 the drug screen as well as the drug sensitivity (GR50) of each subpopulation; the estimates
181 demonstrated good agreement with the known mixture proportions and independently
182 assessed GR50 ranges of the monoclonal T315I+/- populations.

183 *Erlotinib-sensitive and -resistant NSCLC cells.* Additionally, two EGFR-mutant non-
184 small cell lung cancer (NSCLC) lines, HCC827 and H1975, were considered for their differ-
185 ential sensitivity to the drug compound erlotinib. The mutation T790M, which is present
186 in H1975 cells but not in HCC827 cells, confers increased resistance to erlotinib. Monopop-
187 ulations and mixtures of the erlotinib-sensitive and -resistant NSCLC cell lines were treated
188 with four drug concentrations and total cell population count was assessed at 0, 24, 48, and
189 72 hours with four replicates [19]. Figure 2c demonstrates PhenoPop's results on this bulk
190 data. PhenoPop was able to correctly assess when populations were monoclonal, as well
191 as to detect the presence of two populations in the bulk drug response data from mixed
192 populations. Furthermore, using the bulk mixture response data, PhenoPop accurately
193 estimated the mixture fractions and GR50 values of each component subpopulation. The
194 reference GR50 ranges were independently assessed on monoclonal HCC827 and H1975 cell

Figure 2: PhenoPop validation on simulated data and cell-line derived experimental data. **a**, True and estimated mixture fractions and GR50 values for synthetic data. For each row, the “True mixture” pie chart shows the mixture fractions used to generate the data; the “Estimated mixture” pie chart shows the mixture fractions estimated by PhenoPop; in the “GR50 values” panel, the vertical grey lines show the sampled drug concentrations; the true GR50 region of each subpopulation has been marked by coloring the region between the two adjacent observed concentrations in the color belonging to that population (see main text for more details); for each estimated population, the estimated GR50 is marked by a white dot, with the region between the adjacent observed concentrations colored in the estimated clone’s color. **b**, True and estimated mixture fractions and GR50 values for Ba/F3 murine cell line data. **c**, True and estimated mixture fractions and GR50 values for NSCLC cell data.

195 populations.

196 Deconvolution analysis of Multiple Myeloma patient samples

197 Next, PhenoPop was used in a clinical scenario to deconvolve twenty drug sensitivity screens
 198 performed on five Multiple Myeloma (MM) patient samples. MM is a clonal B-cell malignancy characterized by abnormal proliferation of plasma cells in the bone marrow. The
 199 median survival time of MM patients is about 6 years, with a disease course typically
 200 marked by multiple recurrent episodes of remission and relapse [21]. Drug responses and
 201 relapses are currently unpredictable, largely due to unknown complex clonal compositions
 202 and dynamics under treatment [22, 23].

204 Bone marrow samples were taken from each patient, processed, and screened with a set
 205 of MM clinically-relevant drugs, as illustrated in Figure 3a and described in the Materials
 206 and methods section [24]. To perform the drug screens, samples from each patient were
 207 subjected to treatment at varying concentrations with a subset of the following drugs:
 208 Dexamethasone, Ixazomib, Melphafen, Selinexor, Thalidomide, and Venetoclax. We note
 209 that screening data for all drugs for each patient was not available; Figure 3b-g shows
 210 the set of patient samples treated by each drug and summarizes the results of PhenoPop
 211 deconvolution analysis on each set of drug screen data.

212 *Inter-patient similarities in subpopulation GR50s.* In all cases PhenoPop identified
 213 either one or two subpopulations; details of model selection results are shown in supplementary Figure S16. For example, Figure 3b shows that for patient MM1420, PhenoPop
 214 estimates that 87 % of the cells are resistant to Dexamethasone. This matches the clinically observed response, as the patient was refractory to Dexamethasone treatment in vivo.
 215 Interestingly, for all drugs used except Dexamethasone, the inferred subpopulations across
 216 patient samples share comparable GR50 values, although the proportions of these subpopulations may vary between patients (see Figure 3c-g). For example, for three patient
 217 samples treated with Venetoclax, PhenoPop inferred one more-sensitive and one more-resistant population (Figure 3e). However, the estimated proportions of the more-resistant
 218 populations (shown in the plot by the right-pointing arrows) varied from 23% up to 58%.
 219

223 We hypothesized that subpopulations with similar GR50s across patients may in some
 224 cases be driven by similar genetic alterations. To investigate this, we also characterized
 225 the samples with inferred heterogeneous compositions for the presence of high-risk genomic
 226 abnormalities, including Gain(1q21) (2/3) and several mutations co-existing in the same
 227 screened sample (MM36). Interestingly, we noticed that the proportion of MM cells from
 228 two samples (MM1420 and MM195) harboring the aberration gain (1q21) (approximately
 229 50 %) was similar to the PhenoPop-inferred mixture fractions for the more-resistant clone in
 230 the same two samples (50% and 58%, respectively). This supports our hypothesis that these
 231 subpopulations, which have similar levels of drug tolerance in different patients, may be
 232 driven the same alterations, and it is consistent with previous findings showing Gain(1q21)
 233 as negative predictor for Venetoclax efficacy in MM. This analysis provides genetic evidence

234 that supports PhenoPop’s ability to profile phenotypic drug response heterogeneity.
 235 *Treatment response prediction using PhenoPop estimates.* The utility of these pheno-
 236 typic deconvolutions as initial states for predicting and optimizing patient-specific treat-
 237 ment schedules remains to be systematically explored. Here, as a proof of concept, we
 238 present a mathematical model to illustrate how to use the PhenoPop estimates of popula-
 239 tion frequencies and differential drug sensitivities to predict the treatment outcome for the
 240 three patients exposed to Venetoclax. For easier comparison, we assumed that all three
 241 patients start with a total of 10^{12} abnormal plasma cells. Figure 4 demonstrates how the
 242 same treatment dose, $2 \mu M$ of Venetoclax, assumed constant over the simulation for sim-
 243 plicity, leads to highly disparate treatment outcomes in patients with distinct phenotypic
 244 heterogeneity profiles uncovered by PhenoPop. In particular, we note that to observe the
 245 predicted relapse in patient MM36, simulations have to be run for a much longer time
 246 (3000 days) than for the other two patients. See the Materials and methods section for a
 247 description of the used model and its parameterisation.

Figure 3: Phenotypic deconvolution of drug screens from MM patient samples. **a**, Illustration of the experimental protocol described in Materials and methods [24]. Illustration created by the authors using smart.servier.com and biorender.com. **b-g**, Inferred mixtures and GR50 values for 5 MM samples with respect to 5 drugs: b) Dexamethasone, c) Selinexor, d) Melflufen, e) Venetoclax, f) Ixazomib, g) Thalidomide. For each row, the “Estimated mixture” pie chart shows the mixture fractions estimated by PhenoPop; In the “GR50 values” panel, the vertical grey lines show the observed drug concentrations; For each estimated population, the estimated GR50 is marked by a white dot, with the region between the adjacent observed concentrations colored in the estimated clone’s color. If the inferred GR50 value of a population was higher than the highest observed concentration value, the estimated GR50 is instead marked by an arrow pointing towards the right from the highest observed concentration.

248 PhenoPop-recommended experimental design and limitations

249 We next performed a computational study using synthetic drug screen data to identify
250 experimental design strategies that enhance PhenoPop accuracy, and to explore the limi-
251 tations of the method.

252 *Prioritization of experimental efforts: increasing the number of drug concentrations,*
253 *time points, or replicates.* We first considered the relative importance of experimental
254 resolution in drug concentration, time points, and replicates in PhenoPop performance.
255 Figure S2 shows the average gain in accuracy for a mixture of 2 populations (one sensitive,
256 one resistant) when either the replicates R , the number of concentrations N_c or the number
257 of time points N_t are increased while the others are held constant at the value three. To
258 compare the accuracies, 27 two-sided t-tests were made, since 3 effects (increasing R , N_c ,
259 and N_t) were compared pairwise at 3 sample sizes (5, 9 and 17), in 3 different comparison
260 measures. To account for multiple testing, the family-wise error rate was controlled to be
261 below 0.05 using the Bonferroni correction.

262 We find that for accuracy in the mixture parameter, increasing the number of con-
263 centrations or time points gives significantly higher precision than increasing the number
264 of replicates to the same amount. Similarly, to enhance accuracy in the GR50 value of
265 the sensitive population, increasing either the number of concentrations or number of time
266 points gives significantly higher precision compared to increasing the number of replicates
267 by the same number. In addition, increasing the number of concentrations to 9 or 17 is
268 significantly better than increasing the number of time points similarly. No significant
269 differences were found for estimating the GR50 of the resistant population.

270 *Noise level.* We also studied how increasing levels of measurement noise in the data (e.g.
271 in cell counting) impact the precision of the deconvolution results. Results of these tests
272 are shown in Supplementary figures S3, S4, S5 and S6, where the same synthetic data with
273 increasing levels of measurement noise were used as inputs to PhenoPop. We found that for
274 noise levels up to a standard deviation equal to 20% of the initial cell count, PhenoPop is
275 able to correctly deconvolve the bulk response signal into the correct components. Beyond
276 this noise level mixture fractions are off by more than 10% in 2-population mixtures, and
277 populations may go undetected in 3-population mixtures. Supplementary figures S9, S10,
278 S11, S12, and S13 (corresponding to Figure 2a and Supplementary figures S3, S4, S5 and
279 S6) show how model selection was performed in these cases.

280 *Small mixture fractions.* To determine how small population fractions PhenoPop is
281 able to detect, inference was performed on simulated data with a range of small mixture
282 fractions, with a noise level of 5% of the initial cell count. We found that in 2-population
283 mixtures, PhenoPop was able to detect populations at frequencies as low as 1 percent. In
284 3-population mixtures, PhenoPop was able to detect populations with mixture fractions
285 of 3 percent and higher. At noise level of 5%, the estimated mixture parameters were
286 within 1% of the true value and the estimated GR50 values were always within two GR50
287 regions of the true value. Supplementary Figure S7 shows these results. The figure also

Figure 4: Proof-of-concept modeling of Multiple Myeloma disease dynamics under Venetoclax treatment for three patients using PhenoPop deconvolution results. The estimated mixture and drug-response parameters obtained by PhenoPop (see Figure 3e) define the initial percentage of cells and drug-response for each clone and patient. Cells from both clones are assumed to produce monoclonal protein (M-protein), which can be used as a proxy for tumor burden. For easier comparison, we assume that all three patients start with a total of 10^{12} abnormal plasma cells (cell number shown in the right y-axes) and 1g/dL M-protein (shown in the left y-axes). All three patients are exposed to 2 μ M of Venetoclax. See Materials and methods for description of mathematical model.

shows that it is harder to detect two small populations mixed with a large population (bottom row), than it is to infer one small population mixed with two larger ones (fifth row). Supplementary Figure S14 shows how model selection performed for these cases.

Subpopulation similarity. We performed computational experiments to determine the degree of similarity between component subpopulations beyond which PhenoPop was unable to detect distinct populations. We tested a set of 2 similar mixed populations, at a noise level of 5% of the initial cell count. We found that PhenoPop was able to detect populations whose GR50 values were as close as 2 GR50 regions apart. For such close populations, the estimate of the mixture parameters were within 2% of the true value and the estimated GR50 values were within 1 GR50 region of the true value, even for mixtures as unbalanced as 90:10. The results are shown in Figure S8. The figure's third, sixth and ninth rows show that the inferred GR50 values may overlap or swap position if the true GR50 values are less than 2 GR50 regions apart. The figure's eighth row shows that for mixtures of 5% or smaller, the inferred GR50 values can overlap even when the true GR50 values are 2 GR50 regions apart. Figure S15 shows how model selection performed for these cases.

Discussion

Understanding the phenotypic heterogeneity of human tumors, especially in terms of drug response, is essential in treatment planning and prognosis prediction. The optimization of treatment regimens is a long-standing area of research in the mathematical oncology community [25, 26, 27, 28]; however, the initial state of the tumor, which strongly influences optimal treatment strategies, is typically unknown. The PhenoPop method enables the detection of tumor subpopulations, as well as estimation of their frequencies and drug sensitivities. The resulting deconvolved tumor profile can be fed, as an initial state, into mathematical models of tumor dynamics to predict treatment response (see Figure 4) and identify optimal treatment regimens.

Although the mathematical structure of the phenotypic deconvolution problem bears a resemblance to classical clustering based on observing individual responses, a vital difference is that in our setting the observed data is a combined signal from the entire population with unknown mixture frequencies and components. This statistical problem is also similar to the problem considered in blind source separation in digital signal processing, in which one attempts to recover individual source components from a mixture of signals (see e.g., [29]). However, a key assumption in this classic problem is the independence of the constituent components, a restriction that is not needed for PhenoPop. Interaction between individual populations, e.g. due to resource limitation or phenotypic switching, can be incorporated within the PhenoPop framework (see Supplementary Information section entitled Model Extension to Interacting Populations). The mathematical structure used in PhenoPop can also be applied to perform deconvolution analyses for cellular response

326 to many other external stimuli, such as intercellular signaling, the environmental pH level,
 327 mechanical forces and many others. To achieve this, the underlying population dynamic
 328 model of drug response used in PhenoPop can be replaced with another mechanistic or
 329 machine-learning derived model describing response to other stimuli. PhenoPop produces
 330 a heterogeneity profile tailored to each patient sample for each drug in a drug-screen panel.
 331 While this information is useful for identifying successful single-agent therapies and for
 332 optimizing or designing their therapeutic schedules, combination therapy design requires
 333 joint deconvolution analyses that elucidate the mapping between heterogeneity profiles for
 334 multiple drugs. This task will necessitate additional data from combination drug screens,
 335 and further methodological development in experimental design to identify tractable sub-
 336 sets of combination screening experiments that are necessary for identifying these joint
 337 deconvolution profiles. We plan to address this problem in future work.

338 The precision of PhenoPop depends on the amount of observation noise in the data. For
 339 the exponential growth model, normally distributed noise with a standard deviation of up
 340 to 20% of the initial cell count can be tolerated, while higher noise levels lead to errors in
 341 model selection and decreased accuracy in mixture fractions and GR50 estimates. This is
 342 especially seen in the 3-population mixtures, and it is expected that the problem would be
 343 aggravated in mixtures of more than 3 populations. We note that the standard deviation
 344 to mean ratio reported from several of the most common automated or semi-automated
 345 cell counting techniques ranges from 1-15 % [18, 19].

346 At moderate noise levels (standard deviation to mean ratio of 5%), PhenoPop was able
 347 to detect subpopulations as small as 1% of the total population in 2-population mixtures,
 348 while in 3-population mixtures the smallest detectable population fraction was 3 %. The
 349 precision is reduced when subpopulations have very similar GR50 values and the reso-
 350 lution of experimental drug concentrations does not distinguish well between them, but
 351 for predicting treatment response, distinguishing subpopulations that are almost identical
 352 is of limited clinical importance. Additionally, our study suggests that in terms of data
 353 resolution and prioritization of experimental effort, increasing the number of observed con-
 354 centrations improves accuracy the most, followed by the number of time points, and then
 355 the number of replicates.

356 Accurate, efficient techniques for profiling of heterogeneity across multiple axes are
 357 important foundations for personalized treatment decision-making. In this work we have
 358 demonstrated that PhenoPop can provide vital insights into the diversity of drug response
 359 amongst tumor cells. This framework, enabled by mixture population dynamic modeling of
 360 response to therapy, utilizes bulk drug screen data and alleviates the need for costly single-
 361 cell methods in profiling tumor heterogeneity. Although we focus here on tumor drug-
 362 response heterogeneity, the PhenoPop framework can also be applied to detect and profile
 363 heterogeneous cellular response to other stimuli, such as stromal content, nutrient/oxygen
 364 deprivation, and epigenetic modifiers. This general framework can also be applied beyond
 365 cancer to other biological settings in which reproducing populations harbor heterogeneous
 366 responses to environmental stimuli, such as the response of bacterial or viral populations

367 to antibiotic or antiviral therapies.

368 Materials and methods

369 Given a set of experimental drug-screen data on a bulk tumor sample, PhenoPop solves a
 370 series of optimization problems to identify individual subpopulations within the sample and
 371 to estimate their frequencies and drug sensitivities. This problem is challenging because it
 372 requires simultaneous estimation of the number of individual subpopulations present, their
 373 frequencies in the population and their drug response characteristics, all based on noisy
 374 observations of the total cell population. Our solution to this problem is enabled by the
 375 introduction of a mixture population dynamic model of the tumor in which the growth rate
 376 dependence on drug concentration follows a Hill-type functional form (see equation (3)).

377 Model of dose-dependent population dynamics

PhenoPop relies upon an underlying model of heterogeneous tumor population dynamics *in vitro*. The growth of a single population of cells with homogeneous drug response is modelled by

$$X(d, t) = X(0) * \exp [t (\alpha + \log H(d))], \quad (1)$$

where $X(d, t)$ is the number of cells at time t under drug concentration d , $X(0)$ is the initial population size, α is the intrinsic growth rate of the population in the absence of drug, and $H(d)$ is a classic sigmoidal function describing the dependence of the population growth rate on drug concentration d :

$$H(d) = b + \frac{1 - b}{1 + \left(\frac{d}{E}\right)^n}. \quad (2)$$

378 The parameters of this function control the shape of the sigmoid: $b \geq 0$ reflects the max-
 379 imum effect of the drug, E is the log concentration at which 50 percent of the maximum
 380 effect is achieved, and $n > 0$ controls the steepness of the response. This novel form of
 381 the growth rate, $r(d) \equiv \alpha + \log H(d)$, is chosen so that the predicted cell viability curve,
 382 which is the treated viable cell population size normalized by the untreated viable cell
 383 population size at a fixed time, exhibits the standard Hill-shaped dependence on drug con-
 384 centration that is empirically observed in viability assays [16]. Supplementary Figure S1
 385 demonstrates that this model accurately recapitulates experimental cell viability depen-
 386 dence on drug concentration in two BCR-ABL positive Ba/F3 cell lines (with and without
 387 the T315I mutation) treated with the tyrosine kinase inhibitor imatinib. Note that since
 388 we are studying *in vitro* populations prior to confluence, an exponential growth model is
 389 appropriate.

To extend the monoclonal growth model (1) to a population composed of several subpopulations, each with a specific own drug response dynamics, we denote the growth parameters of the i -th subpopulation by α_i, b_i, E_i, n_i . Then the model of a cell population with S subpopulations under drug concentration d at time t is:

$$Z(d, t; \mathcal{P}_S) = Z(0) \sum_{i=1}^S \pi_i \exp [t(\alpha_i + \log H(d; b_i, E_i, n_i))] \quad (3)$$

where $Z(0)$ is the total initial population and π_i is the initial mixture fraction of the i -th subpopulation ($\sum_{i=1}^S \pi_i = 1$). Here, $\mathcal{P}_S \equiv \{\pi_i, \alpha_i, b_i, E_i, n_i : i \in \{1, \dots, S\}\}$ denotes the set of parameters for S populations, and the parameters of the Hill function $H(d; b_i, E_i, n_i)$ are written explicitly to emphasize the individual drug response profile of each subpopulation. Under this formulation, we need to estimate, on the basis of the drug screen data, the unknown number of subpopulations S and the corresponding parameters \mathcal{P}_S . Note that in this case, the heterogeneous population is modelled as a mixture of populations in which individual subpopulations are assumed to grow independently. In the Supplementary Information, we consider a case in which interaction between subpopulations is incorporated.

Estimation procedure

As input, PhenoPop takes bulk tumor sample drug screening observations, in the form of total cell counts at a series of time points and drug concentrations. A variety of experimental techniques is commonly used to generate such observations of cell population counts in drug screening. For example, tetrazolium reduction assays (e.g. MTT, MTS), protease viability markers (e.g. GF-AFC), ATP assays (e.g. Cell Titer-Glo), and more recently developed real-time assays (e.g. Real-Time Glo, live-cell imaging) [30, 31]. The PhenoPop methodology is capable of using experimental input from any of these assays, as long the measurements provide viable cell count or a proxy quantity (e.g. fluorescence intensity) that is proportional to the cell number. Generally, real-time techniques may yield superior deconvolution results due to a reduction in the total noise of the data set.

Given a set of experimental drug-response data on a bulk tumor sample, PhenoPop solves a series of optimization problems to deconvolve and characterize individual subcomponents of the bulk sample in terms of varying drug sensitivity profiles. In particular, each experimental observation, denoted by $\mathcal{O}_{j,k,r}$, corresponds to a cell population number measured under drug concentration $d(j)$ where $j \in \{1, \dots, C\}$, time point t_k , where $k \in \{1, \dots, T\}$, and replicate $r \in \{1, \dots, R\}$. We denote the total set of observations by \mathcal{O} .

For simplicity, we will first assume that there are S subpopulations. Our statistical model of experimental observations will be based on the deterministic model in equation (3). In particular, we model each experimental observation as an independent standard Gaussian random variable with mean $Z(d(j), t(k); \mathcal{P}_S)$ and standard deviation $\sigma(d(j), t(k))$.

Note that we allow the standard deviation σ to vary with dose and time. This is because at low doses and high times we expect a larger variance due to the larger cell counts. Therefore we define

$$\sigma(d, t) = \begin{cases} \sigma_H, & d \leq D_L \text{ and } t \geq T_L \\ \sigma_L, & \text{otherwise.} \end{cases}$$

Our standard deviation is thus characterized by four parameters, $\sigma = (\sigma_L, \sigma_H, D_L, T_L)$. We will denote the set of time-dose observations where we use standard deviation σ_H by I_H , and the set where we use σ_L by I_L . We denote their cardinalities by $|I_H|$ and $|I_L|$.

Assuming S subpopulations we can use this model to write the log-likelihood as

$$\begin{aligned} L(\mathcal{P}_S, \sigma; \mathcal{O}) = & -\frac{1}{2}R|I_H|\log(2\pi\sigma_H^2) - \frac{1}{2}R|I_L|\log(2\pi\sigma_L^2) \\ & - \frac{1}{2\sigma_H^2} \sum_{r=1}^R \sum_{(j,k) \in I_H} (\mathcal{O}_{j,k,r} - Z(d(j), t(k); \mathcal{P}_S))^2 \\ & - \frac{1}{2\sigma_L^2} \sum_{r=1}^R \sum_{(j,k) \in I_L} (\mathcal{O}_{j,k,r} - Z(d(j), t(k); \mathcal{P}_S))^2. \end{aligned} \quad (4)$$

For a fixed S , we thus compute the maximum likelihood estimates of the model parameters by solving the optimization problem

$$(\hat{\mathcal{P}}_S, \hat{\sigma}) = \operatorname{argmax}_{\mathcal{P}_S, \sigma} L(\mathcal{P}_S, \sigma; \mathcal{O}). \quad (5)$$

Model selection using the elbow method. To infer the number of subpopulations in the mixture, PhenoPop is fitted to the data repeatedly, for each number of subpopulations S in $S = \{1, 2, \dots, S_{\max}\}$ in turn, and the S negative log-likelihood values are recorded. We then plot the negative log-likelihood values as a decreasing function of S , and observe the number of subpopulations corresponding to which the negative log-likelihood does not decrease significantly further. This means that no useful increase in model accuracy is gained by including another additional population. This point of inflection of the negative log-likelihood is called the elbow of the curve. The optimal number of populations is then chosen by the experimenter through visual inspection. The resulting estimate $\hat{\mathcal{P}}_{\hat{S}}$ contains the inferred population's drug response substructure: the estimated number of populations along with the estimated mixture frequency and estimated drug sensitivity GR_{50} of each subpopulation. This method is known as the elbow method, and it is a well-known heuristic for model selection in cases where the model fit generally increases with complexity. Model selection is shown in Supplementary figures S17.

Optimization methodology

The maximum likelihood estimate of the parameters $\hat{\theta}_{\text{MLE}}$ was obtained by maximizing the log-likelihood (4), subject to constraints that were placed on the range of each parameter.

437 This constrained optimization problem was performed using the function `fmincon` from the
 438 MATLAB Optimization Toolbox [32], with the default interior-point optimization method.
 439 To combat converging to suboptimal local minima, the log-likelihood was maximized re-
 440 peatedly and independently, by starting from N_{optim} different random initial positions for
 441 the parameter θ , sampled uniformly within their allowed range (except for the parameter
 442 E , which was sampled log-uniformly within the bounds). Among the N_{optim} minima, the
 443 one with the highest log-likelihood value was chosen as estimate $\hat{\theta}_{\text{MLE}}$.

444 Calculation of GR_{50} values

The viability curve and associated metrics of drug response (e.g. IC_{50}, EC_{50}) typically exhibit dependence on the timing of data collection (see [17]). We form a growth rate curve by inferring the growth rate $r(d)$ at each tested dose level d . In contrast to the viability curve the growth rate curve does not have a hidden dependence on the duration of the experiment, assuming exponential growth. Once the parameters of model (3) are estimated for each subpopulation using the inferential procedures above, the GR_{50} for each subpopulation can be explicitly determined using the set of parameters $(\alpha_i, b_i, E_i, \text{ and } n_i)$. Following Sorger and et al [17] we characterize dose-response of clones with a GR_{50} value. This number represents the dose at which the cellular growth rate experiences half of its total reduction. In particular, suppose that we are interested in a homogeneous population with the growth rate at dose d given by

$$GR(d; \alpha, b, E, n) = \alpha + \log H(d; b, E, n).$$

Note that we will generally suppress the dependence on parameters and simply write $GR(d)$. If the maximum dose administered is d_m , and the minimum dose administered is 0, then the median growth rate is $r_m = (GR(0) + GR(d_m))/2$. We then define the GR_{50} as the dosage that results in this growth rate, i.e., the value d such that $GR(d) = r_m$. We can then solve to obtain

$$GR_{50} = E \left(\frac{e^{r_m - \alpha} - 1}{b - e^{r_m - \alpha}} \right)^{1/n}.$$

445 Generation of synthetic population data

446 By defining a number of populations S and a parameter set $\mathcal{P}_S \equiv \{\pi_i, \alpha_i, b_i, E_i, n_i : i \in$
 447 $\{1, \dots, S\}\}$, synthetic data can be generated in a deterministic manner with equation (3).
 448 Table 1 shows the parameters $\{\alpha_i, b_i, E_i, n_i : i \in \{1, 2, 3\}\}$ of the blue, red and yellow
 449 populations in figures 2, S3, S4, S5 and S6.

450 For the synthetic validation, simulated data with initial population size of $Z_0 = 1000$
 451 cells were generated for the following 9 mixtures of the three cell populations in table 1:
 452 $[1, 0, 0]$, $[0, 1, 0]$, $[0, 0, 1]$, $[0.5, 0.5, 0]$, $[0.7, 0.3, 0]$, $[0.3, 0.7, 0]$, $[1/3, 1/3, 1/3]$, $[0.4, 0.3, 0.3]$ and
 453 $[0.6, 0.2, 0.2]$.

	α	b	E	n
Clone 1 (blue)	0.03	0.3	0.0001	3.0
Clone 2 (red)	0.03	0.4	0.01	3.0
Clone 3 (yellow)	0.03	0.5	0.1	3.0

Table 1: Parameters for simulated data.

We chose 17 simulated drug concentrations. One equal to zero, the rest spaced logarithmically in a region designed to cover the GR50 values of the simulated populations. The simulated concentrations were: [0, 0.00000500, 0.0000108, 0.0000232, 0.0000500, 0.000108, 0.000232, 0.000500, 0.00108, 0.00232, 0.00500, 0.0108, 0.0232, 0.0500, 0.108, 0.232, 0.5] μM . Cell counts were measured at 12-hour intervals from 0 to 96 hours, and 4 replicates of the simulation were carried out, where the only difference between the replicates was the randomly sampled observation noise: A random noise term was added to each observed cell count, sampled from an independent and identically distributed (i.i.d.) Gaussian distribution with mean 0 and standard deviation ranging from 1 to 50% of the initial cell count. Any negative cell count caused by the additive noise was set to zero. This gives the following expression for the generated observation $\mathcal{O}_{j,k,r}$ with concentration number j at time k for replicate r :

$$\mathcal{O}_{j,k,r} = \max \left(Z(d, t; \mathcal{P}_S) + \varepsilon_{j,k,r}, 0 \right), \quad \varepsilon_{j,k,r} \sim \mathcal{N}(0, \sigma^2) \text{ i.i.d.} \quad (6)$$

Model of multiple myeloma under treatment

Inspired by [33] we present a mathematical model of M-protein levels of a multiple myeloma patient under treatment with an anti-cancer drug. This model assumes that the patient has two subpopulations of cancer cells with distinct responses to the drug. In particular the cancer cells and M-protein levels are governed by the following system of ordinary differential equations

$$\frac{dx}{dt} = \frac{r_1(d)x}{1 + p(x + y)}, \quad (7a)$$

$$\frac{dy}{dt} = \frac{r_2(d)y}{1 + p(x + y)}, \quad (7b)$$

$$\frac{dz}{dt} = r_3(x + y) - d_3z, \quad (7c)$$

where x and y denote number of myeloma cells in subpopulations 1 and 2 respectively, and z denotes M-protein concentration in plasma. Parameters r_1 and r_2 are the net growth rates under treatment of subpopulations 1 and 2 respectively. We assume the net growth rates can be computed as

$$r_i(d) = \alpha_i + \log H(d; b_i, E_i, n_i), \quad i \in \{1, 2\}, \quad (8a)$$

where $(\alpha_i, b_i, E_i, n_i)$ are the estimated parameters of subpopulation i using PhenoPop. The term $(1 + p(x + y))^{-1}$ in equations 7a and 7b alters the growth rate of both subpopulations when the total number of cells increases. Parameters r_3 and d_3 are the production and decay rate of the M-protein, respectively. Inspired by [33], we use $p = 10^{-13}$, $r_3 = 0.07 * 10^{-13}$ and $d_3 = 0.07$.

Model parameter ranges

For model with $S = \{1, 2, 3, 4\}$ populations, the log-likelihood was maximized $N_{\text{optim}} = 1000$ times or more to combat local minima. For each maximization, the initial estimate was sampled from within the bounds on the parameter range, which were set to the values listed below for the different datasets.

The parameter ranges for the different settings were largely similar. Some differences occur due to different concentration scales in the different experiments or due to parameter estimates hitting the boundary of the domain, in which case the range was expanded. When working with the Ba/F3 cells we needed to adjust the lower bound on the parameter b . Due to the complexity of the optimization problem, the solver had a tendency to push b towards an unrealistically low value. To address this issue we used previous observations and derived a realistic lower bound on b . Denote the net growth rate of the cells by $\lambda = \beta - \mu$, where β is the birth rate and μ the death rate. From [34], we know that $\beta \leq .06$. We can thus write $\mu = \beta - \lambda \leq .06 - \lambda_{\min} = d_0$, where λ_{\min} is the minimum observed growth rate amongst all Ba/F3 cell line experiments. Thus the maximal possible death rate is d_0 , and the minimal possible net growth rate is $-d_0$. Next note that according to our growth rate model, as the dose d goes to infinity the growth rate decreases to the lower limit $\alpha + \log(b)$. Therefore we know that $\alpha + \log(b) \geq -d_0$. We again use that $\alpha \leq .06$, and based on observed data we set $\lambda_{\min} = .04$ and get $d_0 = 0.2$. However to account for any possible errors in the method we increase d_0 to be 0.07. This then gives us the lower bound $\log(b) \geq -0.08$ or equivalently $b \geq 0.878$.

NSCLC data.

$p_i \in [0, 1]$ with the inequality constraint $\sum_{s=1}^{S-1} p_i \leq 1$

$\alpha_i \in [0, 0.1] \text{ hours}^{-1}$

$b \in [0, 1] \text{ hours}^{-1}$

$E \in [0, 50] \mu M$

$$n \in [0, 50]$$

$$\sigma_L, \sigma_H \in [0, 5500]$$

Ba/F3 data.

$$p_i \in [0, 1] \text{ with the inequality constraint } \sum_{s=1}^{S-1} p_i \leq 1$$

$$\alpha_i \in [0, 0.06] \text{ hours}^{-1}$$

$$b \in [0.878, 1] \text{ hours}^{-1}, \text{ see comment below.}$$

$$E \in [0, 50] \mu M$$

$$n \in [0.001, 20]$$

$$\sigma_L, \sigma_H \in [0, 2500]$$

Synthetic data.

$$p_i \in [0, 1] \text{ with the inequality constraint } \sum_{s=1}^{S-1} p_i \leq 1$$

$$\alpha_i \in [0, 0.1] \text{ hours}^{-1}$$

$$b_i \in [0.27, 1] \text{ hours}^{-1}$$

$$E_i \in [10^{-6}, 0.5] \mu M$$

$$n_i \in [0.01, 10]$$

$$S \in [0, 4]$$

$$\sigma_L, \sigma_H \in [10^{-6}, 5000]$$

Multiple Myeloma data.

For the multiple myeloma patient data, an initial parameter range was chosen for all patients. Then if one or more of the inferred parameters happened to lie on or near the upper or lower bound, the parameter range was increased for that patient until the estimate was no longer on the bound. Therefore, the parameter for the E and σ variables are different for some of the patients.

$$p_i \in [0, 1] \text{ with the inequality constraint } \sum_{s=1}^{S-1} p_i \leq 1$$

$$\alpha_i \in [-0.1, 0.1] \text{ hours}^{-1}$$

$$b_i \in [0, 1] \text{ hours}^{-1}$$

$$n_i \in [0.01, 10]$$

$$S \in [0, 5]$$

The E parameter ranges were:

$$E_i \in [10^{-6}, 2] \mu M \text{ for patient MM2108.}$$

$$E_i \in [10^{-6}, 50] \mu M \text{ for patient MM720.}$$

$$E_i \in [10^{-6}, 5] \mu M \text{ for patient MM195.}$$

$$E_i \in [10^{-6}, 5] \mu M \text{ for patient MM36.}$$

$$E_i \in [10^{-6}, 100] \mu M \text{ for patient MM1420.}$$

The σ parameter ranges were:

$$\sigma_L, \sigma_H \in [10^{-6}, 50, 000] \text{ for patient MM2108.}$$

$$\sigma_L, \sigma_H \in [10^{-6}, 1, 000, 000] \text{ for patient MM720.}$$

$$\sigma_L, \sigma_H \in [10^{-6}, 150, 000] \text{ for patient MM195.}$$

$$\sigma_L, \sigma_H \in [10^{-6}, 250, 000] \text{ for patient MM36.}$$

$$\sigma_L, \sigma_H \in [10^{-6}, 150, 000] \text{ for patient MM1420.}$$

Ba/F3 cell line experiments

Preparation of sensitive and resistant cell lines

BCR-Abl-T315I expressing plasmid was established by site-directed mutagenesis of p210 BCR-Abl (Addgene 27481) using QuickChange II XL (Agilent Technologies) with the forward primer 5' GGGAGCCCCCGTTCTATATCATCATTGAGTTCATGACCTACG 3' and the reverse primer 5' CGTAGGTCATGAACTCAATGATGATATAGAACGGGGGCT CCC 3' for T315I. To generate cells stably expressing BCR-Abl (imatinib-sensitive) and BCR-Abl-T315I (imatinib-resistant), parental Ba/F3 cells were transfected with the appropriate plasmids by electroporation using Amaxa biosystems nucleofector II and stable cells were established by selecting with medium containing 500µg/ml Geneticin (Gibco, UK) and lacking the growth factor IL3 (BCR-ABL activity can overcome the requirement for IL3 of untransformed parental cells for survival/proliferation [20]). Furthermore, Ba/F3 cells expressing BCR-Abl were stably transfected with GFP expression, pRNAT-H1.1/Hygro plasmid from Genscript (Piscataway NJ, USA). The resulting subpopulations exhibited

556 distinctive phenotypic differences upon treatment with Imatinib.

557

558 **Cell cultures**

559 Parental Ba/F3 cells were maintained in RPMI-1640 supplemented with 10% heat-inactivated
560 Fetal Bovine Serum (FBS), 7.5 ng/ml IL3 and 1% penicillin and streptomycin at 37°C un-
561 der a humidified atmosphere containing 5% CO₂. Ba/F3 cells stably expressing BCR-Abl
562 and BCR-Abl-T315I were maintained in medium lacking IL3.

563

564 **Experimental procedures**

565 Cells were harvested at 70-80% confluence, stained with trypan blue (ThermoFisher, UK),
566 and counted with a Countess 3 Automated Cell Counter (Life Technologies). Mono- and
567 co-cultures were seeded at different initial ratios in 384 well microplates (Greiner Bio-One)
568 that contained different concentrations of imatinib (Cayman, USA). Imatinib ranging from
569 (0 - 5 μ M) was dispensed using an Echo acoustic liquid dispenser (Labcyte, San Jose, CA,
570 USA) in seven replicates per condition. Then time-lapse microscopy images were obtained
571 for bright field and GFP using IncuCyte (Essen BioScience, UK) every 3 hours over the
572 course of 72 hours.

573

574 **Image Processing**

575 Images were processed with the open-source software ImageJ [35] Images were background
576 subtracted, converted to 8-bit, bandpass filtered, sharpened, contrast enhanced, and thresh-
577 olded. Then images were converted to binary images, watershed segmentation was per-
578 formed, and raw cell numbers were extracted.

579 **NSCLC cell line experiments**

580 **Cell Cultures**

581 HCC827 and H1975 cell lines were maintained in RPMI-1640 media supplemented with
582 10% Fetal Bovine Serum and 1% penicillin and streptomycin under standard cell culture
583 growth conditions (37°C and 5% CO₂).

584 **Experimental Growth Assay**

585 Tumor cells were seeded in 96-well black walled plates at 5,000 cells per well. The following
586 day, the cells were treated with erlotinib at various concentrations (0, 0.1, 1, 10 μ M). Cell
587 counts were determined at 0, 24, and 48 hours post drug treatment using the Cellomics Ar-
588 rayscan High Content Screening Platform. Briefly, cells were stained with 5 g/mL Hoechst
589 33342 (nuclear marker to determine total cell count) and 5 g/mL Propidium Iodide (PI -
590 vital dye to determine dead cells) for 45 minutes prior to imaging. The average intensity
591 for Hoechst and PI was determined for each cell to classify as live or dead. Each condi-
592 tion was performed in replicates of four. For admixture experiments, each cell line was

593 labeled with a different CellTracker dye (CellTracker orange CMTMR and H1975 labeled
594 with CellTracker green CMFDA). The cells were mixed at the specified ratios (total 5,000
595 cells/well) and imaged following the procedures outlined above.

596 **Drug screen of Multiple Myeloma patient samples**

597 **Patient samples**

598 The multiple myeloma (MM) patients enrolled in this study were recruited from the Oslo
599 Myeloma Center at Ullevål Oslo University Hospital under the Regional Committee ap-
600 proval for Medical and Health Research Ethics of South-Eastern Norway (REC-2016/947)
601 The MM samples were obtained following written informed consent in compliance with the
602 Declaration of Helsinki.

603 **Primary MM cells processing**

604 Bone marrow samples from 5 relapsed myeloma patients were collected in ACD tubes.
605 Details about patient ID, treatment lines and refractory status are provided in Supple-
606 mentary Table 1. A Lymphoprep TM (Stemcell Technologies) density gradient centrifuga-
607 tion method was used to obtain bone marrow mononuclear cells (BMMCs) from patient
608 samples. As described in [36], after CD8 T cell depletion by Dynabeads (Life Technolo-
609 gies), BMMCs were then stimulated by activated T helper cells in the presence of Human
610 T-activator CD3/CD28 Dynabeads (Life Technologies) and 100U/ml human interleukin-
611 2 (hIL-2, Roche, Mannheim, Germany). After 24h, CD138+ MM cell enrichment was
612 performed from the BMMC fraction by immune-magnetic microbeads CD138+ (Milteny
613 Biotec, Bergisch Gladbach, Germany).

614 **Drug sensitivity assay**

615 CD138+ MM cells (200,000 cells/ml) derived from activation assays were treated with
616 drugs at 9 concentrations using a drug customized concentration range (0,1-10,000), as
617 described in [24]. The drug panel included clinically relevant anti-myeloma drugs, Dexam-
618 ethasone (0,1-10,000), ixazomib (1-10,000), thalidomide (0,1-10,000), selinexor (0,1-1000),
619 melflufen (0,1-1000) and venetoclax (0,1-10,000). Pre-printed drug plates were made by an
620 acoustic dispenser (Echo 550, LabCyte Inc., San Jose, CA, USA), by the Chemical Biology
621 Platform, NCMM, University of Oslo. Control agents included a negative control, 0,1%
622 solvent solution dimethyl sulfoxide (DMSO), and a positive control 100 uM benzethonium
623 chloride (BzCl). In brief, MM cells were diluted in culture medium (RPMI 1640 medium
624 supplemented with 10% fetal bovine serum, 2mM L-glutamine, penicillin (100U/ml), strep-
625 tomycin (100 μ g/ml), and 25 μ l of cell suspension was transferred to 384-well plates using a
626 Certus Flex liquid dispenser (Fritz Gyger, Switzerland). Afterward, plates were incubated
627 at 37°C and 5% CO2 humidified environment. Cell viability was measured at 4 different
628 time points (0h-96h), using the CellTiterGlo (Promega, Madison, WI, USA) ATP assay
629
630

631 according to manufacturer's instructions and with an Envision Xcite plate reader (Perkin
632 Elmer, Shelton, CT, USA) to measure luminescence.

633 **Data and code availability**

634 All data and code used in this article are publicly available in the online repository of the
635 Oslo Center for Biostatistics and Epidemiology.

J.F. was supported by the US National Science Foundation under grant number DMS-2052465. K.L. was supported by the US National Science Foundation under grant number CMMI-1552764. We acknowledge funding from the Research Council of Norway with project numbers 294916, 261936, 309273 and 262652; the Norwegian Cancer Society with project number 182524; and the Norwegian Health Authority South-East with project number 2019096. The authors also acknowledge the Centre for Digital Life Norway for supporting the partner projects PerCaThe and PINpOINT. We thank the Digital Scholarship Center, University of Oslo, for insightful advice on the visual representation and communication of our research findings.

Supplementary Information

Model Extension to Interacting Populations

Our model currently ignores potential interactions between subpopulations. Based on the sample size of our current data sets we were not able to fit a more complex model that allows for interacting populations. For the situation when sufficient data are available, we propose the model below that allows for interactions between the subpopulation. Assuming that there are S subpopulations, for each $i \in \{1, \dots, S\}$ define the function

$$f_i(\mathbf{X}, d) = \sum_{l=1}^S (\alpha_{il} X_l - c_{il} X_i X_l) + X_i \log H_i(d),$$

where d is possible drug dose and $\mathbf{X} \in \mathbb{R}_+^S$. The parameter α_{il} represent the rate at which type- l cells produce type- i cells, and α_{ii} is the net growth rate of the type- i cells. We assume that each α_{il} term is non-negative. The term c_{il} represents the effect of population l on population i . If $c_{il} > 0$ then population l inhibits population i , if $c_{il} < 0$ then population l encourages population i to grow, and finally if $c_{il} = 0$ then population l has no direct effect on population i . Note that the term c_{ii} represents the effect of type- i cells on itself and we assume that $c_{ii} > 0$. The parameters α_{il} allow for inter-conversion between cell types, and the parameters c_{il} allow for inhibition or promotion between cell types.

For dose d , and initial population vector $\mathbf{x}^0 = (x_1^0, \dots, x_S^0)$, define $\{\mathbf{X}(t, d; \mathbf{x}^0); t \geq 0\}$ as the solution to the differential equation

$$\dot{X}_i(t, d) = f_i(\mathbf{X}, d), \quad \text{for each } i \in \mathcal{S}, \quad (9)$$

with initial condition $X_i(0) = x_i^0$. Define $x_0 = \sum_i x_i^0$ and write $x_i^0 = p_i x_0$. We assume that x_0 is a known quantity, but the proportions $\{p_i\}_{i \in \mathcal{S}}$ are unknown. We denote the model-predicted total population at time t under dose d by $X(t, d)$. Recall that the total population is the observable variable in our model.

In this interacting population model, we have more model parameters, namely the parameter set

$$\mathcal{P} = \{(\{\alpha_{il}\}_{l \in \mathcal{S}}, \{c_{il}\}_{l \in \mathcal{S}}, p_i, \nu_i, b_i, E_i, n_i); i \in \mathcal{S}\}.$$

To make clear the dependence on the parameter set \mathcal{P} , we denote the predicted total population at time t using d units of drug with parameter set \mathcal{P} by $X(t, d; \mathcal{P})$.

Similar to our main model, we will start by simply using additive Gaussian noise for our measurement error. In particular, we assume that observation at dose d_j and time t_k is given by

$$x_{j,k} = X(d_j, t_k; \mathcal{P}) + Z_{j,k},$$

for i.i.d $N(0, \sigma^2)$ random variables $Z_{j,k}$. We can then implement the same maximum likelihood estimation procedure as for our original model. This will be a more computationally

760 challenging problem because evaluating the likelihood function will require numerically
761 solving the non-linear differential equation (9). In addition, this inference problem is more
762 difficult because we have a higher dimensional parameter space to search over.

763 Supplementary figures

Figure S1: Model from Equation (1) of the Materials and methods section accurately recapitulates experimental cell viability dependence on drug concentration in two example BCR-ABL positive Ba/F3 cell lines (with and without the T315I mutation) treated with tyrosine kinase inhibitor imatinib.

Figure S2: Comparison of accuracy gain in mixture fraction and GR50 values when increasing either the number of replicates (R), the number time points (N_t) or the number of concentrations (N_c) while keeping the other two equal to 3. The inference was carried out on 30 datasets generated from a mixture of 40% sensitive and 60% resistant cells. The standard deviation of the observation noise was equal to 10% of the initial cell count. The random seed for the noise was the only parameter varying between the 30 datasets. In a), the accuracy metric is absolute error in inferred mixture parameter; in b) and c) the metric is $\max(GR50_{\text{inferred}}/GR50_{\text{true}}, GR50_{\text{true}}/GR50_{\text{inferred}})$, chosen to address the logarithmic scale of the concentrations. The plots show mean accuracy metrics with 95% confidence intervals for the mean (t-distribution with 29 degrees of freedom). The number of subpopulations (2) was assumed known, and model selection was not performed.

Figure S3: True and estimated mixture fractions and GR50 values for synthetic data with observation noise with standard deviation equal to 1% of the initial cell count. For each row, “True mixture” pie charts show mixture fractions used in the data generation; “Estimated mixture” pie charts show estimated mixture fractions; vertical grey lines show observed concentrations on a logarithmic scale. In the “GR50 values” panel, the region between the two observed concentrations closest to each true GR50 value is given the same color as that subpopulation has in the “True mixtures” pie chart; White dots represent estimated GR50 values, with the region between the closest observed concentrations colored in the same color as the inferred subpopulation in the “Estimated mixture” pie chart.

Figure S4: True and estimated mixture fractions and GR50 values for synthetic data with observation noise with standard deviation equal to 10% of the initial cell count. For each row, “True mixture” pie charts show mixture fractions used in the data generation; “Estimated mixture” pie charts show mixture fractions estimated by the model; vertical grey lines show observed concentrations on a logarithmic scale. In the “GR50 values” panel, the region between the two observed concentrations closest to each true GR50 value is given the same color as that subpopulation has in the “True mixtures” pie chart; White dots represent estimated GR50 values, with the region between the closest observed concentrations colored in the same color as the inferred subpopulation in the “Estimated mixture” pie chart.

Figure S5: True and estimated mixture fractions and GR50 values for synthetic data with observation noise with standard deviation equal to 20% of the initial cell count. For each row, “True mixture” pie charts show mixture fractions used in the data generation; “Estimated mixture” pie charts show mixture fractions estimated by the model; vertical grey lines show observed concentrations on a logarithmic scale. In the “GR50 values” panel, the region between the two observed concentrations closest to each true GR50 value is given the same color as that subpopulation has in the “True mixtures” pie chart; White dots represent estimated GR50 values, with the region between the closest observed concentrations colored in the same color as the inferred subpopulation in the “Estimated mixture” pie chart.

Figure S6: True and estimated mixture fractions and GR50 values for synthetic data with observation noise with standard deviation equal to 50% of the initial cell count. For each row, “True mixture” pie charts show mixture fractions used in the data generation; “Estimated mixture” pie charts show mixture fractions estimated by the model; vertical grey lines show observed concentrations on a logarithmic scale. In the “GR50 values” panel, the region between the two observed concentrations closest to each true GR50 value is given the same color as that subpopulation has in the “True mixtures” pie chart; White dots represent estimated GR50 values, with the region between the closest observed concentrations colored in the same color as the inferred subpopulation in the “Estimated mixture” pie chart.

Figure S7: True and estimated mixture fractions and GR50 values for synthetic data with observation noise with standard deviation equal to 5% of the initial cell count. For each row, “True mixture” pie charts show mixture fractions used in the data generation; “Estimated mixture” pie charts show mixture fractions estimated by the model; vertical grey lines show observed concentrations on a logarithmic scale. In the “GR50 values” panel, the region between the two observed concentrations closest to each true GR50 value is given the same color as that subpopulation has in the “True mixtures” pie chart; White dots represent estimated GR50 values, with the region between the closest observed concentrations colored in the same color as the inferred subpopulation in the “Estimated mixture” pie chart.

Figure S8: True and estimated mixture fractions and GR50 values for synthetic data with observation noise with standard deviation equal to 5% of the initial cell count. For each row, “True mixture” pie charts show mixture fractions used in the data generation; “Estimated mixture” pie charts show mixture fractions estimated by the model; vertical grey lines show observed concentrations on a logarithmic scale. In the “GR50 values” panel, the region between the two observed concentrations closest to each true GR50 value is given the same color as that subpopulation has in the “True mixtures” pie chart; White dots represent estimated GR50 values, with the region between the closest observed concentrations colored in the same color as the inferred subpopulation in the “Estimated mixture” pie chart.

Figure S9: Elbow plots showing the negative log-likelihood for simulated data with observation noise with standard deviation equal to 1% of the initial cell count (Figure S3), with the selected model marked by a circle. The color of the circle also indicates the selected model: blue for 1 population, teal for 2, dark magenta for 3.

Figure S10: Elbow plots showing the negative log-likelihood for simulated cases with observation noise standard deviation equal to 5% of the initial cell count (Figure 2), with the selected model marked by a circle. The color of the circle also indicates the selected model: blue for 1 population, teal for 2, dark magenta for 3.

Figure S11: Elbow plots showing the negative log-likelihood for simulated cases with observation noise with standard deviation equal to 10% of the initial cell count (Figure S4), with the selected model marked by a circle. The color of the circle also indicates the selected model: blue for 1 population, teal for 2, dark magenta for 3.

Figure S12: Elbow plots showing the negative log-likelihood for simulated cases with observation noise with standard deviation equal to 20% of the initial cell count (Figure S5), with the selected model marked by a circle. The color of the circle also indicates the selected model: blue for 1 population, teal for 2, dark magenta for 3.

Figure S13: Elbow plots showing the negative log-likelihood for simulated cases with observation noise with standard deviation equal to 50% of the initial cell count (Figure S6), with the selected model marked by a circle. The color of the circle also indicates the selected model: blue for 1 population, teal for 2, dark magenta for 3.

Figure S14: Elbow plots showing the negative log-likelihood for all cases in Figure S7, with the selected model marked by a circle. The color of the circle also indicates the selected model: blue for 1 population, teal for 2, dark magenta for 3.

Figure S15: Elbow plots showing the negative log-likelihood for all cases in Figure S8, with the selected model marked by a circle. The color of the circle also indicates the selected model: blue for 1 population, teal for 2, dark magenta for 3.

Figure S16: Elbow plots showing the negative log-likelihood for all drugs for all multiple myeloma patients (Figure 3), with the selected model marked by a circle. The color of the circle also indicates the selected model: blue for 1 population, teal for 2, dark magenta for 3.

Figure S17: Elbow plots showing the negative log-likelihood values for all cases in Figure 2b (left) and 2c (right), with the selected model marked by a circle. The color of the circle also indicates the selected model: blue for 1 population, teal for 2, dark magenta for 3.
