20 ABSTRACT

21 When environmental conditions are unpredictable, expressing alternative phenotypes spreads
22 the risk of failure, a mixed strategy called bet-hedging. In the southern part of its range, the
23 Parsley frog *Pelodytes punctatus* breeds from autumn to spring. Our aim was to study the
24 breeding phenology and reproductive success associated with the use of those two seasonal
25 niches to understand how this breeding strategy can be maintained. Field surveys revealed that
26 breeding phenology was typically bimodal with a higher breeding effort in autumn. More
27 importantly, in spring, the survival rate of offspring was severely reduced by the presence of
28 autumn tadpoles, indicating a clear priority effect. However, the autumn cohort often failed to
29 survive over winter, in which case spring cohorts were often successful. Based on those results,
30 we constructed a model in which females can allocate a variable portion of eggs to each season
31 and added a priority effect. We conclude that the existence of the two breeding seasons may
32 indeed constitute a bet-hedging strategy.

33

34 INTRODUCTION

35 Breeding phenology is one of the key components of adaptation to temporally variable
36 environments. Temporal dynamics of both the biotic and abiotic environment impose selective
37 constraints on parental development and physiological state (to be able to reproduce) as well as
38 offspring survival (at the various developmental stages until they reach sexual maturity and
39 start to reproduce) (Rand 1973). There is a vast amount of literature on intraspecific variation
40 of breeding patterns in relation to environmental conditions, in particular latitude, altitude and
41 climate. In the context of current climate change, many species in temperate regions have
42 advanced their breeding time (e.g. Brown et al., 2016; Frederiksen et al., 2004; Møller, 2008),
43 as a result of microevolutionary changes and/or of phenotypic plasticity (Charmantier &
44 Gienapp 2014). Most of these studies concern species with a single reproductive peak in the
45 year, which has to match as precisely as possible a seasonal peak of resource availability in
46 order to maximise reproductive success (e.g. caterpillar availability for tits). The exact date of
47 the resource peak may vary from year to year and species usually rely on cues to anticipate it
48 and plastically delay or advance the onset of reproduction every year. However, in some cases
49 reproductive success depends on even irregular and/or unpredictable conditions. In such
50 situations, species face the risk of complete reproductive failure at any given breeding attempt,
51 a regime that favors expressing alternative phenotypes to spread the risk, a strategy known as
52 bet-hedging (Cohen 1970; Slatkin 1974; Philippi & Seger 1989; Leimar 2005; Venable 2007).
53 Theory predicts that in stochastic environments, selection favors life history traits that reduce
54 temporal fitness variation even if they result in lowered arithmetic mean fitness (Philippi &
55 Seger 1989). In temporally variable environments, long-term fitness of a genotype is measured
56 by the geometric mean of the fitness contribution over successive years at the individual level
57 or over successive generations for a particular genotypic (Lewontin & Cohen 1969; Olofsson
58 *et al.* 2009; Simons 2011; Yasui & Yoshimura 2018). This geometric mean fitness is highly

59 impacted by low values; hence, traits with lower fitness variation may have higher long-term
60 fitness. In principle, lower variation in fitness can be achieved either using the same low-risk
61 strategy (conservative bet-hedging), or displaying several strategies, either at once or over
62 several instances (diversified bet-hedging). While there is an abundant theoretical literature on
63 bet-hedging, empirical studies have provided limited evidence so far (Simons 2011), and the
64 most comprehensive examples concern the timing of germination/diapause and the fraction of
65 dormancy seeds/diapausing eggs (Venable 2007; Gremer *et al.* 2016; García-Roger *et al.* 2017;
66 Wang & Rogers 2018). Some studies even report experimental evolution of bet-hedging traits
67 in response to unpredictable environment (Beaumont *et al.* 2009; Maxwell & Magwene 2017;
68 Tarazona *et al.* 2017).

69 One of the best examples of stochastic, unpredictable environments are temporary ponds,
70 alternating between inundation and drought where each breeding event is a bet as habitat
71 desiccation can occur before the end of the breeding cycle. Several examples of bet-hedging
72 occur in temporary ponds. Fairy shrimps (Anostraca) produce drought-resistant eggs showing
73 asynchronous hatching at different hydroperiods (Saiah & Perrin 1990; Simovich & Hathaway
74 1997; Wang & Rogers 2018). Similarly, rotifers produce diapausing eggs to overpass
75 unfavorable planktonic growing season and only a fraction of those eggs hatch when conditions
76 are suitable (García-Roger *et al.* 2017; Tarazona *et al.* 2017).

77 For amphibian species breeding in temporary ponds, drought can cause 100% mortality of eggs
78 or larvae, resulting in complete failure of one breeding event. One way to reduce the risk of
79 losing a breeding opportunity entirely is to spread this risk at a spatial scale, partitioning brood
80 into various pools as done by the Neotropical poison frog *Allobates femoralis* (Erich *et al.*
81 2015). Another bet-hedging strategy could be to split the breeding effort at a temporal scale and
82 exploit all suitable temporal windows.

83 From an ecological point of view, such temporal niche partitioning is expected to reduce inter
84 and intra-specific competition as well as resource depletion (Carothers & Jaksić 1984). For
85 example, species may share the same habitat but have opposite activity patterns (nocturnal
86 versus diurnal species), as is the case in Neotropical felid community or in grassland ants
87 (Albrecht & Gotelli 2001; Di Bitetti *et al.* 2010). The same type of temporal segregation at a
88 daily scale is also observed within species: brown trout *Salmo trutta* reduces competition for a
89 limiting resource by sequential use of foraging areas (Alanära *et al.* 2001). Voltinism in insect
90 is another well-studied example of temporal partitioning at the annual scale which is an
91 adaptation to predictable seasonal cycles (Kivelä *et al.* 2013; Zeuss *et al.* 2017; Forrest *et al.*
92 2019)

93 However, if successive seasonal cohorts overlap, fitness gains may be asymmetric, because
94 progeny produced by late breeding may suffer from competition or even predation from earlier
95 cohorts (Morin 1987; Ryan & Plague 2004; Eitam *et al.* 2005). Those priority effects are often
96 difficult to disentangle from seasonal effects due to environmental differences experienced by
97 the temporal cohorts (Morin *et al.* 1990). If priority effects are strong, late breeders may select
98 breeding sites in order to limit the competition by conspecifics (Halloy & Fiaño 2000; Halloy
99 2006; Sadeh *et al.* 2009) and this may restrict late breeders to poorer sites (Crump 1991).

100 In amphibians, this temporal partitioning of breeding activity is thought to regulate community
101 dynamics through interspecific competition (Lawler & Morin 1993; Gottsberger & Gruber
102 2004; Richter-Boix *et al.* 2006b, 2007c). Similarly, community composition may depend on
103 species arrival and priority effects whereby species arriving earlier monopolize available
104 resources and gain a competitive advantage over late species (Morin *et al.* 1990; Blaustein &
105 Margalit 1996; Urban & De Meester 2009). In Mediterranean regions, climatic conditions are
106 characterized by dry, hot summers and mild winters, with the maximum rainfalls in autumn and
107 spring. This leads to large breeding asynchrony observed between and within amphibian species

108 (Diaz-Paniagua 1988; Jakob, Poizat et al. 2003; Richter-Boix, Llorente et al. 2006; Vignoli,
109 Bologna et al. 2007): whereas most species typically breed in spring, some species breed earlier
110 at the end of winter, and some even breed in autumn in addition to spring.

111 The Parsley Frog *Pelodytes punctatus* is a small sized Anuran distributed in Spain and most of
112 France (locally reaching neighboring countries). It has a broad ecological niche but has poor
113 competitive abilities and is sensible to fish predation (Morand & Pierre 1995; Crochet *et al.*
114 2004; Richter-Boix *et al.* 2007b); it thus prefers seasonally flooded habitats to than large
115 permanent water bodies (Guyétant *et al.* 1999; Salvidio *et al.* 2004; Richter-Boix *et al.* 2007a).
116 In Spain the parsley frog shows a bimodal breeding pattern with higher reproductive effort in
117 spring than in autumn (Guyétant *et al.* 1999; Richter-Boix *et al.* 2006b). In France, in addition
118 to spring breeding, autumnal breeding is also observed in Mediterranean regions and areas with
119 mild oceanic climate (Guyétant *et al.* 1999; Jakob *et al.* 2003; Richter-Boix *et al.* 2006a;
120 Cayuela *et al.* 2012) but the importance of autumn versus spring reproduction has not been
121 quantified. In the rest of the range and in altitude, only spring breeding occurs.

122 In the Mediterranean areas of southern France, the parsley frog uses temporary ponds that refill
123 in September and October but may dry during autumn or later in late spring. Adults have thus
124 to deal with very unpredictable environmental conditions for their future offspring. In addition
125 to this unpredictable risk, tadpole hatched in autumn or spring are exposed to very different
126 environmental conditions, the most obvious being that the autumn tadpoles overwinter while
127 the spring ones do not. This should result in drastically different developmental trajectories but
128 also in different offspring survivals. Both seasonal cohorts may also interact, leading to a
129 potential competitive advantage to the earlier cohort over the later, i.e. a priority effect. The
130 relative success of each breeding period and the outcome of the interaction between cohorts are
131 key parameters to understand the persistence of this two-peaks breeding strategy. In fact,
132 several pieces of information are still lacking in order to understand the evolutionary basis of

133 this seasonally variable breeding strategy. Do we have a single protracted breeding season or a
134 really bimodal reproduction generated by the coexistence of alternative breeding timing
135 (autumn or spring)? If so, what is the relative importance of autumn versus spring reproduction?
136 What is the survival of offspring produced at the two breeding periods and how is it affected
137 by the presence of conspecifics? Once this basic knowledge is obtained, it can be fed into
138 theoretical models for the evolution of mixed breeding strategies.

139 In this paper, we characterize the breeding phenology (temporal dynamic, relative proportion
140 of each breeding period) of parsley frog in a French Mediterranean area based on results from
141 a 3-year field survey. We monitored the survival of offspring produced in each season to
142 estimate the success of this breeding strategy. We also investigated the factors influencing
143 breeding and tadpole survival, in particular whether there is a priority effects between seasonal
144 cohorts. Finally, using an analytical model adapted from Cohen (Cohen 1966) we tested
145 whether the coexistence of the two breeding periods can be interpreted as a bet-hedging
146 strategy.

147

148 MATERIAL AND METHODS

149 **Field survey**

150 The field study was carried out from September 2007 to August 2010 in 19 ponds situated
151 around Montpellier, southern France (Annex 1). Those ponds are man-made environments,
152 often dug out to provide drinking water for livestock (sheep and cows) or for game. The ponds
153 surveyed included temporary and permanent sites. We define here the autumn breeding season
154 as the period spanning from September to December and the spring breeding season from
155 January to April. We surveyed each pond twice each month. During each visit, we recorded the
156 depth of the pond.

157

158 **Sampling methods**

159 At every visit (mostly diurnal), we looked for newly deposited egg masses throughout the entire
160 water body and classified the egg masses as small, medium and large, corresponding to an
161 average of 75, 150 and 250 eggs per mass, respectively (Salvador & Paris 2001) and personal
162 observation). The parsley frog's embryonic period ranges from 5 days at 15°C to 15 days at
163 10°C (Toxopeus *et al.* 1993). Moreover, embryos stay attached to the jelly for several additional
164 days (Guyétant *et al.* 1999). Thus, with an interval of 15 days between two successive visits,
165 we may have missed a few masses but we have avoided double-counting masses since 15-day
166 old masses can readily be distinguished from new ones based on the developmental stages of
167 the embryos. In only 2% of the larval cohort produced, small larvae were observed in ponds
168 where we did not notice the presence of egg masses before. Note that the probability of
169 detection of an egg mass, even if not perfect, was similar in autumn and in spring.

170 We estimated the number of amphibian larvae and invertebrates present in the ponds using 5
171 to 10 dipnet sweeps (depending on the pond size). The anuran community of the area consists
172 of 7 species: *Pelodytes punctatus*, *Pelobates cultripedes*, *Alytes obstetricans*, *Bufo bufo*, *Epidalea*
173 *calamita*, *Hyla meridionalis*, and *Pelophylax sp.*, (*P. ridibundus* and/or *P. perezi* & *P. kl. grafi*,
174 depending on the sites). Potential predators of tadpoles are urodeles and aquatic invertebrates.
175 Two urodele species (*Lissotriton helveticus* and *Triturus marmoratus*) were recorded in the
176 ponds but due to the rare occurrence of *Triturus marmoratus*, only *Lissotriton helveticus* was
177 included in subsequent analyses (as adults as well as larvae).

178 We also surveyed dragonfly larvae (Anisoptera) and backswimmers (Heteroptera,
179 Notonectidae) that are potential predators of tadpoles (Richter-Boix *et al.* 2007a) except during
180 the first year. Diving beetles (Coleoptera, Dytiscidae) are also known to prey on tadpoles but
181 were very rare in the studied ponds and thus not considered for this study.

182 We divided the total counts for each amphibian larvae and invertebrate predators captured in
183 each pond by the number of dipnet sweeps taken in each pond. This procedure yielded a crude
184 proxy for density on the basis of catch per unit effort and could therefore be compared across
185 localities.

186

187 **Reproductive effort and offspring survival**

188 Reproductive strategy of parsley frog was described by two measures: the probability of
189 spawning and the breeding effort. Spawning probability indicates if any new egg mass was
190 observed during a visit. Breeding effort measures the quantity of eggs produced when there was
191 at least one egg mass. We normalized the number of egg masses by their size (e.g. a small egg
192 mass equals $\frac{1}{2}$ medium egg mass).

193 For each breeding event, we estimated the hatching rate as the ratio of the number of small
194 tadpoles (Gosner stage 26, free swimming tadpole) to the number of eggs spawned. Similarly,
195 we quantified the survival from egg to metamorph as the ratio of the number of metamorphs
196 (Gosner stage 42-43) to the number of eggs spawned. When hatching was successful (i.e. in
197 about one third of the breeding event), we could calculate the survival during larval stage as the
198 product of the two former ratios.

199 The number of tadpoles in a pond was estimated using the mean number of tadpoles caught per
200 dipnet sweep scaled to a sampling surface of 1 m² (we estimated that one dipnet sweep sampled
201 a surface of 0.5 m², taking the dipnet size and the length of the haul into account) and then
202 multiplied by the surface of the pond. This should not be taken as an attempt to estimate
203 precisely the number of tadpoles present in a pond at a given time but as an index of abundance
204 that can be compared between ponds and between breeding events. It was sometimes impossible
205 to follow the larval development and metamorphosis of offspring from a particular breeding
206 event. Indeed, parsley frogs may breed three to four times during each seasonal breeding event.

207 In these cases, the successive sub-cohorts produced are undistinguishable after a few weeks,
208 and we summed the eggs counted in two or three successive visits to evaluate survival from a
209 combination of breeding events within a given season (and within a site). Survival measures
210 should be viewed as an index to assess the differences of reproductive success between seasons
211 as there is no reason to expect any seasonal bias in this index.

212

213 **Explanatory variables**

214 Explanatory variables for the breeding probability and breeding effort are the depth of the pond
215 as well as the presence of conspecific and inter-specific competitors (larvae of anuran species)
216 and predators (invertebrates and adult newts) in the pond. The two last categories of variables
217 were also applied to explain the success (offspring survival) of breeding events. We summed
218 the density of competitors and similarly the density of predators despite the differences in
219 competitive performance and predation pressure of the various species toward parsley frog
220 tadpoles.

221 To assess the potential impact of predation and competition on survival rates, we evaluated the
222 mean density of predators and competitors encountered by parsley frog tadpoles during their
223 larval development. More precisely, data from literature indicates that only small tadpoles (<12
224 mm snout-vent length) have lower survival due to predation by aquatic invertebrates (Tejedo
225 1993). Above this size, the predators will only injure them or even fail to catch them. Larvae
226 laid in autumn reached this limit size in about 3 months, whereas only 1.5 month is necessary
227 for larvae laid in spring (personal observation). Thus, we used the mean density of predators
228 and competitors over a period of 3 months after spawning date for autumn tadpoles and 1.5
229 months for spring tadpoles.

230

231 **Statistical analyses**

232 All statistical analyses were performed on R 3.4.1 (R Core Team 2018). To assess if pond
233 characteristics differed between seasons, we apply a linear model for the depth of the pond and
234 generalized linear models with a quasi-poisson family for all other variables to account for
235 overdispersion. Breeding probability and breeding effort were analysed using a generalized
236 mixed model with site as random effect, with a binomial family or a negative binomial family
237 (to account for overdispersion), respectively. The survival rates were often zero hence we
238 decided to analyse them as binary variables using a generalized mixed model with site as
239 random effect and a binomial family. Those variables, called breeding success and hatching
240 success, are the probability of producing at least one metamorph or one hatchling. The
241 significance of fixed effects were tested using Chi² tests to compare nested models (Zuur *et al.*
242 2009).

243

244

245 **Bet-hedging model**

246 Finally, we wondered if the coexistence of two breeding periods could result from a bet-hedging
247 strategy, with the optimal strategy being to split the breeding effort between the two favourable
248 seasons to spread the risk of complete failure (Seger, J. and Brockman 1987). The following
249 model is derived from Saiah and Perrin (Saiah & Perrin 1990) on the hatching probability of
250 fairy shrimp seasonal cohorts. This model was primarily inspired by Cohen (Cohen 1966),
251 reviewed by (Seger, J. and Brockman 1987) on the optimal reproduction strategy of an annual
252 plant whose seeds can either germinate or remain dormant. In our case, there are two strategies:
253 autumn breeding with initial success (i.e. the ability of offspring to persist until spring)
254 depending on the environmental conditions and spring breeding with success depending mainly
255 on the presence of autumn tadpoles, hence on the initial success of autumn breeding (as
256 suggested by the results on success of autumn and spring breeding events, see below).

257 Let c be the proportion of eggs laid in autumn (thus $1-c$ in spring) – we assume, in agreement
258 with our data (see results), that c represents a fixed strategy, i.e. the frogs cannot predict failure
259 in advance to avoid laying in autumn, nor can they avoid laying eggs in spring when an autumn
260 cohort is present. As mentioned above, the autumn cohort is assumed to succeed or fail, at
261 random, with probability q and $1-q$ respectively. When it succeeds, a fraction s_1 of the offspring
262 survive to reproductive age. The spring cohort completely fails whenever the autumn cohort
263 has survived in a pond (a reasonable simplification based on our survival rates estimates, see
264 below), otherwise a proportion s_2 of spring tadpoles survive. Overall the mean number of
265 individuals produced per female is $c s_1$ when the autumn cohort doesn't fail and
266 $(1 - c) s_2$ when it does.

267 If each frog reproduced only during one year, the optimal strategy would maximize the
268 geometric mean of the annual reproductive outcome (Dempster 1955) which is

$$269 \quad W = (c s_1)^q ((1 - c) s_2)^{1-q}$$

270 Or, equivalently

$$271 \quad \text{Log}(W) = q \text{Log}(c s_1) + (1 - q) \text{Log}((1 - c) s_2)$$

272 However, reproductive life lasts more than one year in frogs (say, n years), which in itself is a
273 way to spread the risk of failure among successive cohorts of offspring – an uncertainty remains
274 however, for each frog, on how many (k) of the n breeding years will not allow the autumn
275 cohort to survive. For each individual, k is distributed binomially with probability $1-q$ so that

$$276 \quad \text{Log}(W) = \sum_{k=0}^n \binom{n}{k} (1 - q)^k q^{n-k} \text{Log}(c s_1 (n - k) + (1 - c) k s_2)$$

277 where $\binom{n}{k}$ represents the number of possible repartitions of the k years with autumn failure
278 among the total number of breeding years n .

279 The selection gradient is

$$280 \quad G[c] = \sum_{k=0}^n \binom{n}{k} (1-q)^k q^{n-k} \frac{(s_1 + s_2) k - n s_1}{c(k(s_1 + s_2) - n s_1) - k s_2}$$

281 We traced the fitness curves and the selection gradients using Mathematica (Wolfram Research
282 Inc. 2018) based on the following parameter combinations. We set survival probabilities based
283 on our estimates of survival from egg to metamorphose: $s_1 = 0.047$ (estimated among breeding
284 events producing offspring that survived until spring) and $s_2 = 0.038$ (in the absence of autumn
285 tadpoles). We assumed that survival and fecundity were equal for both seasonal cohorts for the
286 rest of the life cycle. We set the number of reproductive years $n = 3$ to 5, according to a study
287 of age structure of a breeding population in Spain (Esteban *et al.* 2004). Note that this model
288 applies at the individual level (as developed above) as well as at the genotype level.

289

290 RESULTS

291 **Characteristics of temporal niches**

292 Pond depth was not significantly different between the autumn (here from September to
293 December) and spring (here from January to April) breeding seasons (Table 1). The densities
294 of amphibian larvae (other than parsley frog) were not significantly different. In autumn,
295 extreme densities of *Epidalea calamita* tadpoles were recorded in some small ponds whereas
296 the well-known spring breeding-species (*Hyla meridionalis*, *Pelophylax sp.*, *Triturus*
297 *marmoratus*, *Lissotriton helveticus*) reproduce later than the parsley frog, hence their larvae are
298 only present from April onwards. The density of potential invertebrate predators was higher in
299 autumn than in spring ($\chi^2_{1} = 37.17$, p-value = 0.005) with the lowest density being from
300 December to March. On the contrary, the number of adult newts (potential predators of parsley
301 frog tadpoles) was higher in spring than in autumn ($\chi^2_{1} = 369.36$, p-value = $2.2 \cdot 10^{-16}$).

302

303 **Breeding phenology**

304 We registered 184 breeding events, 79 in autumn and 105 in spring. The breeding effort showed
305 a bimodal pattern with a peak in October and another in February (Figure 1). Note that in two
306 sites, one breeding event was recorded in May.

307 The spawning probability (finding at least one egg mass when visiting a pond) was not
308 significantly different between the two seasons (0.18 (0.02), mean (S.E) per visit in autumn and
309 0.22 (0.02) per visit in spring, (over 429 and 470 visits, respectively) $\chi^2_1=2.31$, p-value= 0.128,
310 see also Annex 2). This spawning probability was not affected by the presence of anurans from
311 other species (larvae), nor by the presence of predators (invertebrates or adult newts). It was
312 positively related to the depth of the pond ($\chi^2_1=20.40$, p-value= 6.3×10^{-6}). The spring spawning
313 probability was not affected by the presence of autumn tadpoles ($\chi^2_1=0.03$, p-value= 0.875).

314 The breeding effort was higher in autumn than in spring (23.0 (4.0) egg masses per breeding
315 event in autumn and 13.7 (2.4) in spring; $\chi^2_1=9.25$, p-value=0.002, Fig. 2 and Annex 3). As a
316 result, autumn breeding contributed slightly more than spring breeding to the production of egg
317 masses (57% versus 42.9%).

318

319 **Breeding success**

320 Hatching success (i.e. the percentage of breeding events producing at least one larvae) was
321 higher in autumn than in spring (68.4% and 43.8% respectively, $\chi^2_1=11.12$, p-value= 0.001).

322 Drought (pond totally dried up) caused the total failure of 7 breeding events (9% of the breeding
323 events) in autumn and of 5 breeding events in spring (4.8%) over the 3 year-survey and the 19
324 sites. Drought caused mortality of offspring at different developmental stages (mostly eggs for
325 autumn cohort and tadpoles for spring cohort). As a consequence, breeding success (i.e. the
326 percentage of breeding events producing at least one metamorph) was not significantly different
327 between the two seasons (34.2% in autumn and 29.8% in spring $\chi^2_1= 0.39$, p= 0.531).

328 Neither breeding success nor hatching success were explained by interspecific competition (the
329 density of other amphibian larvae) or by predation (density of potential invertebrate predators
330 or number of adult newts).

331 Survival rates are represented in Figure 3 and Annex 4. The survival rates from egg to
332 metamorph were similarly low (autumn: 2.24 % (0.61) and spring: 1.97 % (0.73)), resulting in
333 a higher contribution (74.6%) of autumn breeding in the overall production of metamorphs per
334 site and per year (due to the higher breeding effort in autumn, see above).

335 The autumn cohort persisted until spring in 34/79 breeding events (43%, corresponding to the
336 rate of initial success, q , see bet-hedging model). In those cases, tadpoles laid in spring
337 coexisted in their pond with tadpoles from the autumn cohort. From the point of view of spring
338 breeders, in 28/57 cases, they found autumn tadpoles in the pond. The presence of an autumn
339 cohort of parsley frog tadpoles significantly reduced the success of spring breeding event to
340 18.4% in presence of autumn tadpoles, versus 40.0% in absence of autumn tadpoles, $\chi^2_1=10.60$,
341 p -value= 0.005). This reduction effect was not significant for the hatching success (32.6% in
342 presence of autumn tadpoles, versus 53.6% in absence of autumn tadpoles $\chi^2_1=4.63$, p -
343 value=0.099). Accordingly, all survival rates were reduced in the presence of autumn tadpoles
344 and this effect was most pronounced for the survival from egg to metamorphs (3.77 (1.4) versus
345 0.16 (0.08) in absence versus presence of autumn tadpoles, Figure 4 and Annex 5).

346 Finally, the figure 5 summarize the breeding strategy of parsley frog showing the presence of
347 egg masses, tadpoles and the outcome of the breeding event (production of metamorphs) in
348 each studied site, over the three years of survey. It illustrated the quasi-exclusion between the
349 two cohorts.

350

351 **Maintenance of spring breeding**

352 Selection gradients based on our bet-hedging model predict that a mixed strategy is maintained
353 when the rate of initial success of the autumn cohort (q) is between 0.2 and 0.8 for a number of
354 reproductive years $n = 3$. In this condition, a pure autumn strategy is predicted above 0.8, and
355 a pure spring strategy below 0.2. (Figure 4). The maintenance of this strategy is less probable
356 if the number of reproductive years increases ($n = 5$ years of breeding), with a reduced range of
357 q leading to a stable mixed strategy.

358

359 DISCUSSION

360 **Cost and benefits of a bimodal breeding phenology**

361 We used field surveys to describe the breeding phenology of the parsley frog in the French
362 Mediterranean region but also to quantify the relative contribution and success of each seasonal
363 reproduction (autumn and spring reproduction). This quantification, rarely achieved in the wild
364 (but see (Licht 1974; Banks & Beebee 1988; Gascon 1992; Wheeler *et al.* 2015), is essential to
365 understand the evolution of this bimodal breeding strategy. We confirmed the existence of two
366 distinct seasonal peaks in breeding activity, probably mediated by cold temperature in
367 December and January as adult parsley frogs tend to breed in mild and rainy periods as was
368 previously observed (Toxopeus *et al.* 1993; Guyétant *et al.* 1999; Jakob *et al.* 2003). However
369 breeding episodes occurred even in the absence of rainfall as long as ponds were filled with
370 water (personal observations and Richter-Boix *et al.* 2006b)).

371 The breeding effort in our population was higher in autumn than in spring. This is in apparent
372 contradiction with Richter-Boix *et al.* (2006b) who found that spring breeding effort was four-
373 fold higher than autumn breeding effort in the northeast of the Iberian Peninsula. While we
374 don't have a definitive explanation for this difference, we suggest it could be related to higher
375 competition among anuran larvae in autumn in north-east Spain compared to France. In our
376 study area in southern France, larvae of *Pelodytes punctatus* are typically the only anuran larvae

377 found after the summer drought in the ponds in autumn. In contrast, four other species of Anura
378 (*Hyla meridionalis*, *Epidalea calamita*, *Alytes obstetricans* and *Pelophylax perezi*) have
379 tadpoles in autumn and three of them (i.e. all except *E. calamita*) can have overwintering
380 tadpoles in Spanish ponds (Richter-Boix *et al.* 2006b). These authors also showed that
381 *Pelodytes punctatus* tadpoles suffer from interaction with *Hyla meridionalis* (Richter-Boix *et*
382 *al.* 2007b). It is thus possible that increased competition for *Pelodytes punctatus* larvae in
383 autumn and winter compared to our study area make the autumn niche less favourable in
384 northeastern Spain compared to southern France and reduce parsley frog investment in autumn
385 breeding there.

386 Offspring survival (from egg to metamorph) was low in both seasons. The combination of
387 breeding effort and survival rates eventually resulted in a higher contribution of autumn
388 breeding to the overall production of metamorphs. The overall low survival rates of offspring
389 that we found is in line with previous field studies in anurans (e.g. Licht 1974; Banks & Beebee
390 1988) and can be caused by pond desiccation, predation, inter and intra-specific competition
391 for food and parasitism or pathogen infections. Our study revealed no obvious effect of
392 variation in predation on tadpole survival even if the predation pressure encountered by tadpoles
393 at the beginning of their development varies from site to site (but not between seasons). This
394 may seem surprising since many studies experimentally demonstrated that predation cause
395 substantial mortality to tadpole populations (e.g. (Tejedo 1993; Van Buskirk & Arioli 2005)).
396 This may be due to the lack of information about predation during the first year of survey which
397 reduced our statistical power or to the fact that causative factors are numerous and more
398 complex to identify in the field. However, other studies reported no effect of predation on
399 tadpole survival (Hartel *et al.* 2007) or even a positive effect (Barandun & Reyer 1997) probably
400 due to predator-induced phenotypic plasticity. Nevertheless, our results suggest that the
401 predation pressure is probably not a stronger constraint in one season than in the other.

402 Spring tadpoles should be exposed to more competitors during their development than autumn
403 tadpoles since the majority of amphibian species in the local community breed in March and
404 April. Nevertheless, we found no effect of interspecific competition on survival for any of the
405 two seasonal tadpole cohorts. This seems surprising since parsley frog is a poor competitor as
406 a tadpole compared to most species of the anuran community, in particular *Hyla meridionalis*
407 and *Rana perezi*, *perezi* present in spring in permanent ponds (Richter-Boix *et al.* 2007b). On
408 the contrary, in small temporary ponds and during autumn and winter season, Parsley frog
409 tadpoles encounter mostly *Bufo bufo* and *Epidalea calamita* with even lower competitive
410 abilities (Richter-Boix *et al.* 2007b). We hypothesized that interspecific competition effect was
411 not detected in our study due to numerous uncontrolled sources of variation.

412

413 **Priority effects**

414 We revealed a striking negative effect of the presence of conspecific autumn tadpoles on the
415 survival of spring tadpoles in the Parsley Frog. Previous studies have demonstrated the
416 occurrence of such intraspecific priority effect in amphibians in experimental settings (Morin
417 *et al.* 1990; Eitam *et al.* 2005; Murillo-Rincón *et al.* 2017) but as far as we know, our study is
418 the first evidence for intraspecific, inter-cohort competition in amphibians in nature. In the field,
419 we observed in several occasions that large autumn tadpoles were eating freshly laid eggs of
420 their own species, which could partly explain the lower hatching rate of spring eggs in presence
421 of autumn tadpoles. Moreover, (Tejedo 1991) previously described how parsley frog tadpoles
422 predate *Epidalea calamita* eggs. In this latter study, predaceous tadpoles were exclusively old
423 tadpoles and they could cause a loss of 50 to 100% of the eggs. Oophagy has also been
424 demonstrated to be responsible for interspecific priority effect between *Scaphiosus couchii* and
425 *Bufo speciosus* (Dayton & Fitzgerald 2005). Intraspecific oophagy has been described on some

426 anuran species (Summers 1999; Dayton & Wapo 2002) and has been proposed as an energetic
427 opportunistic response in food shortage in temporary ponds.

428 However, the presence of autumn tadpoles also affect the larval survival (post-hatching) of
429 spring tadpoles. This may reflect competition for resources between large autumn and small
430 spring tadpoles as shown in *Rana arvalis* (Murillo-Rincón *et al.* 2017). Interference competition
431 mediated by microorganism may also play a role: smaller tadpoles could display coprophagy
432 instead of feeding on higher quality resources (Beebee & Wong 1992; Baker & Beebee 2000).
433 This large priority effect between the two seasonal tadpole cohorts of parsley frog has a great
434 impact on the overall efficiency of breeding: in most ponds, there could be only one successful
435 breeding period, autumn or spring. Nonetheless, we found no indication that spring breeders
436 select their oviposition site to avoid conspecifics, as other amphibian species sometimes do
437 (Sadeh *et al.* 2009). Accordingly, the spawning probability was also unaffected by the presence
438 of potential competitors or predators.

439

440 **Seasonal partitioning of breeding: a bet-hedging strategy?**

441 The temporal partitioning of breeding activity could reflect several evolutionary processes: 1)
442 the existence of two specialized phenotypes either genetically determined (in which case we
443 would expect temporal genetic differentiation between cohorts) or set by early environmental
444 cues (phenotypic plasticity); 2) a use of alternative strategies by some or all individuals (bet-
445 hedging). We previously demonstrated that the two temporal cohorts do not reflect two
446 genetically distinct temporal populations (Jourdan-Pineau *et al.* 2012) but breeding phenology
447 may still be set once for good for each individual. In this case, breeding in autumn or in spring
448 could be determined by the physiological state (and sexual maturity) of the breeder and
449 maintained year after year, by physiological constraints (typically the case for a capital breeder
450 species which stores energy for future reproduction *e.g.* (Lardner & Loman 2003)). In a

451 diversified bet-hedging strategy, individual breeding activities could vary from year to year
452 (each year, individuals would “choose” one breeding season) or individuals could split their
453 breeding effort between the two seasons in some or most years.

454 Based on our field survey, it appears that the bimodal breeding phenology of parsley frog is a
455 typical diversified bet-hedging strategy. The large priority effect between the two seasonal
456 cohorts, combined with high unpredictability of conditions that result in failure or success of
457 entire cohorts, results in frequency dependent-selection and favour risk-spreading strategies:
458 the best option is to develop in ponds with the smaller number of conspecific competitors. These
459 conditions are found partly in autumn, when the habitat becomes favourable after the dry
460 summer period, or in spring, as some of the autumn cohorts have died in the winter, leaving the
461 habitat free. Poethke et al. (Poethke *et al.* 2016) developed a theoretical model in which they
462 outlined this impact of competition on the evolution of bet-hedging strategy. Using a model for
463 optimal germination fraction, based on field data on desert plants, Gremer and Venable (Gremer
464 & Venable 2014) also showed that density-dependence could explain the observed bet-hedging
465 strategy of germination spread in time (i.e. not all seeds at once).

466 In the parsley frog, our model shows that the observed mixed breeding strategy is maintained
467 if the rate of initial success of the autumn cohort (q) is between 0.2 and 0.8 (if females have on
468 average 3 years of breeding in their lifetime) or between 0.35 and 0.65 (for 5 years of breeding).
469 Those conditions are fulfilled according to our field estimates (0.43). We estimated the
470 proportion of eggs laid in autumn by all breeders (0.57) but could not estimate this proportion
471 at the individual level. Survival rates set in the model were based on our field estimates of
472 survival from egg to metamorphosis; hence, we assumed similar survival after metamorphosis
473 of the two cohorts. Unfortunately, we have no information about survival of parsley frog during
474 its adult terrestrial life. However, the adult survival is an important parameter in our model
475 since it determines the number of reproductive years. The mixed breeding strategy is less stable

476 when the number of breeding opportunities per lifetime increases – as the risk is now spread
477 over several successive years. Indeed, experiencing variation in reproductive success among
478 those opportunities is less harmful when it is possible to try again the next year. A
479 skeletochronology study conducted in a upland population in Spain indicated that the mean age
480 of sampled parsley frog females was 5.01 years (with a standard deviation of 1.99) (Esteban *et*
481 *al.* 2004). Assuming a minimal age at first reproduction of 1 year (as done by Esteban *et al.*
482 2004), this translates into an average number of reproductive years or females of $n = 4$. Our
483 evaluation of the bet-hedging strategy with $n = 5$ is thus probably conservative.

484 We previously showed that the parsley frog successfully exploits two temporal niches in the
485 Mediterranean region thanks to a high phenotypic plasticity of tadpole development to face
486 very different seasonal environments (Jourdan-Pineau *et al.* 2012). Recently, the combination
487 of phenotypic plasticity and bet-hedging has been theoretically investigated, suggesting that
488 phenotypic plasticity could further minimize fitness variances caused by mismatches between
489 phenotype and environment (Haaland *et al.* 2020; Rádai 2020). Interestingly, in the wolf spider,
490 temperature and day length leads to alternative developmental types within broods. This cohort
491 splitting is both probabilistic and sensitive to environment, a phenomenon proposed as being a
492 plastic bet-hedging strategy by Rádai (Rádai 2020). In this case, the various plastic phenotypes,
493 triggered by environmental variations, constitute a bet-hedging response to grassland habitats
494 with substantial and unpredictable year-to-year variation.

495 The breeding strategy of parsley frog seems to constitute an original example of bet-hedging
496 strategy driven by high environmental stochasticity and large inter-cohort priority effect.
497 Characterizing adult survival and individual breeding pattern (using mark-recapture and
498 parentage assignment of egg masses) would allow further refining our model and seeing how it
499 can apply to other anuran species.

697 Table 1: Description of the seasonal niches regarding adult breeding (upper part) and larval development (lower part) of the parsley frog. Mean
 698 and standard error (se) of the explanatory variables depending on the season (autumn and spring). N: sample size. *P.p* is *Pelodytes punctatus*. Depth
 699 are in centimeters. Density of amphibian larvae or invertebrate predators is the mean number of individuals sampled in one dipnet sweep. Parsley
 700 frog is excluded from calculations indicating “amphibian larvae” or “anuran adults”. * denotes significant difference between season for the
 701 considered variable.

Variable	N	Autumn mean	se	N	Spring mean	se
<i>Adult breeding</i>						
Depth	416	58.03	2.16	459	62.86	2.17
Density of amphibian larvae	429	3.25	1.40	470	1.17	0.54
Density of invertebrate predators*	279	0.81	0.13	275	0.41	0.08
Number of adult newts*	429	0.13	0.03	464	1.08	0.12
<i>Tadpole development</i>						
Density of amphibian larvae during development	52	0.67	0.26	54	3.97	1.93
Density of invertebrates predators during development	39	0.66	0.15	46	0.79	0.17
Number of adult newts during development	52	0.34	0.15	54	0.49	0.13

Figure 5: Summary of breeding strategy of the Parsley frog in the 19 studied sites (vertical lines) in the three successive years: presence of eggs (stars), presence of tadpoles (squares) and success of the breeding event (presence of metamorphs, frogs). Grey is indicative of autumn events and black is indicative of spring events.

727

728
729

730 Figure 6: Evolutionary stable strategy (solid black line), based on a bet-hedging model, predicting the proportion of eggs laid in autumn (c, x-axis)

731 in relation to the rate of success of the autumn cohort (q, y-axis), depending on the number of breeding years (n). We set the survival probability

732 of autumn tadpoles and of spring tapdoles (in absence of autumn cohort) to 4.7% and 3.8%, respectively. The horizontal and vertical lines indicates

733 the field estimates of c and q .
