Abstract

Prospective outcomes bias behavior in a "Pavlovian" manner: Reward prospect invigorates action, while punishment prospect suppresses it. Theories have posited Pavlovian biases as global action "priors" in unfamiliar or uncontrollable environments. However, this account fails to explain the strength of these biases—causing frequent action slips—even in well-known environments. We propose that Pavlovian control is additionally useful if flexibly recruited by instrumental control. Specifically, instrumental action plans might shape selective attention to reward/ punishment information and thus the input to Pavlovian control. In two eye-tracking samples (N = 35/ 64), we observed that Go/ NoGo action plans influenced when and for how long participants attended to reward/ punishment information, which in turn biased their responses in a Pavlovian manner. Participants with stronger attentional effects showed higher performance. Thus, humans appear to align Pavlovian control with their instrumental action plans, extending its role beyond action defaults to a powerful tool ensuring robust action execution.

Key words: Pavlovian bias; reinforcement learning, eye-tracking; action preparation; attention

Introduction

The valence of potential outcomes biases action selection: The prospect of rewards invigorates action ("Go"), while the prospect of punishment suppresses it ("NoGo"). These so-called motivational, or "Pavlovian", biases constitute a decision-making strategy that is particularly "fast-and-frugal" [1,2]. Past theorizing has assumed that, while inflexible, these biases are fast, computationally cheap, and likely attuned to global environmental statistics [1]. They can thus act as sensible "default" response strategies in situations in which instrumental, goal-directed control fails to deliver rewards beyond chance levels, such as novel or uncontrollable environments [3–5]. These accounts assume that Pavlovian and instrumental control co-exist, largely segregated from another, and merely compete at the behavioral output level. In case of conflict, the former has to be actively suppressed—a requirement humans only imperfectly master [6–9].

In contrast to such a parallel, strictly segregated architecture, we suggest that the instrumental system can adaptively recruit and steer the Pavlovian system by selecting its input via visual attention. Humans are not just passively exposed to reward and punishment cues that drive these biases. Instead, they can actively seek out or ignore these cues and thereby modulate their influence via selective visual attention ("active sensing") [10–12]. In a world full of distractions, where actions unfold over time and are prone to interference, instrumental control could harness the power of cue-driven, "automatic" behavioral tendencies by directing visual attention to cues that activate them and then automatically trigger the intended action. Such a recruitment or "training" of an inflexible decision system by a more flexible one has previously been shown in retrospective reward revaluation [13,14], credit assignment [15], and memory replay [16]. Previous task designs measuring Pavlovian biases do not match such scenarios in which agents actively seek out information that helps them achieve their goals. We developed a new paradigm that temporally separates action selection, attention to reward and punishment information, and action execution. We then tested whether humans seek out reward and punishment information—and allow Pavlovian biases to shape responding—in a way that is aligned with their action goals. Note that, in the following, we will use the term "goal-directed" to denote such a synchronization between action goals and information search—remaining tacit about whether the underlying cognitive process involves prospective planning or devaluation sensitivity, features typically taken as indicators of "goal-directedness" of behavior[17].

Research in the past decade supports the notion that overt attention (eye gaze) towards positive aspects of choice options predicts their eventual selection [18–20], while attention to negative aspects predicts their rejection[21–23]. In these studies, positive and negative information is required for making the correct choice. Theoretical perspectives have speculated that longer attention to an option facilitates memory retrieval of its features, which could accentuate its value [24,25]. However, attention to task-irrelevant positive or negative cues—which have no apparent relationship to the choice options and thus cannot serve as anchors for memory retrieval—might have similar effects. Indeed, in Pavlovian-to-Instrumental-Transfer (PIT) paradigms, incidental background cues associated with positive/ negative outcomes induce Go/ NoGo actions [26–31]. Linking those PIT effects to the role of attention in value-based choice implies that directing attention to (task-irrelevant) reward or punishment cues should activate the Pavlovian system and, in this way, automatically invigorate or suppress choice.

Beyond effects of attention on action, there is also evidence that action plans themselves can direct attention [32–34]. Task goals modulate which stimulus features we are sensitive to and distracted by [35–37]. "Active sensing" perspectives frame attention as a tool to actively interrogate the environment while implementing action plans [10,38,39]. The premotor theory of attention goes as far as proposing that the primary purpose of attention is to monitor target features relevant for preparing an action towards the target [40,41]. Studies have indeed found perceptual sensitivity to be selectively

sharpened for features relevant for an ongoing action, e.g. object location for reaching movements or
object size and orientation for grasping movements [42–44]. However, in the domain of value-based
decision-making, similar evidence for task goals shaping attention is scarce. One relevant finding
might be that humans tend to seek out a choice option one final time before selecting it ("last
fixation" or "late onset " bias) [18,23], even if they already know this option to be superior to other
options [45,46]. In this case, attention appears to be guided by choice rather than vice versa, extending of
the premotor theory of attention to value-based decision-making.
Taken together, there appear to be mechanisms synchronizing agents' attention with their
action plans, and there is tentative evidence for attention to reward and punishment information
triggering automatic responses in the fashion of Pavlovian biases. Hence, it seems indeed possible that
an instrumental system could "recruit" the Pavlovian system to "aid" the execution of action plans by
strategically steering attention toward relevant information. We tested this idea in two samples (the
second one a direct, pre-registered replication) using eye-tracking. For this purpose, we designed a
novel Go/ NoGo learning task in which action planning and execution were separated by a phase in
which participants could preview the positive or negative outcomes at stake. Notably, information
about these outcomes was not informative for the selection of the correct action. We predicted that
action plans would shape attention to reward and punishment stakes, i.e., that participants' first
fixation (not confounded by bottom-up saliency effects due to a gaze-contingent design) would be
more often on the reward information when participants planned a Go (compared to a NoGo) action.
Vice versa, we predicted an effect of attention duration to rewards vs. punishments on the final
response, i.e., that longer attention to reward compared to punishment information would lead to more
Go responses and speed up reaction times (Fig. 1A, B). Such a goal-directed recruitment of Pavlovian
biases would extend their role beyond mere "default" strategies in novel environments towards a
powerful aiding robust action execution.

Figure 1. Theoretical framework and task design. **A.** Theoretical framework of the interaction between action and attention. An environmental cue elicits an action plan, which directs top-down attention (first fixation) towards information about potential reward/ punishment outcomes (stakes). The first fixation anchors attention and (partly) determines which stakes will receive more attention, which is additionally modulated by bottom-up signals such as the magnitude of the stakes. The relative attention on reward versus punishment stakes (dwell time) biases the final Go/ NoGo action in a Pavlovian manner. **B.** Cartoon illustration of the proposed interaction of action planning and attention. **C.** Task design. Participants learned Go/ NoGo responses to various cues (cover story: feed/ not feed various oyster types to maximize pearls and minimize toxic tumors). Cue presentation (instructing the correct action) and action execution are separated by a phase in which rewards (pearls, here orange) and punishments (toxic tumors, here blue) at stake for correct/ incorrect responses are presented in a gaze-contingent manner. Afterwards, the oyster (black oval) can be fed, and for Go responses, participants have to press the button on the side where it is "still open". Outcomes are delivered in a probabilistic manner (75% feedback validity). On catch trials, participants have to indicate whether the oyster featured more pearls or tumors (cover story: The oyster is stolen by thieves and has to be retrieved back from the police, which requires identification).

Results

Participants (Sample 1: $N = 35$; Sample 2: $N = 64$) performed a newly developed motivational Go/ NoGo task, the Oyster Farming task" (Fig. 1C), while we measured their gaze using eye-tracking. In this task, participants learned whether to feed (Go) or not feed (NoGo) different oyster types (abstract stimuli) in order to maximize the chances to grow pearls (rewards) instead of tumors (punishments). Between the presentation of the action cue (oyster type) instructing the required response (Go/ NoGo) and the release cue instructing which button (left/ right) to press, participants could already inspect the potential numbers of pearls and tumors (reward and punishment stakes, ranging from 1 – 5 items) which the oyster might grow. Participants had to monitor these stakes to indicate on randomly interspersed catch trials whether the oyster featured more potential pearls or tumors. Stakes were revealed in a gaze-contingent manner, preventing bottom-up saliency effects on early peripheral vision and rendering the first fixation of each trial a measure of goal-directed attention. By separating action selection (action cue) and execution (release cue), we aimed to the test for i) an effect of the action plan (action required by the cue) on subsequent attention (first fixation, dwell time) to the reward and punishment stakes (tumors and pearls), and ii) an effect of attention to these stakes on the eventually executed response (Go/ NoGo upon the release cue).

Learning and Pavlovian biases

Overall, participants learned the Go/ NoGo task (% correct, Sample 1: $M = 70.0$, $SD = 10.4$, range 50.0–87.1; Sample 2: $M = 73.4$, $SD = 13.2$, range 36.3–91.7), performing significantly more Go responses to Go cues than NoGo cues (Sample 1: $b = 1.08$, $SE = 0.10$, $\chi^2(1) = 53.2$, $p < .001$; Sample 2: $b = 1.27$, $SE = 0.10$, $\chi^2(1) = 89.2$, $p < .001$; Fig. 2A). Participants also performed well in the catch trials (% correct: Sample 1: $M = 85.8$, $SD = 10.1$, range 56.5–100; Sample 2: $M = 86.2$, $SD = 15.5$, range 25.0–100). Five (seven) people in Sample 1 (2) did not perform significantly above chance (56% correct based on a 1-sided binomial test with 240 trials) in the Go/ NoGo task. In line with our pre-registration, we still included these subjects in all our analyses (for results without these participants, see S02). To account for variability in learning, we estimated action (Q) values for each trial based on a Rescorla-Wagner learning model.

Beyond outcome-based learning, responding was affected by the stake magnitudes in a way similar to previously observed Pavlovian biases. A more positive stake difference (reward minus punishment stake magnitude) increased the proportion of Go responses (Sample 1: $b = 0.12$, $SE = 0.03$, $\chi^2(1) = 15.3$ $p < .001$; Sample 2: $b = 0.09$, $SE = 0.03$, $\chi^2(1) = 7.9$, $p = .005$; Fig. 2B) and increased response speed (Sample 1: $b = -0.041$, $SE = 0.015$, $\chi^2(1) = 7.3$, $p = .007$; Sample 2: $b = -0.025$, $SE = 0.011$, $\chi^2(1) = 6.3$, $p = .012$). Separating these effects for the reward and punishment stakes showed that effects were driven by both valences: Higher (relative to lower) reward stake magnitude increased responding and speeded up responses, while higher (relative to lower) punishment stake magnitude decreased responding and slowed responses (see S03).

In sum, we found evidence that participants learned the task and that the reward and punishment stake magnitudes biased responding in opposite directions, reflecting Pavlovian biases. For reaction times, we found larger reward stake magnitudes to speed up responding and larger punishment stake magnitudes to slow down responding, again in line with Pavlovian biases as reported in previous literature [47,48].

Figure 2. Task performance and Pavlovian biases. A. Performance in the Pavlovian Go/ NoGo task. Trial-by-trial proportion of Go actions (±SEM) for Go cues (blue lines) and NoGo cues (red lines). Shadows indicate standard errors for per-condition-per-participant means. Participants clearly learn whether to make Go actions or not (blue lines go up; red lines go down). B. Pavlovian biases. Participants perform more Go responses on trials where the reward stake was higher than the punishment stake (green bars) than vice versa (red bars). Individual data points reflect response proportion per participant. C. Stake magnitudes biased responding in a continuous fashion. A higher stake difference (i.e., a reward stake minus punishment stake) resulted in a higher proportion of Go responses. Faint grey lines represent regression lines per participant as predicted by the mixed-effects regression model; the bronze line represents the group-level regression line; bronze shading represent mean and 95% confidence intervals. Note the two strong outliers in Sample 2; excluding these outliers did not change conclusions. D. Performance in the catch trials. Individual data points reflect accuracy per participant.

Action plans direct eye gaze

Next, we tested whether participants' attention was synchronized to their action plans. Such a link would allow Pavlovian biases to be elicited specifically by reward/ punishment cues that trigger an action in line with participants' intentions. As a measure of goal-directed attention, we used the first fixation on each trial [49], which was unaffected by any bottom-up saliency effects of the (yet to be uncovered) stakes in our gaze-contingent design. On trials that required a Go response, participants were significantly more likely to first fixate rewards than on trials that required a NoGo response (Sample 1: $b = 0.11$, $SE = 0.04$, $\chi^2(1) = 13.9$, $p < .001$; Sample 2: $b = 0.09$, $SE = 0.03$, $\chi^2(1) = 7.9$, $p = .005$; Fig. 3A).

This analysis used the required response as a predictor on every trial, which is globally appropriate given that participants learnt the task. However, at the beginning of blocks, participants could not know the required response yet. Furthermore, some participants failed to learn the correct response for (some of) the cues. Thus, as a more proximate measure of participants' beliefs of what they should do, we fitted a simple Rescorla-Wagner model [50] to the Go/ NoGo response data of each participant, simulated the action (Q) values for Go and NoGo responses on each trial, and used the difference $Q_{Go} - Q_{NoGo}$ as a regressor to quantify the trial-by-trial relative value of making a Go relative to NoGo response. At the beginning of a block, this regressor will be zero, and it will stay (close to) zero in case participants fail to learn the correct response. We found that the more Q-values favored a Go compared to a NoGo response, the more likely were participants to first fixate the

180   reward (Sample 1: $b = 0.09$, $SE = 0.03$, $\chi^2(1) = 8.3$, $p = .004$; Sample 2: $b = 0.13$, $SE = 0.04$, $\chi^2(1) =$
181   9.4, $p = .002$; Fig. S04B).
182   We furthermore performed exploratory analyses to test whether action plans affect attention
beyond the first fixation, i.e., also the overall difference in dwell time to the stakes (dwell time on the
reward stake minus dwell time on the punishment stake). This difference was higher when the reward
stake was fixated first (Sample 1: $b = 0.18$, $SE = 0.06$, $\chi^2(1) = 12.2$, $p < .001$; Sample 2: $b = 0.16$, $SE =$
0.04, $\chi^2(1) = 13.23$, $p < .001$), showing that the first fixation anchored which stakes would receive
overall more attention. Over and above this effect, action value kept shaping dwell times, such that
people dwelt longer on the reward (compared to the punishment) stake for Go relative to NoGo cues
(Sample 1: $b = 0.03$, $SE = 0.01$, $\chi^2(1) = 4.7$, $p = .030$; Sample 2: $b = 0.03$, $SE = 0.01$, $\chi^2(1) = 13.8$, $p <$
.001; Fig. S04C), corroborated when approximating action plans alternatively via Q-values (Sample 1:
$b = 0.03$, $SE = 0.01$, $\chi^2(1) = 4.2$, $p = .040$; Sample 2: $b = 0.04$, $SE = 0.01$, $\chi^2(1) = 17.5$, $p < .001$; Fig.
S04D). Furthermore, dwell time was influenced by the stake magnitudes, with significantly longer
dwell time on the reward stake compared to the punishment stake for more positive stakes differences
(Sample 1: $b = 0.09$, $SE = 0.02$, $\chi^2(1) = 16.5$, $p < .001$; Sample 2: $b = 0.12$, $SE = 0.02$, $\chi^2(1) = 41.6$, $p <$
.001; see Fig. 3B). This latter effect shows that total dwell time was not completely determined by the
first fixation, which was shaped by "top down" action values, but was additionally sensitive to
bottom-up saliency effects of the stake magnitudes.
198   In sum, we find evidence that that participants' attention to valenced stakes information, in
199   terms of both initial fixation and total dwell time, was synchronized to their initial action plans.
200

201   ## Eye gaze predicts responses
202   We next assessed whether and how attention shaped the ultimate response. We used the difference in
203   dwell times (reward minus punishment stakes) as an integral measure of total attention [49]. We
204   controlled for the required action to show that attention predicted the eventual response even beyond
205   participants' likely intentions.
206   The longer participants attended to rewards compared to punishments, the more likely they
were to make a Go response (Sample 1: $b = 0.13$, $SE = 0.03$, $\chi^2(1) = 12.2$, $p < .001$; Sample 2: $b =$
0.19, $SE = 0.03$, $\chi^2(1) = 28.4$, $p < .001$; Fig. 3B). Furthermore, in Sample 2 (but not Sample 1), longer
attention to rewards compared to punishments lead to faster reaction times (Sample 1: $b = -0.036$, SE
$= 0.026$, $\chi^2(1) = 1.9$, $p = .168$; Sample 2: $b = -0.030$, $SE = 0.012$, $\chi^2(1) = 4.5$, $p = .033$). When
considered in isolation, higher dwell time on rewards increased responding, but did not significantly
affect reaction times, while higher dwell time on punishment decreased responding and slowed
responses (see S05). We did not observe any interaction effects between stakes and dwell time effects
(see S05).
215   As action plans both affected attention as well the ultimate response, on might wonder if the
link between attention and the ultimate response was induced by action plans as a "common cause".
To exclude this possibility, all analyses using dwell times to predict responses included the required
action as a regressor. Furthermore, we obtained causal evidence for an effect of attention on the
ultimate response in a separate online study, in which we manipulated attention. In this study, action
cues were presented simultaneously with stakes, but located in close spatial proximity to either the
reward or the punishment stakes. We reasoned that the stakes closer to the action cue would receive
more attention. Indeed, we observed that action cues were located closer to reward (instead of
punishment) stakes resulted in more and faster Go responses. This additional dataset corroborates a
causal effect of attention on the ultimate choice. For details, see the supplemental materials (S06).
225   In sum, we found evidence in both samples that dwell time on rewards/ punishments drove
226   responses towards Go/ NoGo and speeded/ slowed responses, respectively, such that attention

227 determined the eventual strength of Pavlovian biases. Tentative evidence suggested that effects of
228 stake magnitudes and dwell times were highly similar.
229

Figure 3. Mutual influences between action and attention. A. Action plans direct first fixations. When
required to make a Go action, participants are more likely to first fixate reward information than when a NoGo
action was required. B. First fixation anchors attention. Dwell times are longer on reward stakes compared to
punishment stakes when the first fixation was already on reward stakes. Dwell times are additionally shaped by
other factors such as the stake magnitudes. C. Dwell time differences affect final responses. Longer attention to
reward compared to punishment stakes resulted in a higher proportion of Go responses. Grey lines = regression
lines per participant as predicted by the mixed-effects regression model; Black line = group-level regression
line; Shading = the 95% confidence interval.

Stake magnitude and attentional effects differently relate to performance

Lastly, given that both stake magnitudes and dwell times affected responses and RTs in a
highly similar way, we asked whether these effects also had similar consequences for participants'
overall performance. Crucially, stakes were controlled by the experimental protocol and were
therefore unrelated to the required response on each trial. In contrast, attention was under the control
of the participant. If participants fixated reward or punishment cues in line with their action goals and
then let attention guide their eventual response, strong attention effects could putatively improve their
performance. We performed exploratory analyses testing whether effects of stake magnitudes and
dwell times on responding were related to accuracy across participants.
The effect of stake difference on responses correlated significantly negatively with accuracy,
$r(97) = -0.24$, $p = .017$ (Fig. S07B; after removing two outliers visible: $r(95) = -0.26$, p = .010; Fig.
4A), while the effect of dwell time difference correlated significantly positively with accuracy, $r(97)$
$= 0.45$, p < .001 (Fig. 4B). Effects were not exclusively driven by reward or punishment stakes/ dwell
times, but both (in opposite directions, respectively; see S07). We excluded two simpler explanations
of the association between the attentional effect and task accuracy: First, this association was not
driven by more accurate participants providing higher-quality eye-tracking data (see S07).
Furthermore, accuracy was not linked to a stronger focus on reward information (i.e., more first

fixation to rewards or longer attention to rewards); if anything, more accurate participants showed a
more variable gaze pattern, which support the idea that these participants could rely in their responses
on their gaze patterns (see S07).
In sum, although correlational, these results suggest that strong attentional effects might
facilitate performance, while strong stake magnitudes effects impair it. Based on these analyses, stake
magnitude and attentional effects appear to be dissociable.
254

Figure 4. Between-subjects correlations between global Go/ NoGo task performance and stake magnitude (A) and attentional (B) effects. A. Participants with stronger effects of the stake difference on responding (i.e., steeper slopes in Fig. 2C) showed lower performance. B. Participants with stronger effects of the dwell time difference on responding (i.e., steeper slopes in Fig. 3C) showed higher performance. Individual data points reflect per-participants scores, the red line reflects the regression of accuracy on stake magnitude/ attentional effects (shades for ±1 SE). Points = individual participant effects, purple line = regression line, shading = ±1 SE.

Discussion

We report evidence from two independent samples showing that instrumental action plans
steer attention towards rewards and punishments and in this way shape the input to the Pavlovian
control system, triggering responses in line with those action plans. These results shed new light on
the possible function of Pavlovian control. In contrast to current theories, we suggest that these biases
have an important role beyond providing reasonable response defaults in novel or seemingly
uncontrollable environments. Crucially, in addition, Pavlovian control can support instrumental
control for efficient and robust action execution. In a novel task, participants successfully learned to
perform Go and NoGo actions to various cues. Their responses and reaction times were biased by
task-irrelevant information about potential reward/ punishment outcomes (stakes), similarly to
previously reported Pavlovian biases. Most crucially, we found that participants aligned their attention
to these stakes with their action plans: they paid more attention to reward stakes when they had to
perform a Go action, and relatively more attention to punishment stakes when they had to perform a
NoGo action. In turn, attention to these stakes biased ultimate responses, such that more attention to
rewards increased the frequency and speed of Go responding. Exploratory between-subjects analyses
showed that stronger attentional effects on choice were associated with higher performance, hinting at
the adaptive nature of using attention to elicit an automatic response. In sum, these results support the
notion that humans can adaptively direct attention to reward and punishment information to
selectively elicit Pavlovian biases in line with their action plans.
Current theories often emphasize the "hardwired" nature of Pavlovian biases [1,2] that allow for
fast, but inflexible responding. Under the assumption that these biases embody environmental

statistics on an evolutionary time scale, they should lead to the correct response in most situations.
Normative models assign a dominant role to these biases in contexts that cannot be controlled (yet) by
instrumental knowledge about action-outcome relationships [4]. However, once an environment is
controllable, biases should disappear. Frequent action slips reveal that Pavlovian biases continue to
interfere with goal-directed behavior and require active suppression [6,7]. These cases of interference
seem to question their putatively adaptive nature, warranting an update on previous theories.

282   Here, we suggest that a strong Pavlovian system can be adaptive, even in well-known
environments, when it is actively brought into alignment with the goals of other (instrumental)
systems. Pavlovian and instrumental control do not need to operate in a strict parallel fashion and
merely interact at the output stage. Instead, we show that instrumental control can determine the input
to Pavlovian control by selectively steering attention to (potentially unrelated) reward or punishment
information. In this way, it sets the Pavlovian system on an "ballistic" track that will eventually lead
to the intended response. Having such an auxiliary mechanism that will trigger the intended response
might be particularly adaptive in real-life contexts in which the implementation of actions unfolds
over time and is prone to interruption by distractors. By "aligning" Pavlovian with instrumental
control, action selection becomes more robust against interference. Such an faciliatory effect of
Pavlovian control is in line with our finding of better performance in participants with stronger
attentional shaping of responses.

294   Beyond the context of Pavlovian biases, our results extend previous literature on the upstream
determinants (rather than downstream consequences) of attention allocation. Previous studies have
found that, at least early in the choice process, attention appears to be randomly allocated to choice
options in a way that is independent of their value [23,51]. In contrast, recent Bayesian accounts of
"active sensing" have proposed that attention should be actively driven by the value and uncertainty
of choice options in order to gather the maximal amount of information [52–54]. We highlight yet another
role of attention allocation: to stabilize (or even speed up) action implementation in face of delays and
distraction. This role stipulates that (visual) attention is at least partly under control of ongoing motor
processes—as proposed by the premotor-theory of attention [34,40,41]—as well as recent accounts
highlighting that vision and visual working memory primarily serve action [32,33].

304   The idea of Pavlovian biases being recruited by instrumental action plans extends such
accounts into the domain of value-based decision-making. It provides a potential explanation for why
humans seek out a choice option right before selecting it, even when this will not reveal new
information on what is the optimal choice [45,46]. Fixating an (appetitive) option might trigger Pavlovian
biases that ensure its selection in face of distractors. Even more so, after participants have made the
decision to select an option, its collection and consumption (potentially in face of competitors) might
require further motor actions that can benefit from invigoration via these biases. Hence, the role of
Pavlovian biases in invigorating motor programs might potentially explain phenomena of human (and
animal) curiosity and information seeking [55,56] even after the decision process is finished.

313   Our results also shed new light on the potential mechanisms by which attention to different
choice options affects their eventual choices. Past research has not yet provided evidence on how
fixating a choice option (e.g., a well-known food item like a Snickers) helps its evaluation or affords
more information about it. Most accounts have proposed that attention towards a choice option
facilitates memory retrieval of its features and in this way reduces uncertainty about its value [24,52]. In
contrast, our results suggest that attentional effects might be "Pavlovian" in nature in the sense that
attending to (any) positive information disinhibits motor cortex and facilitates selection, while
attending to (any) negative information inhibits motor cortex and leads to rejection. Crucially, in our
paradigm, positive and negative information was unrelated (and orthogonal) to the action that needed
to be selected, and thus should not be incorporated into the choice process. However, even this
unrelated information did bias choice. To dissociate whether attentional effects are truly driven by

increased knowledge about an option's features rather than a simple (dis-) inhibitory effect of its
valence, future research should systematically manipulate the relevance of positive and negative
option features to the eventual choice.
327   There are a few important considerations when generalizing our findings to real world
situations. First, possible outcomes of a choice are often not explicitly presented to an agent. Rather,
agents must make a selection among many potentially relevant pieces of information on what they
deem important. Our task tried to mimic such situations by allowing agents to freely choose how
much to attend to information about rewards and punishments at stake. Still, attention allocation
differed from "naturalistic" free viewing settings in two important ways. Participants were not
completely free to attend to the stakes, but were incentivized to do so by the secondary catch task.
Furthermore, only two pieces of potential information—exemplary of positive and negative aspects of
the situation—were presented, which is a drastic simplification of our information-dense environment.
Future extensions of this research should provide participants with a larger set of information to select
from, allowing them complete freedom to seek out any information during action preparation.
338   Second, in real life situations as well as in this task, people might initiate an action plan, but
then change their mind. We only had access to the participants' ultimate response, which does not
allow us to disentangle situations in which they maintained a determined action plan throughout the
trial from situations in which actions plans were changed based on reward/ punishment information.
Neuroimaging techniques with high temporal resolution such as EEG and MEG could shed light on
the dynamic interactions between motor processes and how these change as a function of attentional
focus.
345   Third and finally, exploratory analyses suggested that participants whose ultimate response
relied more strongly on attentional inputs showed higher performance. This result corroborates the
postulated adaptive nature of a strong Pavlovian system that can be harnessed by instrumental
systems. In contrast, the degree to which responses were shaped by the stakes magnitudes (i.e., larger
magnitudes resulting in stronger Pavlovian biases) was associated with lower performance. This—at
first perhaps surprising—dissociation likely arose from our task design in which stakes magnitudes
were orthogonal to action requirements. When participants performed substantially above chance,
stakes magnitudes had a greater potential to disturb action selection on "incongruent" trials (where the
required action and the action triggered by the net stakes difference mismatched) than to facilitate it
on "congruent" trials. In contrast, in many real-world contexts, it is adaptive to take into account the
size of available rewards or punishments when choosing whether and how vigorously to respond.
356   Still, even if stakes magnitudes and attention to stakes are both meaningful contributors to
choices in real-world settings, it is noteworthy that both had different consequences for performance
in our task, suggestive of dissociable behavioral phenotypes. While relying on stake magnitudes might
be linked to "sign-tracking" behavior previously observed in animals and humans [57–59] and suggested
to constitute a risk factor for addiction [60–62], relying on attention might be a "novel" phenotype
reflecting a strategic recruitment of Pavlovian biases. To conclusively demonstrate the adaptive nature
of using attention to invigorate Pavlovian biases, future studies would need to causally manipulate
participants' strategies. Such studies could for example train participants to strategically seek out
reward or punishment information under a certain action plan. The ability to strategically up- or
down-regulate Pavlovian biases could then be relevant for future interventions in psychopathologies
characterized by aberrant biases, such as depression [63] or alcohol addiction [59,61,62,64].
367   In sum, our results suggest a broadening of the current view of Pavlovian control: In addition
368   to providing sensible "default" actions in novel or uncontrollable environments, a strong Pavlovian
369   system can be adaptive even in well-known environments when its robust, almost "ballistic" nature is
370   recruited to ensure that an action plan is implemented even in face of distraction.

Methods

Participants and exclusion criteria

In Sample 1, we recorded eye-tracking data from 35 participants (M_{age} = 23.7, SD_{age} = 4.1, range 18–35, one outlier at age 58; 27 women, 8 men; 30 right-handed; 21 with the right eye as dominant eye). In Sample 2 (replication sample), we recorded data from 64 participants (M_{age} = 21.5, SD_{age} = 3.0, range 18–34; 50 women, 13 men, 1 other; 62 right-handed; 41 with the right eye as dominant eye). In this replication sample, data collection and analyses were pre-registered (https://osf.io/nsy5x). The sample size for this sample was based on the effect size of the primary effect of interest in Sample 1, i.e., action requirements affecting first fixations (z = 2.89, Cohen's d = 0.49), which yielded a required sample of N = 57 to detect such an effect with 95% power (two-sided one-sample t-test) [65]. We initially collected data from 57 participants, but given that seven participants did not perform significantly above chance level, we collected additional seven participants. Performance above 56% in 240 trials was significantly above chance (one-sided binomial test). Note that, in line with our pre-registration, all results in the main text are based on all participants (see S01 for an overview of all results); results for only those participants that performed significantly above chance are reported in S02 and led to identical conclusions.

Participants were recruited via the SONA Radboud Research Participation System of Radboud University. Exclusion criteria comprised glasses, color blindness, and prior treatment for neurological or psychiatric disorders. The study protocol was identical for both samples. Participants took part in a 1h session that comprised informed consent, eye-tracker calibration, a 10-minute practice phase including written instructions and practice trials, and finally the 30-minute eye-tracking experiment. Upon completion of the task, participants filled in a structured debriefing about their presumed hypothesis of the experiment, and any strategies they applied. None of the participants guessed the study hypotheses. Participants received a participation fee of €10 or 1h of course credit plus a performance dependent-bonus of €0–2 (Sample 1: M = €0.77, SD = €0.43, range €0.09–1.58; Sample 2: M = €0.91, SD = €0.47, range €0.10–1.67). Research was approved by the local ethics committee of the Faculty of Social Sciences at Radboud University (proposal no. ECSW-2018-171).

Apparatus

Reporting follows recently suggested guidelines for eye-tracking studies [66]. The experiment was performed in a dimly lit, sound-attenuated room, with participants' head stabilized with a chin rest. The experimental task was coded in PsychoPy 2020.2.7 on Python 3.7.0, presented on a 24'' BenQ XL2420Z screen of resolution (1920 x 1080 pixels resolution, refresh rate 144 Hz). Manual button presses were applied via a custom-made button box with two buttons (index and middle finger of the dominant hand). Participants' dominant eye was tracked with an EyeLink 1000 tracker (SR Research, Mississauga, Ontario, Canada; sampling rate of 1,000 Hz; spatial resolution of 0.01° of visual angle, monocular recording), controlled via Pylink for Python 3.7.0. The eye-tracker was placed 20 cm in front of the screen, and participants' chin rest 90 cm in front of the screen. Before the task, participants performed a 9-point calibration and validation procedure (software provided by SR Research). Calibration was repeated until an error < 1° was achieved for all points. The screen background grey tone (RGB 180, 180, 180) was constant across calibration and the experimental task.

Task

Participants performed a Go/ NoGo learning task with delayed response execution, called the Oyster Farming Task (Fig. 1C). On each trial, participants cultivated an oyster that could either grow 1–5 pearls or 1–5 hazardous tumors. Pearls gained money while tumors cost money for disposal. To maximize the probability that oysters grew pearls, participants needed to learn which oysters to "feed"

(Go) and which ones not to feed ("NoGo"). Crucially, participants could choose to reveal the reward
(number of pearls) and punishment (number of tumors) at stake prior to action execution in a gaze-
contingent design. Participants' score of accumulated money was turned into a bonus of 0–2€ at the
end of the task. Participants performed 264 trials split into three blocks of 88 trials (80 trials of the
Go/ NoGo task, 8 catch trials), each with a new set of four oyster types.

Each trial started with one (of four) abstract *action cues* (letters from the Agathodaimon
alphabet; size 5.2° x 5.2°) presented for 700 ms in the center of the screen, representing an oyster
type. For each oyster type, there was an optimal action (feed or not feed) that participants needed to
learn by trial-and-error. Feeding was only possible when the oysters "opened" later in the trial. The
optimal action led to rewards (pearls) in 75% of (valid) trials, otherwise to punishments (tumors; on
"invalid trials"). Vice versa, suboptimal actions led to punishments on valid trials, but to rewards on
invalid trials. During action cue presentation, participants were informed about the sides (left vs.
right) on which upcoming stakes information (rewards vs. punishments) would appear via faintly
colored semi-circles in the respective colors (blue and orange, counter-balanced across participants).

Directly after action cue off-set, participants were cued with the exact locations of the stakes
and given 1,500 ms to unveil the tumors and pearls at stake on the respective trial. Stakes were
revealed in a gaze-contingent fashion: fuzzy circular color patches appeared on the semi-circles,
which changed into the number of pearls/ tumors at stake when participants fixated them. This
eliminated any bottom-up saliency effects (e.g., of stake magnitude) on peripheral vision that could
affect participants' first fixations. To prevent exact pre-programming of saccades, exact locations of
stakes varied across trials. Stakes were located on an invisible circle with a radius of 5.2° visual angle
around the screen center (i.e., distance of stakes from the center was kept constant), with a potential
vertical displacement of -45 – +45 degrees from the horizontal midline. Vertical displacement was
always identical for both pearls and tumors. Stakes were represented by circular areas of interest
(AOI) of 150 pixels (2.7°), with a minimal distance between stakes (at maximal vertical displacement)
of 514 pixels (9.4°) and a maximal distance (positioned on the horizontal midline) of 852 pixels
(15.6°). Stakes were presented in orange (RGB 200, 100, 7) and blue (RGB 104, 104, 255) of equal
luma. Stakes varied in magnitude (1–5 items; total display size 2.6° x 2.6°) and magnitude was
balanced within action cues (i.e., each of the 20 possible combinations used once per cue, excluding
the five possible combinations in which both magnitudes were identical). The mapping of pearls and
tumors to the left/ right side varied across trials and was balanced within action cues (each side 10
times per cue) to control for possible participant-specific side biases in gaze.

Stakes offset was followed by a variable interval of 100–500 ms (uniform distribution in steps
of 100 ms), after which a release cue (black oyster shape and a food can, 5.2° x 5.2°) appeared for 600
ms, indicating that the oyster was about to close and could be fed if necessary. The oyster remained
open at either the left or right side, indicating the side where the oyster could be fed. If participants
chose to feed the oyster, they had to press the respective button on the open side. The uncertainty
about the response side (left/ right) at the time of the action cue, which was only resolved with the
release cue, prevented pre-mature responding. In-time responses were confirmed by the food can (1.7°
x 1.7°) tipping over to the respective side. 700 ms after release cue offset, the outcome (3.5° x 3.5°)
was presented for 1,000 ms. Late responses during the release cue-outcome interval were recorded,
but did not affect the outcome. Pressing the incorrect button (i.e., the oyster was open on the left/
right, but participants pressed the right/ left button) counted as incorrect (i.e., yielded tumors on valid
trials) and was confirmed by the can tipping over in the respective direction. Participants received a
number of either pearls or tumors, depending on the stakes, their response, and trial validity. Trials
finished with a variable inter-trial interval between 1,200 and 1,800 ms (uniform distribution in steps
of 100 ms).

On 8 out of 88 trials per block, participants performed a catch task which incentivized
attention to the stakes: Instead of the release cue, participants had to report whether the reward or
punishments stakes were of greater magnitude (Fig. 1D). These catch trials encouraged participants to
monitor both stakes and process their magnitude.
467

Preprocessing

Behavior

Catch trials were excluded from all analyses of responses and RTs. We further excluded trials
with RTs below 200 ms (% trials with button presses per participant: Sample 1: $M = 0.1$, $SD = 0.3$,
range 0–1.5; Sample 2: $M = 0.2$, $SD = 0.3$, range 0–1.1) because such fast responses could not be
expected to incorporate processing of the cue. Likewise, we excluded trials RTs above 800 ms (%
trials with button presses per participant: Sample 1: $M = 0.9$, $SD = 1.6$, range 0–6.8; Sample 2: $M =$
0.5, $SD = 1.8$, range 0–14.0). This deadline was 200 ms after release cue offset (i.e., closing of the
response window) as we reasoned that any later responses could have been triggered by the release
cue offset.

Eye-tracking preprocessing

Gaze data was processed in R with custom-code. Continuous data was epoched into trials of
1500 ms relative to stakes onset. Gaps of missing samples up to a duration of 75 ms (due to blinks or
saccades) were interpolated using linear interpolation. Trials with more than 50% of missing samples
were discarded altogether (% trials per participant: Sample 1: $M = 4.5$, $SD = 8.0$, range 0–34.1;
Sample 2: $M = 3.5$, $SD = 7.9$, range 0–52.7). Gaze position was marked as being on the reward/
punishment stakes when gaze position was less than 150 pixels away from the center of the respective
stakes image, which was also the criterion in our gaze-contingent design for rendering stakes visible.
For each trial, we computed the first fixation on any stakes object (reward or punishment) as well as
the total duration (in ms) with which rewards and punishments were fixated over the entire trial
("dwell time"). Absolute dwell times were converted into dwell time difference (reward time minus
punishment time) and dwell time ratios (reward time divided by the sum of reward and punishment
time) [23].

On some trials, participants only fixated one stake (% trials with at least one fixation per
participant: Sample 1: $M = 11.0$, $SD = 14.6$, range 0–61.4; Sample 2: $M = 10.0$, $SD = 14.4$, range 0–
50.4), leading to ratios of 0 or 1. We thus deviated from our pre-registration and report results for
dwell time difference (reward minus punishment dwell time) in the main text, which avoids such an
accumulation of values at the edges; analyses of dwell time ratio are reported in S01 and lead to
identical conclusions.

Analyses

General strategy

We tested hypotheses using mixed-effects linear regression (function lmer) and logistic regression
(function glmer) as implemented in the package lme4 in R [67]. We used generalized linear models with
a binomial link function (i.e., logistic regression) for binary dependent variables such as responses
(Go vs NoGo) and first fixation, and linear models for continuous variables such as RTs or dwell
time. We used zero-sum coding for categorical independent variables. All continuous dependent and
independent variables were standardized such that regression weights can be interpreted as
standardized regression coefficients. We added all possible random intercepts, slopes, and correlations
to achieve a maximal random effects structure [68]. P-values were computed using likelihood ratio tests
with the package afex [69]. We considered p-values smaller than $\alpha = 0.05$ as statistically significant.

The main analyses were pre-registered for Sample 2 (replication sample; preregistration
available under https://osf.io/nsy5x). We deviated from our pre-registration by reporting results based
on dwell time differences (reward minus punishment dwell time) instead of dwell time ratios (reward
dwell time divided by reward plus punishment dwell time) in the main text. When participants fixated
only one stake, the dwell time ratios were either 0 or 1, regardless of the absolute dwell time on each
single fixated option, leading to a loss of information and an accumulation of values at the edges,
yielding a distribution with three modes. In contrast, dwell time differences are approximately
normally distributed and statistically more comparable to stake differences. Nonetheless, analyses of
dwell time ratio and dwell time differences lead to identical conclusions as reported in the
supplementary materials (see S01).

Baseline learning and Pavlovian biases
First, following previously established motivational Go-NoGo learning tasks [47,48], we tested i)
the degree to which participants learned the task, i.e., performed more Go responses to Go cues than
NoGo cues, and ii) whether responses were influenced by the magnitude of the reward and
punishment stakes, reflecting the presence of a Pavlovian bias. For this purpose, we fitted mixed-
effects regressions with responses (Go/ NoGo) and (as secondary variable) reaction times as
dependent variables and a) the required action (Go/ NoGo) as well as b) the difference in reward and
punishment stake magnitude (ranging from -4 to +4) as independent variables. A significant effect of
stake difference was followed up with post hoc analyses separating the effects of reward and
punishment stake magnitudes, reported in the supplementary materials (see S03).
528

Analysis of gaze patterns
Our first key prediction was that action plans, elicited by the oyster cues, directed attention
towards action-congruent stakes (reward stake for Go requirement, punishment stake for NoGo
requirement). The crucial test of this prediction was whether the action requirement elicited by the cue
affected the location of the first fixation (on the reward versus the punishment stake). This first
fixation was not confounded by any bottom-up saliency effects since, in our gaze-contingent design,
the magnitudes of the stakes was not visible yet. We used both required action (Go or NoGo) and the
difference in the modeled Q-values for Go relative to NoGo responses as independent variables to
predict the first fixation. These analyses also included catch trials since, during the stakes phase,
participants were unaware of whether the trial would be a Go/ NoGo or catch trial. All eye-tracking
analyses contained a regressor capturing any participant-specific side biases (overall preference to
fixate the left or right).

Computational modelling of action values
We tested the impact of participants' action intentions on their attention towards the reward and
punishment stakes using two operationalizations: Firstly, we approximated participants' intentions by
the action required by the presented cue (oyster type). However, this operationalization assumes that
participants (have learned and) know the required action. This assumption is violated i) at the
beginning of blocks when participants cannot know the required action yet and still have to acquire it
through trial-and-error, and ii) even more so in participants who fail to learn the correct response for
(some of) the cues. Thus, secondly, as a more proximate measure of participants' beliefs of what they
should do, we fitted a simple Rescorla-Wagner model to the Go/ NoGo response data of each
participant. This model uses outcomes r (+1 for rewards, -1 for punishments; given that the exact
outcome magnitude is irrelevant for learning) to update the action-value Q for the chosen action a
towards cue s:

$$Q_t(a_t, s_t) = Q_{t-1}(a_t, s_t) + \alpha * (r - Q_{t-1}(a_t, s_t)) \qquad (1)$$

Action values were then translated to action probabilities using a Softmax choice rule:

556
$$p(Go, s_t) = \frac{\beta * e^{Q_t(Go,s_t)}}{\beta * e^{Q_t(Go,s_t)} + \beta * e^{Q_t(NoGo,s_t)}}$$
(2)

The model featured the free parameters α and β. The learning rate α determines the impact of
prediction errors (i.e., higher α leads to stronger incorporation of recent outcomes and discounting of
past outcomes). The inverse temperature β determines the stochasticity of choices (i.e., higher β leads
to more deterministic choices in line with action values and lower β to more noisy, stochastic
choices). Both parameters were estimated to each participants' data using a grid search, with α in the
range [0, 1] in steps of 0.01 (Sample 1: $M = 0.07$, $SD = 0.08$, range 0.01–0.35; Sample 2: $M = 0.14$,
$SD = 0.18$, range 0.001–0.84) and β in the range of [1, 20] in steps of 0.1 (Sample 1: $M = 7.11$, $SD =$
5.87, range 1.0–20.0; Sample 2: $M = 6.63$, $SD = 5.74$, range 1.0–19.5). Starting values for Q_{Go} and
Q_{NoGo} were set to 0. Using each participants' best fitting parameters as well as their action and
outcomes on each trial, we then simulated the action values for Go and NoGo responses on each trial
using one-step-ahead predictions [70]. We used the difference term $Q_{Go} - Q_{NoGo}$ as more proximate
measure of participants' action intentions on each trial based on their past experience with each cue.
On catch trials and trials with a response to the incorrect direction (i.e., press left when the oyster was
open on the right, counting as incorrect and mostly leading to tumors), Q-values were not updated, but
simply maintained from the last cue encounter.

Analysis of effects of attention on responses and reaction times
Our second key prediction was that attention to the reward and punishment stakes would
shape action execution. To test this prediction, we tested whether the dwell time difference
(milliseconds spent on reward stakes minus milliseconds spent attending to punishment stakes)
predicted responses (Go vs. NoGo) and response speed (RT, for Go responses only). These analyses
excluded catch task trials (where responses did not relate to learning but to comparing stake
magnitudes). All analyses involving responses or reaction times as dependent variable controlled for
the required response as well as participant-specific side biases (overall preference to first fixate the
left or right).

Between-subjects correlations of accuracy
If humans synchronized their attention with their action plans such that Pavlovian biases
would align with instrumental action requirements, one would expect this process to facilitate task
performance and lead to higher accuracy. To test whether participants with stronger effects of
attention on the final response indeed showed higher accuracy, we performed exploratory analyses by
computing between-subjects correlations between overall task accuracy and i) the degree to which
stake differences (reward minus punishment stake magnitude) affected responses as well as ii) the
degree to which relative dwell time (reward minus punishment dwell time) affected responses. For
this purpose, we refit the respective models on all participants, collapsing across both samples (total N
= 99), and computed between-subjects correlations between participants' percent correct responses
and their respective regression coefficient (fixed + random effect extracted).

S02: Results overview: Participants not significantly above chance excluded

We report an overview over all major statistical results as reported in the main text and the supplementary material, but excluding the five (seven) participants in Sample 1 (2) that did not perform significantly above chance level, i.e., did not learn the task. For details on how mixed-effects regression were performed, see the Methods section of the main text. These analyses led to the same conclusions as the analyses based on the full samples reported in S01.

[1]Controlling for first fixation and the stake difference. All effects are significant with required action/ Q-value difference as sole predictor.

S03: Effect of stake magnitudes on responses and reaction times

Given that stake differences (reward minus punishment stake) affected both Go/ NoGo responses and reaction times, we additionally tested for separate effects of the reward and punishment stake magnitude on responses and reaction times using in mixed-effects logistic regressions (for Go/ NoGo responses) and linear regressions (for reaction times). We coded reward and punishment stake magnitudes as separate regressors (rather than their difference).

The effect of reward stake magnitude on responses was significant in both samples (Sample 1: $b = 0.14$, $SE = 0.03$, $\chi^2(1) = 20.8$, $p < .001$; Sample 2: $b = 0.08$, $SE = 0.03$, $\chi^2(1) = 8.2$, $p = .004$; Fig. S03A), while the effect of punishment stake magnitude was only significant in Sample 2 (Sample 1: $b = -0.05$, $SE = 0.03$, $\chi^2(1) = 3.3$, $p = .069$; Sample 2: $b = -0.06$, $SE = 0.03$, $\chi^2(1) = 4.7$, $p = .030$; Fig. S03B). In contrast, for RTs, higher reward stake magnitude predicted faster responses only in Sample 1 (Sample 1: $b = -0.03$, $SE = 0.01$, $\chi^2(1) = 4.0$, $p = .046$; Sample 2: $b = -0.01$, $SE = 0.01$, $\chi^2(1) = 0.03$, $p = .861$; Fig. S03C), while higher punishment stake magnitude consistently predicted slower responses (Sample 1: $b = 0.03$, $SE = 0.02$, $\chi^2(1) = 4.0$, $p = .045$; Sample 2: $b = 0.03$, $SE = 0.01$, $\chi^2(1) = 7.4$, $p = .006$; Fig. S03D). Note that RTs are only available for Go responses; hence, the amount of data (and resulting statistical power) are lower compared to the Go/ NoGo response data.

In conclusion, effects of stake magnitude on driving Pavlovian biases reported in the main manuscript were driven by variations in both the reward and the punishment stake. These effects resemble effects of Pavlovian biases reported before, but in this study emerged in a graded fashion, i.e., more and faster Go responding the larger the reward stake was, and less and slower Go responding the larger the punishment stake was.

Figure S03. Effect of stake magnitudes on responses and reaction times. A higher reward stake magnitude led to a higher proportion of Go responses (**A**; significant in both studies), while a higher punishment stake magnitude led to a lower proportion of Go responses (**B**; only significant in Study 2). Similarly, a higher reward stake magnitude tended to speed up reaction times (**C**; significant only in Study 1), while a higher punishment stake magnitude tended to slow down reaction times (**D**; significant in both studies).

849

S04: Effect of action plans on attentional measures

As our first key prediction, we tested whether attention allocation to reward and punishment stake was affected by action requirements. For this purpose, we regressed attention measures (first fixation and dwell time difference) on participants' trial-by-trial action plans (required action and Q-value differences) using mixed-effects logistic (first fixation) and linear (dwell time difference) regression. Results are reported in the main text as well as in S01. First fixations were more likely on rewards when a Go action was required/ Q-values favored Go over NoGo. Similarly, participants looked overall longer at the reward (compared to the punishment) stake when a Go action was required/ Q-values favored Go over NoGo. Taken together, all these results suggest that attention to rewards/ punishments was synchronized to participants' action plans.

Figure S04. Effect of action plans on attention measures. Action requirements, i.e., whether participants should make a Go or a NoGo response based on the cue they see, biases participants' attention during the stakes phase: A Go compared to a NoGo requirements led to a higher proportion of first fixations on the reward stake (**A**) and longer dwell time on rewards (compared to punishments) (**C**). The same finding was obtained when fitting a Rescorla-Wagner model to participants' responses and using the Q-values based on responses from past trials to predict what participants should do on the current trial (**B** and **D**).

S05: Effect of dwell times on responses and reaction times

Given that dwell time differences (reward minus punishment dwell times) affected both Go/ NoGo responses and reaction times, we additionally tested for separate effects of reward and punishment dwell times on responses and reaction times using in mixed-effects logistic (for Go/ NoGo responses) and linear (for reaction times) regressions. Dwell time on rewards predicted a higher proportion of Go responses significantly only in Sample 2 (Sample 1: $b = 0.04$, $SE = 0.03$, $\chi^2(1) = 0.9$, $p = .331$; Sample 2: $b = 0.07$, $SE = 0.03$, $\chi^2(1) = 4.6$, $p = .032$; Fig. S04A). Dwell time on punishments significantly predicted a lower proportion of Go responses in both samples (Sample 1: $b = -0.19$, $SE = 0.04$, $\chi^2(1) = 18.0$, $p < .001$; Sample 2: $b = -0.28$, $SE = 0.04$, $\chi^2(1) = 35.1$, $p < .001$; Fig. S04B). Reward dwell time did not significantly predict RTs in either sample (Sample 1: $b = -0.03$, $SE = 0.03$, $\chi^2(1) = 1.6$, $p = .203$; Sample 2: $b = -0.01$, $SE = 0.02$, $\chi^2(1) = 0.8$, $p = .384$; Fig. S04C), but punishment dwell time predicted slower RTs in Sample 2 (Sample 1: $b = 0.03$, $SE = 0.03$, $\chi^2(1) = 0.9$, $p = .333$; Sample 2: $b = 0.04$, $SE = 0.01$, $\chi^2(1) = 7.7$, $p = .006$; Fig. S04D). Note that RTs are only available for Go responses; hence, the amount of data (and resulting statistical power) are lower compared to Go/ NoGo response data.

Interestingly, stake magnitudes and dwell times exerted highly similar effects on both responses and reaction times, with higher reward stake magnitude as well as more attention to them increased Go responding and speeded responses, while higher punishment stake magnitude as well as more attention to them decreased Go responding and slowed responses. Given that stake magnitudes and dwell times exerted such highly similar effects, one might expect them to operate through the same underlying mechanism. One consequence following from such a shared architecture is that the effects might influence each other, predicting an interaction effect. We hence performed exploratory analyses testing for such an interaction effect, reflecting whether effects of longer vs. shorter attention to the reward (punishment) stake were amplified when participants saw many vs. few potential rewards (punishments) or vice versa. The interaction between the stake difference and the dwell time difference on responses was not significant in either study (Sample 1: $b = -0.03$, $SE = 0.03$, $\chi^2(1) = 0.8$, $p = .379$; Sample 2: $b = -0.03$, $SE = 0.02$, $\chi^2(1) = 1.4$, $p = .229$), and neither was the case for RTs (Sample 1: $b = 0.04$, $SE = 0.02$, $\chi^2(1) = 2.3$, $p = .133$; Sample 2: $b = -0.003$, $SE = 0.011$, $\chi^2(1) = 0.03$, $p = .856$), providing no evidence for attention amplifying effects of stake magnitudes or vice versa.

In conclusion, longer dwell time on rewards led to more and faster responding while longer dwell time on punishments led to less and slower responding. However, effects on reaction times were only significant in the punishment domain. We did not find evidence for an interaction between stake magnitudes and dwell times, yielding no conclusive evidence whether both effects rely on the same underlying mechanism or not.

Figure S05. Effect of dwell times on responses and reaction times. Higher absolute dwell time on rewards led to a higher proportion of Go responses (**A**; only significant in Study 2), while higher absolute dwell time on punishments led to a lower proportion of Go responses (**B**; significant in both studies). Similarly, higher dwell time on rewards tended to speed up reaction times (**C**; though not significant in either study), and higher dwell time on punishment tended to slow down reaction times (**D**; only significant in Study 2).

S06: Supplementary online study manipulating attention to reward and punishment stakes

In the results from our eye-tracking studies reported in the main text, we observed an effect of (manipulated) action requirements on eye-gaze (first fixation and dwell time) and an effect of (measured) eye-gaze on the ultimate response. Given that both action requirements and eye-gaze predicted the ultimate response, on might wonder whether the link between eye-gaze and the ultimate response was spurious, induced by action plans as a "common cause" (an instance of the "third variable problem"). Note that all analyses regressing responses onto dwell time reported in the main text controlled for the action plans. In addition, we tested for a causal effect of attention to reward/ punishment information on responses in a separate online study in which we manipulated attention. This study was performed as a thesis project for Bachelor students at the beginning of the COVID-19 pandemic.

Participants and exclusion criteria

We collected data from 34 participants (M_{age} = 22.4, SD_{age} = 2.1, range 19–27; 18 female, 31 right-handed). Data collection and analyses were pre-registered (https://osf.io/kzdhm). Data was collected under a stopping rule of N = 55 as maximal sample size or May 10, 2020 as final data collection date (set by financial/ time constraints). As pre-registered, we conducted all analyses in two ways, once including all participants and once excluding participants who a) guessed the research hypotheses (zero participants) or b) did not significantly perform above chance (based on a per-participant logistic regression with response as dependent and required action as independent variable, with p < .05 as cut-off; three participants). Both ways led to identical conclusions.

We recruited participants via the SONA Radboud Research Participation System of Radboud University. Participants were required to be at least 18 years old, understand English at a sufficient level (self-reported), not be color-blind, perform the experiment on a PC with a keyboard (no phones or tablets) and complete the study within a maximum of 90 minutes (i.e., 1.5 times the expected completion time). The experiment was administered via the Gorilla platform (Anwyl-Irvine et al. 2020). After providing informed consent and demographic information on age, gender, and handedness, participants completed the "reversed-dot-probe" version of the Motivational Go/ NoGo Task for 30-40 minutes (see below). Afterwards, they filled out the brief (13-item) version of the Self-Control Scale (SCS) (Tangney et al. 2004) and the Behavioral Activation/ Behavioral Inhibition System Scales (BIS/BAS) (Carver and White 1994). Additionally, participants completed two vignettes (measuring omission bias) in which they rated the experienced regret and responsibility of two football coaches who won/ lost a match, afterwards changed/ kept their match plan, and then lost the next game (adapted from (Zeelenberg et al. 2002). Finally, participants performed a debriefing questionnaire asking them to a) guess the hypotheses of the experiment, b) report any (non-instructed) strategies they used, and c) guess whether the additional instructions helped them perform the task better. Participants were then debriefed about the purposes of the study. In compensation for participation, participants received 1 hour of course credit. Furthermore, participants with at least 60% accuracy in the Go/ NoGo task received tickets (proportional to performance) for a lottery featuring two 20€ gift card vouchers. Research was approved by the local ethics committee of the Faculty of Social Sciences at Radboud University (proposal no. ECSW-2018-171).

Task

Participants performed an adapted version of the Motivational Go/ NoGo learning task termed "reverse-dot-probe version" (Fig. S08A). On each trial, they first saw how many points they could win for a correct response (printed in green font with a "+") or lose for an incorrect response (printed in red font with a "-", termed "stakes"). Stakes varied between 10 and 90 points drawn from a uniform distribution. Reward and punishment stake were presented on the left/ right side of the screen, with positions counterbalanced across blocks. Participants were instructed to attend to the stakes because these were relevant for a catch task implemented on some of the trials (see below). After 500 ms, in addition to the stakes, one out of four action cues (letter from the Agathodaimon alphabet) appeared

on the screen, which required either a Go response (space bar press) or a NoGo response (no button press). Participants had to learn the correct response from trial-and-error and respond within 1,500 ms. The action cue was presented in close proximity to either the reward stake or the punishment stake, nudging participants to direct more attention to one of the two stakes. Cue position was counterbalanced across trials and orthogonal to action requirements. After a brief fixation cross screen (700 ms), participants received the outcome (either the reward or the punishment stake previously shown) displayed for 1,500 ms. Feedback was probabilistic in that 86% (12 out of 14) trials were "valid" with a correct response winning points and an incorrect response losing points, while the remaining 14% of trials were "invalid" with a correct response losing points and an incorrect response winning points. Trials ended with a variable inter-trial interval (uniform distribution from 1,100 ms till 1,900 ms in steps of 100 ms).

On 12 trials within the first two blocks, after the outcome phase, a catch task occurred. Reward and punishment stake magnitudes were presented together with a "decoy" number (all numbers printed in white font on black boxes without +/- signs, random assignment of numbers to positions). Participants had to indicate the "other" outcome they could have received (i.e., points-to-be-won in case they lost points, points-to-be-lost in case they won points) by clicking on it with the mouse within 20 seconds. The catch task required participants to memorize the exact stake magnitudes seen earlier in the trial, incentivizing attention to them. For the latter two blocks, we did not include any catch trials to not interfere with participants applying the additional instructions (see below).

After the second block, participants received additional instructions that explicitly encouraged them to look at the reward stake in case they planned to perform a Go response, and look at the punishment stake in case they planned to perform a NoGo response. In this way, we aimed to test whether participants could voluntarily align their attention with their action plans and in this way reduce the effect of the action cue's position on responses.

Participants completed 224 trials split into four blocks à 56 trials, each blocks featuring four novel cues with 14 repetitions. Trial features (action cue identity, action requirement, stake magnitudes and positions, ITI) were controlled by one of ten pseudo-randomly drawn "spreadsheets" (preventing cue to repeated on more than two consecutive trials) randomly allocated to participants.

Data preprocessing

In line with the pre-registration, we excluded reaction times shorter than 300 ms from all analyses (as those are too fast to be induced by the presented cue). Using 200 ms as alternative cut-off (as used in our eye-tracking samples) did not change the conclusions.

Analyses

We analyzed participants' responses (Go/ NoGo) using mixed-effects logistic regression models and their reaction times using mixed-effects linear regression as implemented in the lme4 package in R (Bates et al. 2015). For all categorical independent variables, sum-to-zero coding was used. Continuous dependent and independent variables were standardized such that regression weights can be interpreted as standardized regression coefficients. We included all possible random intercepts, slopes, and correlations to achieve a maximal random effects structure (Barr et al. 2013). P-values were computed using likelihood ratio tests with the package afex (Singmann et al. 2018). We considered p-values smaller than $\alpha = 0.05$ as statistically significant.

As pre-registered (https://osf.io/kzdhm), firstly, we tested whether the action cue position (i.e., the cue being closer to the reward stake or to the punishment stake) as a proxy for participants' induced attention affect their Go/ NoGo responses and reaction times, expecting a main effect of cue position. Secondly, we tested whether instructing people to attend to stake that matched their action plan reduced the effect of cue position, expecting an interaction between cue position and instructions. We tested both hypotheses in a single model (a logistic regression model for responses, a linear regression model for reaction times) featuring the regressors required response (Go/ NoGo), cue position (on the reward/ punishment side), and instructions (before /after) as well as all possible

interactions. As mentioned in the pre-registration, we also report the interaction between required
action and instructions as well as the three-way interaction between required action, cue position, and
instructions.
Furthermore, we specified two exploratory analyses in our pre-registration. Firstly, we tested
whether the difference in stakes (reward minus punishment stake) affected participants' responses and
reaction times, expecting more positive differences to lead to more and faster Go responses. For this
purpose, we fitted a model with stake difference as sole regressor. Secondly, we calculated
participants' mean score on the self-control scale (SCS), BIS and BAS scales and regret judgements
and tested whether these scores modulated participants' cue position effect. For this purpose, we fitted
a new model for each score featuring cue position, the respective score, and their interaction.

Figure S08. Task design and results from the online study manipulation attention to reward and punishment
information **A.** Task design. On each trial, participants saw many points they could win for correct responses or
lose for incorrect responses ("stakes"). After 500 ms, a Go/ NoGo action cue was displayed either next to the
reward or the punishment stake, nudging participants to direct more attention to the respective stake.
Participants learned whether a cue required a Go or NoGo response from trial-and-error. Outcomes are
delivered in a probabilistic manner (86% feedback validity). On catch trials, participants indicated which other
stake (i.e., the one they did not receive as an outcome) they had seen before. **B.** Proportion of Go responses as a
function of action requirement and cue position. Participants performed significantly more Go responses to Go
cues than NoGo cues and when cues were presented next to the reward stake compared to the punishment stake.
C. Reaction times as a function of action requirement and cue position. Participants showed significantly faster
responses to Go cues than NoGo cues and when cues were presented next to the reward stake compared to the
punishment stake. **D.** Proportion of Go responses as a function of stake difference (reward minus punishment
stake). As net stakes became more positive, participants performed significantly more Go responses. **E.**
Reaction times as a function of stake difference (reward minus punishment stake). As net stakes became more
positive, participants became faster, but this effect was not significant.

1050

Results

Overall, participants learned the Go/ NoGo task (% correct: $M = 79.0$, $SD = 12.0$, range 52.7–
94.2), performing significantly more Go responses to Go cues than NoGo cues (main effect of
required action: $b = 1.60$, $SE = 0.14$, $\chi^2(1) = 54.5$, $p < .001$). Three participants did not perform
significantly above chance (per-participant logistic regression with response as dependent and
required response as independent variable, which is significant for accuracy levels of at least 56%). In
line with our pre-registration, we report results with and without these participants. Performance in

the catch task was above chance (3 response options imply a chance level of 33.3%; a one-sided
binomial test based on 12 trials is significant for 63% accuracy and higher) in only 25 out of 34
participants. Also, the group-level performance was hardly above chance (% correct: $M = 66.4$, $SD =$
18.6, range 25.0–81.7), likely reflecting that this task was very demanding.

Firstly, in line with our pre-registration, we tested whether the cue position (action cue on the
reward/ punishment side) affected participants' Go/ NoGo responses. Participants performed more Go
responses when the action cue was on the side of the reward stake compared to the side of the
punishment stake (main effect of cue position: $b = 0.19$, $SE = 0.05$, $\chi^2(1) = 10.9$, $p < .001$; Fig. S08B),
suggesting that increased attention to rewards (compared to punishments) induced more Go responses.
Similarly, participants performed faster Go responses when the action cue was on the side of the
reward stake compared to the side of the punishment stake (main effect of cue position: $b = -0.03$, SE
$= 0.01$, $\chi^2(1) = 25.7$, $p < .001$; Fig. S08C). These results suggested that more attention directed to
reward/ punishment stake causally affects participants' responses and reaction times in the fashion of
Pavlovian biases.

Secondly, in line with our pre-registration, we tested whether the effect of cue position
became smaller after participants were instructed to attend to the stake that matched their action plan.
The interaction effect between cue position and instructions was not significant ($b = -0.03$, $SE = 0.04$,
$\chi^2(1) = 0.6$, $p = .458$), providing no evidence for responses becoming less affected by the cue position
once participants tried to voluntarily deploy their attention. In fact, the sign of the effect suggested the
effect of cue position to become stronger (instead of weaker) after additional instructions were
administered. However, there was a significant interaction between required action and instructions (b
$= -0.38$, $SE = 0.07$, $\chi^2(1) = 29.3$, $p < .001$), suggesting that participant overall performed better after
receiving instructions. In absence of a control group, this effect cannot be disentangled from an
increase in performance over time, providing inconclusive evidence for whether instructions affected
participants' responses or not. The three-way interaction effect between required action, cue position,
and instruction was not significant ($b = 0.01$, $SE = 0.03$, $\chi^2(1) = 1.8$, $p = .182$). Apart from responses,
also the effect of cue position on reaction times was not significantly changed by instructions ($b =$
0.01, $SE = 0.01$, $\chi^2(1) = 1.7$, $p = .199$), and neither was the interaction between required action and
instructions ($b = 0.001$, $SE = 0.01$, $\chi^2(1) = 0.04$, $p = .840$) nor the three-way interaction effect between
required action, cue position, and instruction ($b = -0.0003$, $SE = 0.005$, $\chi^2(1) = 0.004$, $p = .948$)
significant.

Thirdly, as part of the exploratory analyses mentioned in the pre-registration, we tested
whether the difference in stakes (reward minus punishment stake) affected participants' responses or
reaction times. As expected, as the difference in stakes increased (relatively more points to win than
to lose), participants performed significantly more Go responses ($b = 0.08$, $SE = 0.02$, $\chi^2(1) = 8.1$, $p =$
.004; Fig. S08D), suggesting that the difference in available rewards/ punishments biased their
responses in the fashion of Pavlovian biases. Reaction times were not significantly affected by the
stake difference ($b = -0.004$, $SE = 0.004$, $\chi^2(1) = 1.0$, $p = .316$; Fig. S08E).

Fourthly, as part of the exploratory analyses mentioned in the pre-registration, we tested
whether the effect of cue position on responses was predicted by participants' score on the self-control
scale (SCS), the BIS and BAS scales, or the regret and responsibility ratings in the omission bias
vignettes. We did not find any significant modulation of the cue position effect by SCS scores ($b = -$
0.03, $SE = 0.03$, $\chi^2(1) = 0.7$, $p = .403$), BAS Drive scores ($b = -0.04$, $SE = 0.04$, $\chi^2(1) = 1.0$, $p = .310$),
BAS Reward Responsiveness scores ($b = -0.01$, $SE = 0.03$, $\chi^2(1) = 0.1$, $p = .756$), rated regret for
changing the match plan after a previous football win ($b = -0.02$, $SE = 0.04$, $\chi^2(1) = 0.1$, $p = .710$),
rated responsibility asymmetry when changing/ keeping the match plan after a previous football win
($b = 0.02$, $SE = 0.03$, $\chi^2(1) = 0.4$, $p = .532$), rated regret for changing the match plan after a previous
football defeat ($b = -0.01$, $SE = 0.03$, $\chi^2(1) = 0.1$, $p = .750$), or rated responsibility asymmetry when
changing/ keeping the match plan after a previous football defeat ($b = -0.004$, $SE = 0.04$, $\chi^2(1) = 0.01$,
$p = .933$). However, the cue position effect was significantly modulated by BIS scores ($b = -0.07$, SE
$= 0.03$, $\chi^2(1) = 4.3$, $p = .038$) with participants with higher BIS scores showing weaker cue position

effects, and by BAS Fun Seeking scores (b = -0.07, SE = 0.03, $\chi^2(1)$ = 4.6, p = .031) with participants
with higher BAS scores showing again weaker cue position effects. Given the sample only comprised
34 participants and several between-participants analyses were run, these results should be interpreted
with caution.
We repeated all analyses while excluding three participants who did not perform significantly
above chance in the Go/ NoGo task. Firstly, still, participants performed more (b = 0.18, SE = 0.05,
$\chi^2(1)$ = 9.0, p = .003) and faster (b = -0.04, SE = 0.01, $\chi^2(1)$ = 27.5, p < .001) Go responses when the
action cue was on the side of the reward stake compared to side of the punishment stake. Secondly,
the effect of cue position on responses was again not significantly different after compared to before
additional instructions were administered (b = -0.02, SE = 0.04, $\chi^2(1)$ = 0.2, p = .623), but the effect of
required action was again stronger after compared to before responses (b = -0.41, SE = 0.07, $\chi^2(1)$ =
23.39, p < .001), with again no significant three-way interaction (b = 0.01, SE = 0.04, $\chi^2(1)$ = 0.06, p =
.800). Regarding reaction times, again, neither the effect of cue position (b = 0.01, SE = 0.01, $\chi^2(1)$ =
2.0, p = .159) nor the effect of required action (b = 0.003, SE = 0.01, $\chi^2(1)$ = 0.3, p = .597) was
significantly modulated by instructions, and neither was the three-way interaction significant (b = -
0.001, SE = 0.01, $\chi^2(1)$ = 0.1, p = .779). Thirdly, as the stake difference increased, participants again
performed significantly more Go responses (b = 0.06, SE = 0.02, $\chi^2(1)$ = 5.7, p = .017), but not
significantly faster responses (b = -0.006, SE = 0.004, $\chi^2(1)$ = 2.3, p = .127). Fourthly, we again did
not find any significant modulation of the cue position effect by SCS scores (b = -0.04, SE = 0.03,
$\chi^2(1)$ = 1.2, p = .264), BAS Drive scores (b = -0.02, SE = 0.04, $\chi^2(1)$ = 0.3, p = .582), BAS Reward
Responsiveness scores (b = -0.01, SE = 0.04, $\chi^2(1)$ = 0.1, p = .751), rated regret for changing the
match plan after a previous football win (b = 0.02, SE = 0.04, $\chi^2(1)$ = 0.3, p = .603), rated
responsibility asymmetry when changing/ keeping the match plan after a previous football win (b =
0.02, SE = 0.04, $\chi^2(1)$ = 0.2, p = .632), rated regret for changing the match plan after a previous
football defeat (b = -0.004, SE = 0.03, $\chi^2(1)$ = 0.1, p = .909), or rated responsibility asymmetry when
changing/ keeping the match plan after a previous football defeat (b = 0.007, SE = 0.04, $\chi^2(1)$ = 0.02,
p = .877). The modulation by BIS scores was not significant any more (b = -0.06, SE = -0.03, $\chi^2(1)$ =
2.33, p = .127), while the modulation by BAS Fun Seeking scores was still significant (b = -0.06, SE
= 0.03, $\chi^2(1)$ = 4.2, p = .041). Overall, analyses excluding the three participants who did not perform
the Go/ NoGo task significantly above chance led to identical conclusions as analyses including all
participants.
Discussion
In this study, we manipulated attention by displaying Go/ NoGo action cues next to either the
reward or punishment stake, nudging participants to pay relatively more attention to the stake that we
next to the action cue. We obtained causal evidence that attention to reward information (compared to
punishment information) leads to more Go (compared to NoGo) responses as well as to faster
responses. We did not find evidence for instructions to voluntarily deploy attention in line action
plans reducing the attentional effect. Potentially, the task was too demanding and the trial time course
too fast for participants to voluntarily steer attention in a way that supported their action plans. Future
studies might use different instructions or an altered task design that gives participants more time to
deploy attention before they perform an action.
Furthermore, we found evidence for overall stake differences (reward minus punishment
stake) biasing responses (but not reaction times) in the fashion of Pavlovian biases. These results
support the effect of stake differences on responses reported in the main text. Finally, we did not find
any strong modulation of the attentional effect by self-reported measures such as the Self-Control
Scale, the BIS/ BAS scales, or regret and responsibility ratings in two vignettes measuring omission
biases. Although there was some evidence for stronger BIS and BAS Fun Seeking scores predicting
weaker attention effects, these results should be treated with caution given the limited sample size and
the higher number of tests. Future studies should test for such links in larger samples. In sum, the core
conclusion is that the results of this study support a causal effect of attention on Go/ NoGo responses.

S07: Effects of stake magnitudes and dwell times on responses predict interindividual differences in task performance

Both stakes and dwell times affected Go/ NoGo responses (and reaction times) in a similar way, i.e., a higher reward stake as well as more attention to it increased Go responding and speeded responses, while a higher punishment stake as well as more attention to it decreased Go responding and slowed responses. Given such highly similar effects, one might expect them to operate through the same underlying mechanism. First, one consequence following from such a shared architecture is that effects should influence each other, i.e., the presence of a higher stake could alter the impact of dwell times on responses, or vice versa, which predicts an interaction effect. However, we observed no evidence for such an interaction effect (see S05), tentatively suggesting that effects operate independently of each other (though curiously with highly similar consequences).

An alternative way of assessing how comparable these effects are is to probe their consequences for task performance across participants: Does letting responses be strongly guided by stake differences (reward minus punishment stake magnitudes) vs. strongly guided by dwell time differences (reward minus punishment dwell times) have similar or different consequences for overall performance in the Go/ NoGo task? For this purpose, we re-fitted regression models across both samples, extracted per-participant regression coefficients (fixed-effect plus participant-specific random effect), and correlated these coefficients with participant overall performance (% correct responses).

Performance was significantly lower in those participants in which stake difference more strongly shaped their responses (Figure S08A, B). This finding was in stark contrast to significantly higher performance in those participants in which dwell time differences (reward minus punishment dwell time) more strongly affected response. It is noteworthy that the stake differences are experimentally controlled, and thus purely "bottom-up", while in contrast, dwell time differences were under participants' control and synchronized to action plans, both directly (effect on dwell time difference) and indirectly (effect on first fixations).

We performed control analyses to exclude the possibility that the association between attentional effects on responses and task performance was driven by better performing participants showing higher eye-tracking data quality. First, we computed the number of trials with any (opposed to no) fixation on any of the two stakes. This number was significantly positively correlated with performance, $r(97) = 0.23$, $p = .025$, but not with the attentional effect on responses, $r(97) = 0.13$, $p = .208$. When using both task performance and number of trials with any fixation to predict attention effects in a multiple linear regression, the effect of task performance was still strongly significant, $t(96) = 4.79$, $p < .001$. Second, we calculated the total time (in ms) that people attended to any of the two stakes objects. This number was neither significantly correlated with performance, $r(97) = 0.09$, $p = .389$, nor with the attentional effect on responses, $r(97) = 0.13$, $p = .183$, and when using both task performance and total fixation time to predict attention effects in a multiple linear regression, the effect of task performance was still strongly significant, $t(96) = 4.90$, $p < .001$. In sum, it is unlikely that the correlation between performance and attentional effects on responses is driven by more accurate participants providing higher-quality eye-tracking data.

Furthermore, we performed control analyses checking whether performance, being associated with how many rewards (rather than punishments) participants received, was associated with differential fixation patterns (more first fixations or longer fixations) to reward vs. punishment stakes. It is possible that performance affects information search: high performing participants can reasonably expect to receive rewards most of the time, so they might be more interested in and attend more to reward stakes. Vice versa, lower performing participants might expect occasional punishments and thus also attend to punishment stakes. There was no significant correlation between task performance and the number of first fixations on rewards vs. punishments, $r(97) = -0.11$, $p = .298$ and the association between task performance and the attentional effect on responses remained significant

when controlling for the number of first fixations, $t(96) = 4.97$, $p < .001$. There was however though a
significantly negative correlation between task performance and overall dwell time difference (dwell
time on reward stakes minus dwell time on punishment stakes), $r(97) = -0.27$, $p = .007$: participants
with higher performance showed a more variable (i.e., less biased towards reward stakes) gaze pattern
and attended relatively more to punishments compared to participants with low performance. The
association between task performance and the attentional effect on responses remained significant
when controlling for the this overall dwell time difference, $t(96) = 5.20$, $p < .001$. In sum, we found
no evidence for high performing participants exclusively focusing on reward stakes and low
performing participants also attending to punishment stakes. If anything, we found the opposite
pattern of high performing participants showing a more variable gaze pattern (also attending to
punishment stakes), which chimes with the idea that these participants could rely their response on
their (more adaptive/ flexible) gaze pattern.
Note that all these performance-dependent results are exploratory and should be interpreted
with caution.
1224

Figure S08. Association between interindividual variability of accuracy and in the effects of stake magnitudes and dwell times on responses. Participants' mean accuracy correlated significantly negatively with their respective effect of stake differences on responses (**A**), also when two outliers removed (**B**), which was driven both by a negative correlation with the effect of the reward stake (**C**; note that these effects tend to be positive) as well as a positive correlation with the effect of the punishment stake (**D**; note that these effects tend to be negative, i.e., participants with stronger negative effects showed worse performance). These correlations suggest that participants with strong stake difference effects showed poor performance. The opposite pattern occurred for the effect of dwell time on responses: This effect correlated significantly positively with accuracy, both for the difference between reward and punishment dwell times (**E**) as well as the relative dwell time (ratio) on rewards (**F**). Again, this effect was driven by reward dwell times (**G**) rather than punishment dwell times (**H**). These correlations suggest that participant with strong attention effects showed high performance.
