**Acknowledgments:** This work was supported by research grants from EMBL (H.A.). The EMBL Genetic and Viral Engineering Facility is acknowledged for virus production; and EMBL IT Support for provision of computer and data storage servers. We thank Lin Tian (University of California Davis) for providing axon-targeted GCaMP construct; Simone Calabrese, Ilaria Sauve, Grace Cunliffe, and Matteo Tripodi for supporting experiments; and all the Asari lab members as well as Santiago Rompani for many useful discussions.

**Author contributions:** D.M. and H.A. designed the study; D.M. performed experiments; D.M, T.B. and H.A. analyzed the results; and D.M. and H.A. wrote the manuscript.

**Competing interests:** The authors declare no competing financial interests.

**Abbreviated title:** retinotopic RGC axon tiling in SC.

**Key words:** retinal ganglion cells; retinotopy; axonal imaging; superior colliculus; mouse.

**Acronyms:** 2D, two-dimensional; AAV, adeno-associated virus; CNMF, constrained non-negative matrix factorization; RF, receptive field; RGC, retinal ganglion cells; SC, superior colliculus; SD, standard deviation.

## 1 **Abstract**

2 Retinotopy is generally preserved across the visual system, but its precise cellular-level  
3 organization remains elusive. Using two-photon axonal imaging, we performed functional  
4 mapping of the retinocollicular projection at a single-cell resolution in awake mice. We found  
5 a near-perfect match between the tiling patterns of retinal ganglion cell axon terminals in the  
6 superior colliculus and their corresponding receptive fields, indicating that retinotopy arises  
7 from topographic projection of axons at single-cell precision.

## 8 **Main**

9 Visual perception fundamentally relies on the transmission of topographically preserved  
10 information from the eye. The retina first forms a topographic representation of the visual field  
11 with its highly structured organization – namely, retinal mosaics where individual types of  
12 retinal neurons are evenly distributed to tile the retinal surface, so that each part of the visual  
13 field is equally processed by every cell type (Gollisch and Meister, 2010; Masland, 2012).  
14 Visual information is then conveyed to the brain by retinal ganglion cells (RGCs) whose axons  
15 are bundled into an optic nerve. In general, neighboring RGCs project to neighboring regions  
16 in their targets (Frisén et al., 1998; McLaughlin et al., 2003; Cang and Feldheim, 2013; Arroyo  
17 and Feller, 2016). This forms a retinotopic map in the primary retinorecipient areas, such as  
18 the lateral geniculate nucleus (Malpeli and Baker, 1975) and the superior colliculus (SC;  
19 Dräger and Hubel, 1976; Cang et al., 2018), and retinotopy is likewise transferred throughout  
20 the entire visual pathways (Wandell et al., 2007; Cang and Feldheim, 2013).

21         How precisely is topographic information transmitted from the retina? While both  
22 anatomical and physiological properties of individual RGC types have been well characterized  
23 (Gollisch and Meister, 2010; Masland, 2012; Baden et al., 2016), only global retinotopy  
24 principles are known for the retinal projections (Frisén et al., 1998; McLaughlin et al., 2003;  
25 Cang and Feldheim, 2013; Arroyo and Feller, 2016). In the optic nerve, RGC axons are mixed  
26 and they lose retinotopic organization (Figure 1; Horton et al., 1979; Colello and Guillery, 1998).

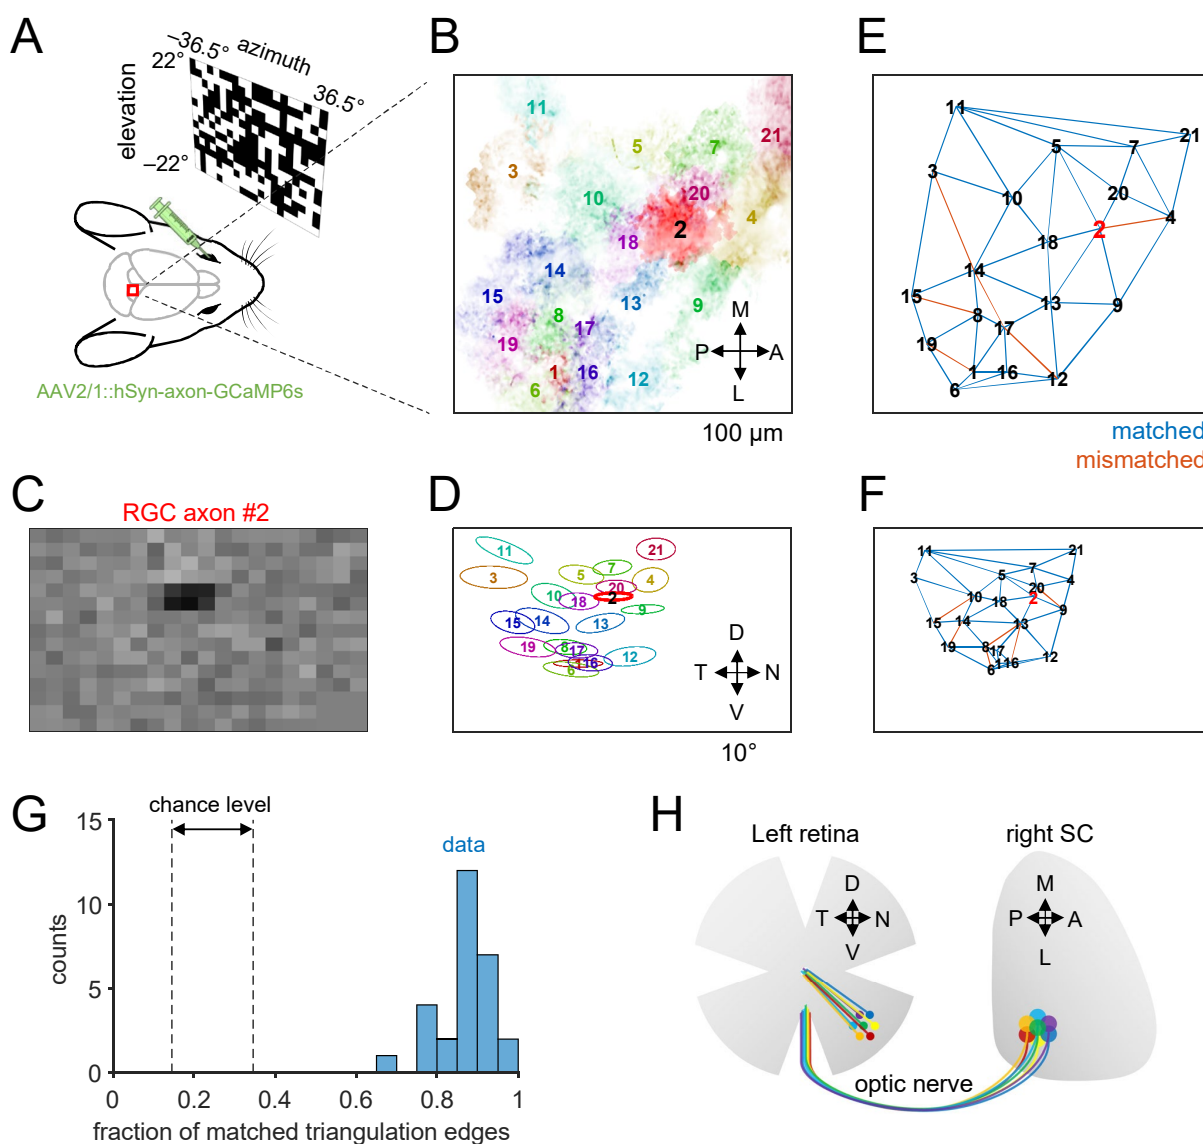

27 A fundamental question is then if RGC axons can nevertheless find precise targets even after  
 28 they get “lost” in the long-range projection (Figure 1A), or if target neurons need to reconstruct  
 29 the topography by elaborating local circuitry (Figure 1B). A recent study using Neuropixel  
 30 probes has demonstrated a more precise one-dimensional mapping of RGC projections to the  
 31 mouse SC surface (Sibille et al., 2021); however, local two-dimensional (2D) organizations of  
 32 RGC axons remain elusive in any retinorecipient area because such long-range projections of  
 33 dense axonal fibers preclude a precise anatomical characterization of the projection patterns  
 34 at a single-cell resolution (Hong et al., 2011).

35  
 36 **Figure 1: Possible retinocollicular projection models.** Retinotopy in SC (color-coded) can  
 37 arise from either (A) precisely retinotopic projection of RGC axons, innervating to exact target  
 38 locations in SC; or (B) roughly retinotopic projection of RGC axons while SC neurons identify  
 39 appropriate partners. Note a loss of retinotopic organization in the optic nerve (Horton et al.,  
 40 1979; Colello and Guillery, 1998).

41 To overcome this barrier, here we performed functional mapping of the RGC  
 42 projections to the superficial layer of SC at a single-cell resolution in awake head-fixed mice.  
 43 Specifically, we expressed axon-targeted calcium indicators (GCaMP6s; Broussard et al.,  
 44 2018) in RGCs via intravitreal injection of recombinant adeno-associated viruses (AAVs)  
 45 harboring the pan-neuronal human synapsin (hSyn) promoter, and monitored the visual  
 46 responses of the labeled RGC axons in SC using *in vivo* two-photon microscopy (Figure 2A).  
 47 To segment axonal patches of individual RGCs and isolate their activity, we used constrained  
 48 non-negative matrix factorization (CNMF) that allows to extract morphological and temporal  
 49 features from noisy time-lapse calcium activities based on their spatiotemporal correlations  
 50 (Giovannucci et al., 2019). For a field of view of approximately 0.3 mm<sup>2</sup> (0.57-by-0.57 mm),

51 we detected up to 29 axonal patches ( $21 \pm 5$ ; mean  $\pm$  standard deviation (SD) here and  
 52 thereafter;  $N = 23$ ) displaying independent activity patterns (Figure 2B). The size of the  
 53 individual axonal patches ( $0.016 \pm 0.008 \text{ mm}^2$ ;  $N = 491$ ) is consistent with the past anatomical  
 54 measurement (Hong et al., 2011), with a substantial overlap between them over the SC  
 55 surface ( $40 \pm 11 \%$ ). This supports a successful signal extraction and a good coverage of RGC  
 56 axonal labelling. These data allowed us to faithfully reconstruct the local 2D map of the  
 57 individual RGC axon terminals in SC (Figure 2B).

58

59 **Figure 2: Retinal ganglion cell axons retinotopically tiled the mouse superior colliculus**  
 60 **at single-cell precision.** **A:** Schematic diagram of experimental set up. **B:** RGC axon patches  
 61 in SC from a representative recording session. Different axon patches are shown in different  
 62 colors: M-L, medial-lateral axis of the contralateral SC; P-A, posterior-anterior axis. **C:**

63 Representative RF of RGC axons (#2 in B) from reverse-correlation analysis. *D*: RFs of all the  
64 simultaneously recorded RGC axons (1 SD Gaussian profile; same color code as in B): D-V,  
65 dorsal-ventral axis of the visual field; T-N, temporal-nasal axis. *E, F*: Delaunay triangulation of  
66 the RGC axonal patch locations (*E*; from B) and the RF centers (*F*; from D): blue, matched  
67 edges between the two triangulation patterns; red, mismatched edges. *G*: Population data for  
68 the fraction of matched triangulation edges between the RGC patch locations and their RF  
69 centers ( $N = 23$ ). Dotted lines indicate the chance level range at  $\alpha = 0.05$  (lower bound, 17%;  
70 upper bound, 39%). *H*: Summary diagram of our result, showing fine-scale retinotopic  
71 projection from the retina to SC despite a lack of retinotopy in the optic nerve (see also Figure  
72 1A; Horton et al., 1979; Colello and Guillery, 1998).

73            Presence of a well-defined receptive field (RF) is a characteristic feature of all RGC  
74 types (Gollisch and Meister, 2010; Baden et al., 2016). To map the RF of the RGC axons, we  
75 exploited stimulus ensemble statistical techniques (“reverse correlation”; Chichilnisky, 2001).  
76 Specifically, we computed the response-weighted average of the presented random  
77 checkerboard stimuli (frame rate, 4 Hz; rectangular fields  $3.7^\circ$  in width and  $2.9^\circ$  in height) and  
78 fitted a 2D Gaussian at the peak latency to characterize the spatial RF profile (Figure 2C,D).  
79 Most identified axonal patches had RFs within the stimulation screen ( $\pm 22^\circ$  in elevation and  
80  $\pm 36.5^\circ$  in azimuth from the mouse eye; Boissonnet et al., 2022). In accordance with *ex vivo*  
81 retinal physiology (Baden et al., 2016), the average RF size of the RGC axons was  $6.6^\circ \pm 3.9^\circ$   
82 ( $N = 443$ ), estimated as the mean of the long- and short-axis diameters of the 2D Gaussian  
83 profile at 1 SD. There was no significant correlation between the RF size and the RGC axonal  
84 patch size (Pearson's  $r = 0.06$ ,  $p = 0.18$ ). The RFs (1 SD Gaussian profiles) locally tiled the  
85 visual field with  $9 \pm 4\%$  overlap, where the center of every RF occupied a unique location in  
86 the visual field (Figure 2D). This ensures that these RFs belong to different RGCs because  
87 the RF center location of RGC axons should correspond well to the location of their somata in  
88 the retina – hence, the RF tiling faithfully represents retinotopy.

89            How well does the tiling pattern of RGC axons in SC agree with that of their RFs? As  
90 expected from the global retinotopy in SC (Dräger and Hubel, 1976; Cang et al., 2018), relative  
91 positions of the RGC axonal patches (Figure 2B) agreed well with those of the corresponding  
92 RFs (Figure 2D). For quantification, we used the geometric centers of the individual axonal  
93 patches and the RF center locations as landmark points in each space, and computed the

94 Delaunay triangulation, respectively, to characterize the Euclidean adjacency relationship  
95 regardless of their absolute positions (Figure 2E, axonal patches; Figure 2F, RF centers).  
96 Specifically, the edges of this triangulation connect all the adjacent pairs of the landmark points  
97 in a given space as a dual graph of the Voronoi tessellation that separates the space into  
98 territories close to each landmark point. We then calculated the fraction of the common edges  
99 between the two Delaunay triangulations (blue edges in Figure 2E,F) as a measure of an  
100 agreement between the two tiling patterns, and found a near-perfect match between them ( $88$   
101  $\pm 5$  %;  $N=23$ ; Figure 2G). This proves that RGC axons tile the SC surface in an exactly  
102 retinotopic manner at a single-cell precision (Figure 2H). The axon terminals of each RGC can  
103 thus retinotopically innervate to a precise target location despite a loss of topographical  
104 organization in the optic nerve (Figure 1A; Horton et al., 1979; Colello and Guillery, 1998).

105 Mammalian SC is an analogue of non-mammalian optic tectum, and serves as a low-  
106 level sensory integrator that coordinates visual reflexes by coupling visual and other sensory  
107 inputs with motor outputs (Cang et al., 2018). One of the most remarkable features of SC is a  
108 co-alignment of visual, sensory and motor maps. This is important for generating proper  
109 behavior as it needs to integrate spatial information from different sensory modalities. Given  
110 a precise retinotopy in SC (Figure 2), the other topographic maps in SC may also be organized  
111 at a fine-scale to match the spatial resolution between them.

112 Having a precise retinotopy facilitates spatial information processing not only at the  
113 global level, but also at local circuit levels. For example, looming detection has been  
114 suggested to arise *de novo* in the superficial layer of SC (Lee et al., 2020). In principle, this  
115 can be achieved even in the absence of retinotopy by elaborating the wiring among local  
116 neurons. It is, however, much more efficient to exploit a precise topographical information  
117 because it helps minimize the connectivity length and its complexity to extract and process  
118 spatial information locally at any point in the visual field.

119 How can then such a precise retinotopic projection be formed from the retina? The  
120 retinotopic map formation in SC occurs during the first postnatal week in mice, involving both

121 genetic and activity-dependent factors (Cang and Feldheim, 2013; Arroyo and Feller, 2016).  
122 These factors also play a key role in the development of a fine-scale organization in other  
123 sensory systems, such as the chemotopic map in the olfactory bulb where olfactory sensory  
124 neurons expressing the same olfactory receptor type project exclusively to the same single  
125 glomerulus (Imai et al., 2010). While overall sensory map formation is genetically  
126 predetermined by molecular cues (e.g., ephrin-Eph signaling; Frisén et al., 1998), a precise  
127 topography is established only after refinement that involves spontaneous activity, such as  
128 retinal waves during development (Arroyo and Feller, 2016), and eventually experience-driven  
129 alignment (McLaughlin et al., 2003). In particular, here we suggest that this refinement process  
130 of the retinocollicular projection should be extremely precise, to the extent that retinotopy  
131 arises at a single-cell resolution regardless of the RGC types in adult animals (Figure 2). It is  
132 interesting to further study how long-range axonal projections are generally formed at a fine  
133 scale in other retinal targets (Liang, et al., 2018) and also in other neuronal systems, such as  
134 callosal projections where axons from one cortical hemisphere first converge into the  
135 commissural fibers and then diverge to different target areas in the other hemisphere (Fame  
136 et al., 2011).

137 In summary, here we performed *in vivo* functional mapping of the retinocollicular  
138 projection in awake mice, and showed a precise retinotopic tiling of RGC axons in SC at a  
139 single-cell resolution (Figure 2). These axons can thus innervate to their exact target locations  
140 even after a loss of topographic organization in the middle of the long-range projection (Figure  
141 1A; Horton et al., 1979; Colello and Guillery, 1998). Such a precise spatial organization is  
142 likely advantageous for efficiently processing visual images while keeping topographic  
143 information with minimal wiring lengths among local neurons. It is a future challenge to  
144 investigate whether precise retinotopy is also preserved in the downstream visual pathways,  
145 and how these retinotopic maps are organized relative to other visual maps, such as the  
146 orientation or ocular dominance maps (Feinberg and Meister, 2015; de Malmazet et al., 2018),  
147 to facilitate visual computation and ultimately generate our coherent sensory perception.

## 148 **Methods**

149 No statistical method was used to predetermine the sample size. All experiments involving  
150 animals were performed under the license 233/2017-PR from the Italian Ministry of Health.  
151 The data analyses were done in Python and MATLAB (Mathworks). All data statistics are  
152 reported in the format of mean  $\pm$  standard deviation (SD). The significance level was 0.05.

## 153 **Animals**

154 A total of 10 female C57BL/6J mice were used at around 6-10 weeks of age at the time of the  
155 first surgery. Mice were kept on a 12-h light / 12-h dark cycle and given water and food *ad*  
156 *libitum*. After surgery, the animals were kept in groups operated on the same day. Mice were  
157 between 12-24 weeks of age at the time of imaging experiments.

## 158 **Viral injections**

159 Intravitreal injection of recombinant adeno-associated virus (AAV) chimeric serotype 1/2 was  
160 used to deliver hSyn-axon-GCaMP6s expression cassette (Broussard et al., 2018) to the  
161 mouse retinal ganglion cells (RGCs). For the viral injection, mice were anesthetized (induction,  
162 4% isoflurane in oxygen; maintenance, 1.8-2.0%) and kept on a heated plate (Supertech  
163 Physiological Temperature Controller) to avoid hypothermia. Both eyes were protected by  
164 saline drop or viscous eye ointment (VitA-POS, Ursapharm). The scleral surface on the left  
165 eye was exposed and a small piercing was made with a sterile 28-30G needle in between the  
166 sclera and the cornea. An injection pipette (~50  $\mu$ m tip diameter with 30-40° bevel) prefilled  
167 with a virus solution (~ $1.5 \times 10^{14}$  vg/mL in phosphate-buffered saline with 0.001% pluronic F68  
168 and 0.001% FastGreen) was then inserted into the vitreous chamber approximately 1 mm  
169 deep. The injection pipette was made from a borosilicate glass capillary (1B120F-3, WPI) with  
170 a pipette puller (DMZ, Zeitz) and a microgrinder (EG-45, Narishige). After a good sealing of  
171 the pipette was formed, 1.2  $\mu$ L of the virus solution was injected at a rate of 10 nL/s using a  
172 microinjection pump (either Neurostar NanoW or WPI NanoLiter 2010) with mineral oil (Sigma

173 M5904) filled in the displacement space by a stainless steel plunger. The pipette was slowly  
174 withdrawn at least 5 minutes after the completion of the injection, and the treated eye was  
175 covered with the eye ointment. The animal was then allowed to recover from anesthesia in a  
176 warmed-up chamber and brought back to its home cage.

## 177 **Cranial implantations**

178 We adapted methods described in Feinberg and Meister (2015) for the cranial window  
179 implantation over the mouse superior colliculus (SC). A cranial window assembly was made  
180 in advance, where the surface of a circular glass coverslip (5 mm diameter, 0.13-0.15 mm  
181 thickness; Assistant Karl Hecht) was activated by a laboratory corona treater (BD-20ACV  
182 Electro-Technic Products) and fused to a cylindrical silicone plug (1.5 mm diameter, 0.75 mm  
183 height; Kwik-Sil, WPI) by baking if for 24 hours at 70-80°C.

184 For the implantation, animals were anesthetized (induction, 4% isoflurane in oxygen;  
185 maintenance, 1.5-2.0%) and placed inside a stereotaxic apparatus (Stoelting 51625).  
186 Throughout the surgery, temperature was maintained at 37°C using a heated plate (Supertech  
187 Physiological Temperature Controller) to avoid hypothermia, and the eyes were protected with  
188 eye ointment (VitA-POS, Ursapharm). After disinfecting and removing the scalp (Betadine  
189 10%, Meda Pharma), the skull surface was scratched and cleaned to ensure good cement  
190 adhesion. A craniotomy of a size about 3.0 mm (anterior-posterior; AP) by 2.5 mm (medial-  
191 lateral; ML) was made over the right SC using a high-speed surgical drill (OmniDrill35, WPI)  
192 with a 0.4 mm ball-tip carbide bur (Meisinger). To prevent bleeding, the craniotomy was treated  
193 by haemostatic sponges (Cutanplast, Mascia Brunelli) soaked with sterile cortex buffer (NaCl  
194 125 mM, KCl 5 mM, Glucose 10 mM, HEPES 10 mM, CaCl<sub>2</sub> 2 mM, MgSO<sub>4</sub> 2 mM, pH 7.4).  
195 The implant was then placed in a way to push the transversal sinus and posterior cortex  
196 approximately 0.5 mm forward and position the silicone plug over the medial-caudal region of  
197 the right SC. Tissue adhesive (Vetbond, 3M) was used to fix and seal the implant. A custom-  
198 made titanium headplate (0.8 mm thick) was then cemented to the skull using acrylic cement  
199 powder (Paladur, Kulzer) pre-mixed with cyanoacrylate adhesive (Loctite 401, Henkel).

200 After the surgery, the animal was recovered from anesthesia in a warmed-up chamber  
201 and returned to its home cage. For postoperative care, animals were given intraperitoneally 5  
202 mg/kg Rimadyl (Zoetis) and 5 mg/kg Baytril (Bayer) daily for 3-5 days. We waited for another  
203 10-15 days until the cranial window completely recovered before starting *in vivo* two-photon  
204 imaging sessions.

## 205 **Visual stimulation**

206 Visual stimuli were presented to the subject animals as described previously (Boissonnet et  
207 al., 2022). In short, a custom gamma-corrected digital light processing device was used to  
208 project images (1280-by-720 pixels; frame rate, 60 Hz) to a spherical screen (radius, 20 cm)  
209 placed ~20 cm to the contralateral side of an animal's eye, stimulating the visual field  $\pm 22^\circ$  in  
210 elevation and  $\pm 36.5^\circ$  in azimuth (Figure 2A). We presented 1) random water-wave stimuli (10  
211 min) for generating binary masks for signal source extraction in calcium image analysis (see  
212 below); and 2) randomly flickering black-and-white checkerboard stimuli (10 min) for the  
213 receptive field mapping, with rectangular fields  $3.7^\circ$  in width and  $2.9^\circ$  in height, each modulated  
214 independently by white noise at 4 Hz.

## 215 ***In vivo* two-photon imaging**

216 Prior to *in vivo* imaging sessions, animals were habituated to stay head-fixed and locomote  
217 freely on a custom-made treadmill disc (8-10 habituation sessions in total over a week, each  
218 for 2 hours). For the imaging session, animals were kept on the treadmill with their head fixed  
219 for no longer than 2 hours (2-5 sessions/animal). Two-photon calcium imaging was done on a  
220 galvo-resonant multiphoton microscope (Scientifica HyperScope with SciScan image  
221 acquisition software) equipped with a mode-locked tunable laser (InSight DS+, Spectra-  
222 Physics) and a plan fluorite objective (CFI75 LWD 16X W, Nikon). In each imaging session,  
223 we performed single-plane time-lapse recordings (frame rate, 15.4 Hz) at a depth of 120-140  
224  $\mu\text{m}$  from the SC surface. The axon-GCaMP6 fluorescent signal (excitation wavelength, 920  
225 nm; average laser power under the objective, 40-80 mW) was bandpass-filtered (BP 527/70,

226 Semrock) and detected with a non-descanned gallium arsenide phosphide photomultiplier  
227 tube (Hamamatsu GaAsP PMT). Each frame was acquired at 1024-by-1024 pixels (16-bit  
228 depth), corresponding to a field of view of around 0.65-by-0.65 mm.

## 229 **Calcium image analysis**

230 For preprocessing, the original images were first downsampled to 512-by-512 pixels (2-by-2  
231 pixels averaging) to reduce noise. To correct motion artifacts, we performed 1) two iterations  
232 of Fourier-based rigid image registration in ImageJ, followed by cropping the image border by  
233 16 pixels; and then 2) ten iterations of non-rigid motion correction (NoRMCorre) in CalmAn  
234 (Giovannucci et al., 2019), followed by a 12-pixel border crop. The resulting images (456-by-  
235 456 pixels) represent a field of view of around 0.57-by-0.57 mm (1.3  $\mu\text{m}/\text{pixel}$ ).

236 From the preprocessed images, we identified the axonal patches of individual RGCs  
237 and extracted their signals in CalmAn. Specifically, using a part of the recordings (3,000-5,000  
238 frames representing the random water-wave stimulus presentation period), we first ran two  
239 iterations of constrained non-negative matrix factorization (CNMF) in CalmAn, where we set  
240 the number of expected components (*params.K*) to be 60 as an initialization parameter. From  
241 the identified components, we manually selected those with a uniformly-filled oval-like shape  
242 that had a size of around 50-150  $\mu\text{m}$  as biologically relevant ones (Hong et al. 2011), and  
243 converted them into binary spatial masks to run two iterations of masked CNMF for processing  
244 the entire time-lapse recordings. The resulting set of spatial components (*estimates.A*) and  
245 deconvolved neural activities (*estimates.S*) was used for the subsequent analyses.

246 The area of the individual RGC axonal patches  $P_i$  was estimated from the identified  
247 spatial components in CalmAn (1.3  $\mu\text{m}/\text{pixel}$ ). The fraction of the overlap between them was  
248 calculated as the ratio of the areas between the intersection of any two patches  $\bigcup_{i \neq j} (P_i \cap P_j)$   
249 and the union of all patches  $\bigcup_i P_i$ .

## 250 **Receptive field analysis**

251 The receptive fields (RFs) of the RGC axon patches were estimated by reverse-correlation  
252 methods using the random checkerboard stimuli (Chichilnisky, 2001). Specifically, we  
253 calculated the response-weighted average of the stimulus waveform (0.5 s window; 1/60 s bin  
254 width), and characterized its spatial profile by the two-dimensional (2D) Gaussian curve fit at  
255 the peak latency. The RF center was assigned to the center of that 2D Gaussian profile, and  
256 the RF size was estimated as twice the mean SD of the long and short axes. The fraction of  
257 the overlap between the RFs (1 SD Gaussian profiles) was computed similarly as for the  
258 axonal patches. The Pearson correlation coefficient between the RF size and the RGC axonal  
259 patch size was calculated with the 95% interval of the data to eliminate the outliers.

## 260 **Tiling data analysis**

261 To compare the tiling patterns between the RGC axon patches and their RFs, we first  
262 computed the Delaunay triangulation of their centroid locations using the Euclidean distance  
263 in each space. As a measure of similarity between the two tiling patterns, we then calculated  
264 the number of matched edges, divided by the mean of the total number of edges in each  
265 triangulation. The chance level was calculated by a bootstrap method (10,000 repetitions).
