Abstract

Prospective outcomes bias behavior in a "Pavlovian" manner: Reward prospect invigorates action, while punishment prospect suppresses it. Theories have posited Pavlovian biases as global action "priors" in unfamiliar or uncontrollable environments. However, this account fails to explain the strength of these biases—causing frequent action slips—even in well-known environments. We propose that Pavlovian control is additionally useful if flexibly recruited by instrumental control. Specifically, instrumental action plans might shape selective attention to reward/ punishment information and thus the input to Pavlovian control. In two eye-tracking samples (N = 35/ 64), we observed that Go/ NoGo action plans influenced when and for how long participants attended to reward/ punishment information, which in turn biased their responses in a Pavlovian manner. Participants with stronger attentional effects showed higher performance. Thus, humans appear to align Pavlovian control with their instrumental action plans, extending its role beyond action defaults to a powerful tool ensuring robust action execution.

Keywords: decision-making; motivation; Pavlovian biases; attention; eye-tracking

Goal-directed recruitment of Pavlovian biases through selective visual attention

The valence of potential outcomes biases action selection: The prospect of rewards invigorates action

("Go"), while the prospect of punishment suppresses it ("NoGo"). These so-called motivational, or

"Pavlovian", biases have first been observed in animal studies in which the presence of a reward-

associated cue invigorated cue-unrelated behaviors (Estes, 1943, 1948; LoLordo et al., 1974; Lovibond,

1983; Schwartz, 1976). While at first interpreted as seemingly irrational, recent theorizing has suggested

that these biases in fact constitute a decision-making strategy that is particularly "fast-and-frugal"

(Boureau et al., 2015; Dayan et al., 2006)—similar to other "heuristics" that humans use as (simple, but

efficient) strategies in decisions under uncertainty (Gigerenzer & Gaissmaier, 2011). Past theorizing

has assumed that, while inflexible, these biases are fast, computationally cheap, and likely attuned to

global environmental statistics (Dayan et al., 2006). They can thus act as sensible "default" response

strategies in situations in which instrumental, goal-directed control fails to deliver rewards beyond

chance levels, such as novel or uncontrollable environments (Daw et al., 2005; Dorfman & Gershman,

2019; O'Doherty et al., 2017). These accounts assume that Pavlovian and instrumental control co-exist,

largely segregated from another, and merely compete at the behavioral output level. In case of conflict,

the former has to be actively suppressed—a requirement humans only imperfectly master (Breland &

Breland, 1961; Cavanagh et al., 2013; Hershberger, 1986; Swart et al., 2018).

In contrast to such a parallel, strictly segregated architecture, we suggest that the instrumental

system can adaptively recruit and steer the Pavlovian system by selecting its input via visual attention.

Humans are not just passively exposed to reward and punishment cues that drive these biases. Instead,

they can actively seek out or ignore these cues and thereby modulate their influence via selective visual

attention ("active sensing") (Friston et al., 2010; Gottlieb & Oudeyer, 2018; Yang et al., 2016). In a

world full of distractions, where actions unfold over time and are prone to interference, instrumental

control could harness the power of cue-driven, "automatic" behavioral tendencies by directing visual

attention to cues that activate them and then automatically trigger the intended action. Such a

recruitment or "training" of an inflexible decision system by a more flexible one has previously been

shown in retrospective reward revaluation (Gershman et al., 2014; M. J. F. Robinson & Berridge, 2013),

credit assignment (Moran et al., 2019), and memory replay (Mattar & Daw, 2018). Previous task designs

measuring Pavlovian biases do not match such scenarios in which agents actively seek out information

that helps them achieve their goals. We developed a new paradigm that temporally separates action

selection, attention to reward and punishment information, and action execution. We then tested

whether humans seek out reward and punishment information—and allow Pavlovian biases to shape

responding—in a way that is aligned with their action goals. Note that, in the following, we will use the

term "goal-directed" to denote such a synchronization between action goals and information search—

remaining tacit about whether the underlying cognitive process involves prospective planning or

devaluation sensitivity, features typically taken as indicators of "goal-directedness" of

behavior(Balleine & Dickinson, 1998).

Research in the past decade supports the notion that overt attention (eye gaze) towards positive

aspects of choice options predicts their eventual selection (Cavanagh et al., 2014; Fiedler & Glöckner,

2012; Krajbich et al., 2010), while attention to negative aspects predicts their rejection (Armel et al.,

2008; Pachur et al., 2018; Westbrook et al., 2020). In these studies, positive and negative information

is required for making the correct choice. Theoretical perspectives have speculated that longer attention

to an option facilitates memory retrieval of its features, which could accentuate its value (Shadlen &

Shohamy, 2016; Weilbächer et al., 2021). However, attention to task-irrelevant positive or negative

cues—which have no apparent relationship to the choice options and thus cannot serve as anchors for

memory retrieval—might have similar effects. Indeed, in Pavlovian-to-Instrumental-Transfer (PIT)

paradigms, incidental background cues associated with positive/ negative outcomes induce Go/ NoGo

actions (Estes, 1943, 1948; Geurts et al., 2013a, 2013b; Huys et al., 2011; Rescorla & Soloman, 1967).

Linking those PIT effects to the role of attention in value-based choice implies that directing attention

to (task-irrelevant) reward or punishment cues should activate the Pavlovian system and, in this way,

automatically invigorate or suppress choice.

Beyond effects of attention on action, there is also evidence that action plans themselves can

direct attention (Heuer et al., 2020; Olivers & Roelfsema, 2020; van Ede, 2020). Task goals modulate

which stimulus features we are sensitive to and distracted by (Eimer & Kiss, 2008; Folk et al., 1992;

Van der Stigchel & Hollingworth, 2018). "Active sensing" perspectives frame attention as a tool to

actively interrogate the environment while implementing action plans (Cisek & Pastor-Bernier, 2014;

Gottlieb & Oudeyer, 2018; Yang et al., 2016). The premotor theory of attention goes as far as proposing

that the primary purpose of attention is to monitor target features relevant for preparing an action

towards the target (Rizzolatti et al., 1987; Sheliga et al., 1997). Studies have indeed found perceptual

sensitivity to be selectively sharpened for features relevant for an ongoing action, e.g. object location

for reaching movements or object size and orientation for grasping movements (Bekkering & Neggers,

2002; Craighero et al., 1999; Fagioli et al., 2007). However, in the domain of value-based decision-

making, similar evidence for task goals shaping attention is scarce. One relevant finding might be that

humans tend to seek out a choice option one final time before selecting it ("last fixation" or "late onset

" bias) even if they already know this option to be superior to other options (Hunt et al., 2016; Kaanders

et al., 2021). In this case, attention appears to be guided by choice rather than vice versa, extending of

the premotor theory of attention to value-based decision-making.

Taken together, there appear to be mechanisms synchronizing agents' attention with their action

plans, and there is tentative evidence for attention to reward and punishment information triggering

automatic responses in the fashion of Pavlovian biases. Hence, it seems indeed possible that an

instrumental system could "recruit" the Pavlovian system to "aid" the execution of action plans by

strategically steering attention toward relevant information. We tested this idea in two samples (the

second one a direct, pre-registered replication) using eye-tracking. For this purpose, we designed a

novel Go/ NoGo learning task in which action planning and execution were separated by a phase in

which participants could preview the positive or negative outcomes at stake. Notably, information about

these outcomes was not informative for the selection of the correct action. We predicted that action

plans would shape attention to reward and punishment stakes, i.e., that participants' first fixation (not

confounded by bottom-up saliency effects due to a gaze-contingent design) would be more often on the

reward information when participants planned a Go (compared to a NoGo) action. Vice versa, we

predicted an effect of attention duration to rewards vs. punishments on the final response, i.e., that

longer attention to reward compared to punishment information would lead to more Go responses and

speed up reaction times (Fig. 1A, B). Such a goal-directed recruitment of Pavlovian biases would extend

their role beyond mere "default" strategies in novel environments towards a powerful aiding robust

action execution.

Figure 1. Theoretical framework and task design. **A.** Theoretical framework of the interaction between action and attention. An environmental cue elicits an action plan, which directs top-down attention (first fixation) towards information about potential reward/ punishment outcomes (stakes). The first fixation anchors attention and (partly) determines which stakes will receive more attention, which is additionally modulated by bottom-up signals such as the magnitude of the stakes. The relative attention on reward versus punishment stakes (dwell time) biases the final Go/ NoGo action

in a Pavlovian manner. **B.** Cartoon illustration of the proposed interaction of action planning and attention. **C.** Task design. Participants learned Go/ NoGo responses to various cues (cover story: feed/ not feed various oyster types to maximize pearls and minimize toxic tumors). Cue presentation (instructing the correct action) and action execution are separated by a phase in which rewards (pearls, here orange) and punishments (toxic tumors, here blue) at stake for correct/ incorrect responses are presented in a gaze-contingent manner. Afterwards, the oyster (black oval) can be fed, and for Go responses, participants have to press the button on the side where it is "still open". Outcomes are delivered in a probabilistic manner (75% feedback validity). On catch trials, participants have to indicate whether the oyster featured more pearls or tumors (cover story: The oyster is stolen by thieves and has to be retrieved back from the police, which requires identification).

Methods

</div>

Participants and Exclusion Criteria

In Sample 1, we recorded eye-tracking data from 35 participants ($M_{age} = 23.7$, $SD_{age} = 4.1$, range 18–35, one outlier at age 58; 27 women, 8 men; 30 right-handed; 21 with the right eye as dominant eye). In Sample 2 (replication sample), we recorded data from 64 participants ($M_{age} = 21.5$, $SD_{age} = 3.0$, range 18–34; 50 women, 13 men, 1 other; 62 right-handed; 41 with the right eye as dominant eye). In this replication sample, the study design, hypotheses, and analysis plan were pre-registered (https://osf.io/nsy5x). The sample size for this sample was based on the effect size of the primary effect of interest in Sample 1, i.e., action requirements affecting first fixations ($z = 2.89$, Cohen's $d = 0.49$), which yielded a required sample of N = 57 to detect such an effect with 95% power (two-sided one-sample t-test) (Murayama et al., 2020). We initially collected data from 57 participants, but given that seven participants did not perform significantly above chance level, we collected additional seven participants. Performance above 56% in 240 trials was significantly above chance (one-sided binomial test). Note that, in line with our pre-registration, all results in the main text are based on all participants (see Supplemental Material 1 for an overview of all results); results for only those participants that performed significantly above chance are reported in Supplemental Material 2 and led to identical conclusions.

Participants were recruited via the SONA Radboud Research Participation System of Radboud

University. Exclusion criteria comprised glasses, color blindness, and prior treatment for neurological

or psychiatric disorders. The study protocol was identical for both samples. Participants took part in a

1h session that comprised informed consent, eye-tracker calibration, a 10-minute practice phase

including written instructions and practice trials, and finally the 30-minute eye-tracking experiment.

Upon completion of the task, participants filled in a structured debriefing about their presumed

hypothesis of the experiment, and any strategies they applied. None of the participants guessed the study

hypotheses. Participants received a participation fee of €10 or 1h of course credit plus a performance

dependent-bonus of €0–2 (Sample 1: M = €0.77, SD = €0.43, range €0.09–1.58; Sample 2: M = €0.91,

SD = €0.47, range €0.10–1.67). Research was approved by the local ethics committee of the Faculty of

Social Sciences at Radboud University (proposal no. ECSW-2018-171).

Apparatus

Reporting follows recently suggested guidelines for eye-tracking studies (Fiedler et al., 2020). The

experiment was performed in a dimly lit, sound-attenuated room, with participants' head stabilized with

a chin rest. The experimental task was coded in PsychoPy 2020.2.7 on Python 3.7.0, presented on a 24''

BenQ XL2420Z screen of resolution (1920 x 1080 pixels resolution, refresh rate 144 Hz). Manual

button presses were applied via a custom-made button box with two buttons (index and middle finger

of the dominant hand). Participants' dominant eye was tracked with an EyeLink 1000 tracker (SR

Research, Mississauga, Ontario, Canada; sampling rate of 1,000 Hz; spatial resolution of 0.01° of visual

angle, monocular recording), controlled via Pylink for Python 3.7.0. The eye-tracker was placed 20 cm

in front of the screen, and participants' chin rest 90 cm in front of the screen. Before the task, participants

performed a 9-point calibration and validation procedure (software provided by SR Research).

Calibration was repeated until an error < 1° was achieved for all points. The screen background grey

tone (RGB 180, 180, 180) was constant across calibration and the experimental task.

Task

Participants performed a Go/ NoGo learning task with delayed response execution, called the

Oyster Farming Task (Fig. 1C). On each trial, participants cultivated an oyster that could either grow

1–5 pearls or 1–5 hazardous tumors. Pearls gained money while tumors cost money for disposal. To

maximize the probability that oysters grew pearls, participants needed to learn which oysters to "feed"

(Go) and which ones not to feed ("NoGo"). Crucially, participants could choose to reveal the reward

(number of pearls) and punishment (number of tumors) at stake prior to action execution in a gaze-

contingent design. Participants' score of accumulated money was turned into a bonus of 0–2€ at the end

of the task. Participants performed 264 trials split into three blocks of 88 trials (80 trials of the Go/

NoGo task, 8 catch trials), each with a new set of four oyster types. For detailed information on the

instructions, see the original materials used in this study available in the data sharing collection under

[All data and code will be made available upon manuscript acceptance].

Each trial started with one (of four) abstract *action cues* (letters from the Agathodaimon

alphabet; size 5.2° x 5.2°) presented for 700 ms in the center of the screen, representing an oyster type.

For each oyster type, there was an optimal action (feed or not feed) that participants needed to learn by

trial-and-error. Feeding was only possible when the oysters "opened" later in the trial. The optimal

action led to rewards (pearls) in 75% of (valid) trials, otherwise to punishments (tumors; on "invalid

trials"). Vice versa, suboptimal actions led to punishments on valid trials, but to rewards on invalid

trials. During action cue presentation, participants were informed about the sides (left vs. right) on

which upcoming stakes information (rewards vs. punishments) would appear via faintly colored semi-

circles in the respective colors (blue and orange, counter-balanced across participants).

Directly after action cue off-set, participants were cued with the exact locations of the stakes

and given 1,500 ms to unveil the tumors and pearls at stake on the respective trial. Stakes were revealed

in a gaze-contingent fashion: fuzzy circular color patches appeared on the semi-circles, which changed

into the number of pearls/ tumors at stake when participants fixated them. This eliminated any bottom-

up saliency effects (e.g., of stake magnitude) on peripheral vision that could affect participants' first

fixations. To prevent exact pre-programming of saccades, exact locations of stakes varied across trials.

Stakes were located on an invisible circle with a radius of 5.2° visual angle around the screen center

(i.e., distance of stakes from the center was kept constant), with a potential vertical displacement of -45

– +45 degrees from the horizontal midline. Vertical displacement was always identical for both pearls

and tumors. Stakes were represented by circular areas of interest (AOI) of 150 pixels (2.7°), with a

minimal distance between stakes (at maximal vertical displacement) of 514 pixels (9.4°) and a maximal

distance (positioned on the horizontal midline) of 852 pixels (15.6°). Stakes were presented in orange

(RGB 200, 100, 7) and blue (RGB 104, 104, 255) of equal luma. Stakes varied in magnitude (1–5 items;

total display size 2.6° x 2.6°) and magnitude was balanced within action cues (i.e., each of the 20

possible combinations used once per cue, excluding the five possible combinations in which both

magnitudes were identical). The mapping of pearls and tumors to the left/ right side varied across trials

and was balanced within action cues (each side 10 times per cue) to control for possible participant-

specific side biases in gaze.

Stakes offset was followed by a variable interval of 100–500 ms (uniform distribution in steps

of 100 ms), after which a release cue (black oyster shape and a food can, 5.2° x 5.2°) appeared for 600

ms, indicating that the oyster was about to close and could be fed if necessary. The oyster remained

open at either the left or right side, indicating the side where the oyster could be fed. If participants

chose to feed the oyster, they had to press the respective button on the open side. The uncertainty about

the response side (left/ right) at the time of the action cue, which was only resolved with the release

cue, prevented pre-mature responding. In-time responses were confirmed by the food can (1.7° x 1.7°)

tipping over to the respective side. 700 ms after release cue offset, the outcome (3.5° x 3.5°) was

presented for 1,000 ms. Late responses during the release cue-outcome interval were recorded, but did

not affect the outcome. Pressing the incorrect button (i.e., the oyster was open on the left/ right, but

participants pressed the right/ left button) counted as incorrect (i.e., yielded tumors on valid trials) and

was confirmed by the can tipping over in the respective direction. Participants received a number of

either pearls or tumors, depending on the stakes, their response, and trial validity. Trials finished with

a variable inter-trial interval between 1,200 and 1,800 ms (uniform distribution in steps of 100 ms).

On 8 out of 88 trials per block, participants performed a catch task which incentivized attention to the

stakes: Instead of the release cue, participants had to report whether the reward or punishments stakes

were of greater magnitude (Fig. 1D). These catch trials encouraged participants to monitor both stakes

and process their magnitude.

Data Preprocessing

Behavior. Catch trials were excluded from all analyses of responses and RTs. We further

excluded trials with RTs below 200 ms (% trials with button presses per participant: Sample 1: $M = 0.1$,

SD = 0.3, range 0–1.5; Sample 2: *M* = 0.2, *SD* = 0.3, range 0–1.1) because such fast responses could

not be expected to incorporate processing of the cue. Likewise, we excluded trials RTs above 800 ms

(% trials with button presses per participant: Sample 1: *M* = 0.9, *SD* = 1.6, range 0–6.8; Sample 2: *M* =

0.5, *SD* = 1.8, range 0–14.0). This deadline was 200 ms after release cue offset (i.e., closing of the

response window) as we reasoned that any later responses could have been triggered by the release cue

offset. Go responses with the incorrect hand were very rare (% trials with incorrect hand response per

participant: Sample 1: *M* = 1.7, *SD* = 3.1, range 0–14.6; Sample 2: *M* = 1.3, *SD* = 2.4, range 0–13.3)

and not significantly influenced by stakes or dwell times.

Eye-tracking preprocessing. Gaze data was processed in R with custom-code. Continuous

data was epoched into trials of 1500 ms relative to stakes onset. Gaps of missing samples up to a duration

of 75 ms (due to blinks or saccades) were interpolated using linear interpolation. Trials with more than

50% of missing samples were discarded altogether (% trials per participant: Sample 1: *M* = 4.5, *SD* =

8.0, range 0–34.1; Sample 2: *M* = 3.5, *SD* = 7.9, range 0–52.7). Gaze position was marked as being on

the reward/ punishment stakes when gaze position was less than 150 pixels away from the center of the

respective stakes image, which was also the criterion in our gaze-contingent design for rendering stakes

visible. For each trial, we computed the first fixation on any stakes object (reward or punishment) as

well as the total duration (in ms) with which rewards and punishments were fixated over the entire trial

("dwell time"). Absolute dwell times were converted into dwell time difference (reward time minus

punishment time) (Westbrook et al., 2020).

On some trials, participants only fixated one stake (% trials with at least one fixation per

participant: Sample 1: *M* = 11.0, *SD* = 14.6, range 0–61.4; Sample 2: *M* = 10.0, *SD* = 14.4, range 0–

50.4), leading to ratios of 0 or 1. We thus deviated from our pre-registration and report results for dwell

time difference (reward minus punishment dwell time) in the main text, which avoids such an

accumulation of values at the edges; analyses of dwell time ratio are reported in Supplemental Material

1 and led to identical conclusions. Analyses using only the trials on which participants fixated both

stakes led to largely identical conclusions.

Data Analysis

General strategy. We tested hypotheses using mixed-effects linear regression (function lmer)

and logistic regression (function glmer) as implemented in the package lme4 in R (Bates et al., 2015).

We used generalized linear models with a binomial link function (i.e., logistic regression) for binary

dependent variables such as responses (Go vs NoGo) and first fixation, and linear models for continuous

variables such as RTs or dwell time. We used zero-sum coding for categorical independent variables.

All continuous dependent and independent variables were standardized such that regression weights

can be interpreted as standardized regression coefficients. All regression models contained a fixed

intercept. We added all possible random intercepts, slopes, and correlations to achieve a maximal

random effects structure (Barr et al., 2013). *P*-values were computed using likelihood ratio tests with

the package afex (Singmann et al., 2018). We considered *p*-values smaller than $\alpha = 0.05$ as statistically

significant.

The main analyses were pre-registered for Sample 2 (replication sample; preregistration

available under https://osf.io/nsy5x). We deviated from our pre-registration by reporting results based

on dwell time differences (reward minus punishment dwell time) instead of dwell time ratios (reward

dwell time divided by reward plus punishment dwell time) in the main text. When participants fixated

only one stake, the dwell time ratios were either 0 or 1, regardless of the absolute dwell time on each

single fixated option, leading to a loss of information and an accumulation of values at the edges,

yielding a distribution with three modes. In contrast, dwell time differences are approximately normally

distributed and statistically more comparable to stake differences. Nonetheless, analyses of dwell time

ratio and dwell time differences led to identical conclusions as reported in the Supplemental Material

1.

Baseline learning and Pavlovian biases. First, following previously established motivational

Go-NoGo learning tasks (Guitart-Masip et al., 2011; Swart et al., 2017), we tested i) the degree to which

participants learned the task, i.e., performed more Go responses to Go cues than NoGo cues, and ii)

whether responses were influenced by the magnitude of the reward and punishment stakes, reflecting

the presence of a Pavlovian bias. For this purpose, we fitted mixed-effects regressions with responses

(Go/ NoGo) and (as secondary variable) reaction times as dependent variables and a) the required action

(Go/ NoGo) as well as b) the difference in reward and punishment stake magnitude (ranging from -4 to

+4) as independent variables. A significant effect of stake difference was followed up with post hoc

analyses separating the effects of reward and punishment stake magnitudes, reported in Supplemental

Material 3.

Analysis of gaze patterns. Our first key prediction was that action plans, elicited by the oyster

cues, directed attention towards action-congruent stakes (reward stake for Go requirement, punishment

stake for NoGo requirement). The crucial test of this prediction was whether the action requirement

elicited by the cue affected the location of the first fixation (on the reward versus the punishment stake).

This first fixation was not confounded by any bottom-up saliency effects since, in our gaze-contingent

design, the magnitudes of the stakes was not visible yet. We used both required action (Go or NoGo)

and the difference in the modeled Q-values for Go relative to NoGo responses as independent variables

to predict the first fixation. These analyses also included catch trials since, during the stakes phase,

participants were unaware of whether the trial would be a Go/ NoGo or catch trial. All eye-tracking

analyses contained a regressor capturing any participant-specific side biases (overall preference to fixate

the left or right).

Computational modelling of action values. We tested the impact of participants' action

intentions on their attention towards the reward and punishment stakes using two operationalizations:

Firstly, we approximated participants' intentions by the action required by the presented cue (oyster

type). However, this operationalization assumes that participants (have learned and) know the required

action. This assumption is violated i) at the beginning of blocks when participants cannot know the

required action yet and still have to acquire it through trial-and-error, and ii) even more so in participants

who fail to learn the correct response for (some of) the cues. Thus, secondly, as a more proximate

measure of participants' beliefs of what they should do, we fitted a simple Rescorla-Wagner Q-learning

model to the Go/ NoGo response data of each participant. This model uses outcomes r (+1 for rewards,

-1 for punishments; given that the exact outcome magnitude is irrelevant for learning) to update the

action-value Q for the chosen action a towards cue s:

$$Q_t(a_t, s_t) = Q_{t-1}(a_t, s_t) + \alpha * (r - Q_{t-1}(a_t, s_t)) \qquad (1)$$

Action values were then translated to action probabilities using a Softmax choice rule:

$$p(Go, s_t) = \frac{\beta * e^{Q_t(Go, s_t)}}{\beta * e^{Q_t(Go, s_t)} + \beta * e^{Q_t(NoGo, s_t)}} \qquad (2)$$

The model featured the free parameters α and β. The learning rate α determines the impact of

prediction errors (i.e., higher α leads to stronger incorporation of recent outcomes and discounting of

past outcomes). The inverse temperature β determines the stochasticity of choices (i.e., higher β leads

to more deterministic choices in line with action values and lower β to more noisy, stochastic choices).

Both parameters were estimated to each participants' data using a grid search, with α in the range [0, 1]

in steps of 0.01 (Sample 1: $M = 0.07$, $SD = 0.08$, range 0.01–0.35; Sample 2: $M = 0.14$, $SD = 0.18$, range

0.001–0.84) and β in the range of [1, 40] in steps of 0.1 (Sample 1: $M = 8.27$, $SD = 8.21$, range 1.0–

32.7; Sample 2: $M = 8.64$, $SD = 9.57$, range 1.0–34.8). Starting values for Q_{Go} and Q_{NoGo} were set to 0.

Using each participants' best fitting parameters as well as their action and outcomes on each trial, we

then simulated the action values for Go and NoGo responses on each trial using one-step-ahead

predictions (Steingroever et al., 2014). We used the difference term $Q_{Go} - Q_{NoGo}$ as more proximate

measure of participants' action intentions on each trial based on their past experience with each cue. On

catch trials (on which participants did not make a Go/ NoGo response and did not receive feedback),

Q-values were not updated, but were carried over from the last cue encounter. Similarly, Q-values were

not updated on trials on which participants responded in the incorrect direction (i.e., pressed left when

the oyster was open on the right or vice versa) since participants were instructed that such "directional"

errors were always counted as incorrect. Feedback was thus not informative as to whether a Go or NoGo

response would have been correct for this cue.

Analysis of effects of attention on responses and reaction times. Our second key prediction

was that attention to the reward and punishment stakes would shape action execution. To test this

prediction, we tested whether the dwell time difference (milliseconds spent on reward stakes minus

milliseconds spent attending to punishment stakes) predicted responses (Go vs. NoGo) and response

speed (RT, for Go responses only). These analyses excluded catch task trials (where responses did not

relate to learning but to comparing stake magnitudes). All analyses involving responses or reaction

times as dependent variable controlled for the required response as well as participant-specific side

biases (overall preference to first fixate the left or right). Results did not change when controlling for

the Q-value difference instead of the required response.

353   **Between-subjects correlations of accuracy.** If humans synchronized their attention with their

action plans such that Pavlovian biases would align with instrumental action requirements, one would

expect this process to facilitate task performance and lead to higher accuracy. To test whether

participants with stronger effects of attention on the final response indeed showed higher accuracy, we

performed exploratory analyses by computing between-subjects correlations between overall task

accuracy and i) the degree to which stake differences (reward minus punishment stake magnitude)

affected responses as well as ii) the degree to which relative dwell time (reward minus punishment

dwell time) affected responses. For this purpose, we refit the respective models on all participants,

collapsing across both samples (total $N = 99$), and computed between-subjects correlations between

participants' percent correct responses and their respective regression coefficient (fixed + random effect

extracted).

366   under [All data and code will be made available upon manuscript acceptance].

367   **Results**

Learning and Pavlovian biases

369   Overall, participants learned the Go/ NoGo task (% correct, Sample 1: $M = 70.0$, $SD = 10.4$,

range 50.0–87.1; Sample 2: $M = 73.4$, $SD = 13.2$, range 36.3–91.7), performing significantly more Go

responses to Go cues than NoGo cues (Sample 1: $b = 1.08$, 95% CI [0.88 1.27], $\chi^2(1) = 53.19$, $p < .001$;

Sample 2: $b = 1.27$, 95% CI [1.09 1.44], $\chi^2(1) = 89.19$, $p < .001$; Fig. 2A). Participants also performed

well in the catch trials (% correct: Sample 1: $M = 85.8$, $SD = 10.1$, range 56.5–100; Sample 2: $M = 86.2$,

$SD = 15.5$, range 25.0–100; Fig. 2D). Five (seven) people in Sample 1 (2) did not perform significantly

above chance (56% correct based on a 1-sided binomial test with 240 trials) in the Go/ NoGo task. In

line with our pre-registration, we still included these subjects in all our analyses (for results without

these participants, see Supplemental Material 2). To account for variability in learning, we estimated

action (Q) values for each trial based on a Rescorla-Wagner learning model.

Beyond outcome-based learning, responding was affected by the stake magnitudes in a way

similar to previously observed Pavlovian biases. A more positive stake difference (reward minus

punishment stake magnitude) increased the proportion of Go responses (Sample 1: $b = 0.12$, 95% CI

[0.06 0.17], $\chi^2(1) = 15.32$, $p < .001$; Sample 2: $b = 0.09$, 95% CI [0.03 0.15], $\chi^2(1) = 7.92$, $p = .005$; Fig.

2B, C) and increased response speed (Sample 1: $b = -0.04$, 95% CI [-0.07 -0.01], $\chi^2(1) = 7.32$, $p = .007$;

Sample 2: $b = -0.03$, 95% CI [-0.05 -0.004], $\chi^2(1) = 6.31$, $p = .012$). The effect of stakes differences did

not become weaker over trials or blocks (see Supplemental Material 3). Separating these effects for the

reward and punishment stakes showed that effects were driven by both valences: Higher (relative to

lower) reward stake magnitude increased responding and speeded up responses, while higher (relative

to lower) punishment stake magnitude decreased responding and slowed responses (see Supplemental

Material 3).

In sum, we found evidence that participants learned the task and that the reward and punishment

stake magnitudes biased responding in opposite directions, reflecting Pavlovian biases. For reaction

times, we found larger reward stake magnitudes to speed up responding and larger punishment stake

magnitudes to slow down responding, again in line with Pavlovian biases as reported in previous

literature (Guitart-Masip et al., 2011; Swart et al., 2017).

Figure 2. Task performance and Pavlovian biases. A. Performance in the Pavlovian Go/ NoGo task. Trial-by-trial proportion of Go actions (±SEM) for Go cues (blue lines) and NoGo cues (red lines). Shadows indicate standard errors for per-condition-per-participant means. Participants clearly learn whether to make Go actions or not (blue lines go up; red lines go down). B. Pavlovian biases. Participants perform more Go responses on trials where the reward stake was higher than the punishment stake (green bars) than vice versa (red bars). Individual data points reflect response proportion per participant. C. Stake magnitudes biased responding in a continuous fashion. A higher stake difference (i.e., a reward stake minus punishment stake) resulted in a higher proportion of Go responses. Faint grey lines represent regression lines per participant as predicted by the mixed-effects regression model; the bronze line represents the group-level regression line; bronze shading represent mean and 95% confidence intervals. Note the two strong outliers in Sample 2; excluding these outliers did not change conclusions. D. Performance in the catch trials. Individual data points reflect accuracy per participant.

Action plans direct eye gaze

Next, we tested whether participants' attention was synchronized to their action plans. Such a link would allow Pavlovian biases to be elicited specifically by reward/ punishment cues that trigger an action in line with participants' intentions. As a measure of goal-directed attention, we used the first fixation on each trial (Konovalov & Krajbich, 2016), which was unaffected by any bottom-up saliency effects of the (yet to be uncovered) stakes in our gaze-contingent design. On trials that required a Go response, participants were significantly more likely to first fixate rewards than on trials that required a NoGo response (Sample 1: $b = 0.11$, 95% CI [0.04 0.19], $\chi^2(1) = 13.92$, $p < .001$; Sample 2: $b = 0.09$, 95% CI [0.03 0.15], $\chi^2(1) = 7.88$, $p = .005$; Fig. 3A).

This analysis used the required response as a predictor on every trial, which is globally appropriate given that participants learnt the task. However, at the beginning of blocks, participants could not know the required response yet. Furthermore, some participants failed to learn the correct response for (some of) the cues. Thus, as a more proximate measure of participants' beliefs of what they should do, we fitted a simple Rescorla-Wagner model (Rescorla & Wagner, 1972) to the Go/ NoGo response data of each participant, simulated the action (Q) values for Go and NoGo responses on each

trial, and used the difference $Q_{Go} - Q_{NoGo}$ as a regressor to quantify the trial-by-trial relative value of

making a Go relative to NoGo response. At the beginning of a block, this regressor will be zero, and it

will stay (close to) zero in case participants fail to learn the correct response. We found that the more

Q-values favored a Go compared to a NoGo response, the more likely were participants to first fixate

the reward (Sample 1: $b = 0.09$, 95% CI [0.03 0.19], $\chi^2(1) = 8.04$, $p = .005$; Sample 2: $b = 0.13$, 95% CI

[0.05 0.22], $\chi^2(1) = 9.17$, $p = .002$; Supplemental Material 4).

We furthermore performed exploratory analyses to test whether action plans affect attention

beyond the first fixation, i.e., also the overall difference in dwell time to the stakes (dwell time on the

reward stake minus dwell time on the punishment stake). This difference was higher when the reward

stake was fixated first (Sample 1: $b = 0.18$, 95% CI [0.07 0.30], $\chi^2(1) = 8.81$, $p < .001$; Sample 2: $b =$

0.16, 95% CI [0.08 0.24], $\chi^2(1) = 13.23$, $p < .001$; not significant in either sample when only analyzing

trials with both stakes fixated), showing that the first fixation anchored which stakes would receive

overall more attention. Over and above this effect, action value kept shaping dwell times, such that

people dwelt longer on the reward (compared to the punishment) stake for Go relative to NoGo cues

(Sample 1: $b = 0.03$, 95% CI [0.01 0.05], $\chi^2(1) = 4.71$, $p = .030$; Sample 2: $b = 0.03$, 95% CI [0.02 0.05],

$\chi^2(1) = 13.79$, $p < .001$; Supplemental Material 4), corroborated when approximating action plans

alternatively via Q-values (Sample 1: $b = 0.03$, 95% CI [0.01 0.05], $\chi^2(1) = 4.36$, $p = .037$; Sample 2: b

$= 0.04$, 95% CI [0.02 0.06], $\chi^2(1) = 24.82$, $p < .001$; Supplemental Material 4). Furthermore, dwell time

was influenced by the stake magnitudes, with significantly longer dwell time on the reward stake

compared to the punishment stake for more positive stakes differences (Sample 1: $b = 0.09$, 95% CI

[0.05 0.13], $\chi^2(1) = 16.49$, $p < .001$; Sample 2: $b = 0.12$, 95% CI [0.09 0.15], $\chi^2(1) = 41.59$, $p < .001$;

see Fig. 3B). This latter effect shows that total dwell time was not completely determined by the first

fixation, which was shaped by "top down" action values, but was additionally sensitive to bottom-up

saliency effects of the stake magnitudes.

In sum, we find evidence that that participants' attention to valenced stakes information, in

terms of both initial fixation and total dwell time, was synchronized to their initial action plans.

Eye gaze predicts responses

We next assessed whether and how attention shaped the ultimate response. We used the

difference in dwell times (reward minus punishment stakes) as an integral measure of total attention

(Konovalov & Krajbich, 2016). We controlled for the required action to show that attention predicted

the eventual response even beyond participants' likely intentions.

The longer participants attended to rewards compared to punishments, the more likely they

were to make a Go response (Sample 1: $b = 0.13$, 95% CI [0.07 0.20], $\chi^2(1) = 12.20$, $p < .001$; Sample

2: $b = 0.19$, 95% CI [0.13 0.26], $\chi^2(1) = 28.44$, $p < .001$; Fig. 3C). Furthermore, in Sample 2 (but not

Sample 1), longer attention to rewards compared to punishments led to faster reaction times (Sample 1:

$b = -0.04$, 95% CI [-0.09 0.02], $\chi^2(1) = 1.90$, $p = .168$; Sample 2: $b = -0.03$, 95% CI [-0.05 -0.01], $\chi^2(1)$

$= 4.53$, $p = .033$). When considered in isolation, higher dwell time on rewards increased responding,

but did not significantly affect reaction times, while higher dwell time on punishment decreased

responding and slowed responses (see Supplemental Material 5). We did not observe any interaction

effects between stakes and dwell time effects (see Supplemental Material 5).

As action plans both affected attention as well the ultimate response, on might wonder if the

link between attention and the ultimate response was induced by action plans as a "common cause". To

exclude this possibility, all analyses using dwell times to predict responses included the required action

as a regressor. Furthermore, we obtained causal evidence for an effect of attention on the ultimate

response in a separate online study, in which we manipulated attention. In this study, action cues were

presented simultaneously with stakes, but located in close spatial proximity to either the reward or the

punishment stakes. We reasoned that the stakes closer to the action cue would receive more attention.

Indeed, we observed that action cues were located closer to reward (instead of punishment) stakes

resulted in more and faster Go responses. This additional dataset corroborates a causal effect of attention

on the ultimate choice. For details, see the Supplemental Material 6.

In sum, we found evidence in both samples that dwell time on rewards/ punishments drove

responses towards Go/ NoGo and speeded/ slowed responses, respectively, such that attention

determined the eventual strength of Pavlovian biases. Tentative evidence suggested that effects of stake

magnitudes and dwell times were highly similar.

Figure 3. Mutual influences between action and attention. A. Action plans direct first fixations. When required to make a Go action, participants are more likely to first fixate reward information than when a NoGo action was required. B. First fixation anchors attention. Dwell times are longer on reward stakes compared to punishment stakes when the first fixation was already on reward stakes. Dwell times are additionally shaped by other factors such as the stake magnitudes. C. Dwell time differences affect final responses. Longer attention to reward compared to punishment stakes resulted in a higher proportion of Go responses. Grey lines = regression lines per participant as predicted by the mixed-effects regression model; Black line = group-level regression line; Shading = the 95% confidence interval.

Stake magnitude and attentional effects differently relate to performance

Lastly, given that both stake magnitudes and dwell times affected responses and RTs in a highly

similar way, we asked whether these effects also had similar consequences for participants' overall

performance. Crucially, stakes were controlled by the experimental protocol and were therefore

unrelated to the required response on each trial. In contrast, attention was under the control of the

participant. If participants fixated reward or punishment cues in line with their action goals and then let

attention guide their eventual response, strong attention effects could putatively improve their performance. We performed exploratory analyses testing whether effects of stake magnitudes and dwell times on responding were related to accuracy across participants.

The effect of stake difference on responses correlated significantly negatively with accuracy, $r(97) = -0.24$, 95% CI [-0.42, -0.04], $p = .017$ (see Supplemental Material 7; after removing two outliers visible: $r(95) = -0.26$, 95% CI [-0.44, -0.06], $p = .010$; Fig. 4A), while the effect of dwell time difference correlated significantly positively with accuracy, $r(97) = 0.45$, 95% CI [0.27, 0.60], $p < .001$ (Fig. 4B). Effects were not exclusively driven by reward or punishment stakes/ dwell times, but both (in opposite directions, respectively; see Supplemental Material 4). We excluded two simpler explanations of the association between the attentional effect and task accuracy: First, this association was not driven by more accurate participants providing higher-quality eye-tracking data (see Supplemental Material 7). Furthermore, accuracy was not linked to a stronger focus on reward information (i.e., more first fixation to rewards or longer attention to rewards); if anything, more accurate participants showed a more variable gaze pattern, which support the idea that these participants could rely in their responses on their context-appropriate gaze patterns (see Supplemental Material 4).

In sum, although correlational, these results suggest that strong attentional effects might facilitate performance, while strong stake magnitudes effects impair it. Based on these analyses, stake magnitude and attentional effects appear to be dissociable.

A. Stake difference effects predict low performance   B. Attentional effects predict high performance

Figure 4. Between-subjects correlations between global Go/ NoGo task performance and stake magnitude (A) and attentional (B) effects. A. Participants with stronger effects of the stake difference on responding (i.e., steeper slopes in Fig. 2C) showed lower performance. B. Participants with stronger effects of the dwell time difference on responding (i.e., steeper slopes in Fig. 3C) showed higher performance. Individual data points reflect per-participants scores, the red line reflects the regression of accuracy on stake magnitude/ attentional effects (shades for ±1 SE). Points = individual participant effects, purple line = regression line, shading = ±1 SE.

Discussion

We report evidence from two independent samples showing that instrumental action plans steer attention towards rewards and punishments and in this way shape the input to the Pavlovian control system, triggering responses in line with those action plans. These results shed new light on the possible function of Pavlovian control. In contrast to current theories, we suggest that these biases have an important role beyond providing reasonable response defaults in novel or seemingly uncontrollable environments. Crucially, in addition, Pavlovian control can support instrumental control for efficient and robust action execution. In a novel task, participants successfully learned to perform Go and NoGo actions to various cues. Their responses and reaction times were biased by task-irrelevant information about potential reward/ punishment outcomes (stakes), similarly to previously reported Pavlovian biases. Most crucially, we found that participants aligned their attention to these stakes with their action plans: they paid more attention to reward stakes when they had to perform a Go action, and relatively more attention to punishment stakes when they had to perform a NoGo action. In turn, attention to these stakes biased ultimate responses, such that more attention to rewards increased the frequency and speed of Go responding. Exploratory between-subjects analyses showed that stronger attentional effects on choice were associated with higher performance, hinting at the adaptive nature of using attention to elicit an automatic response. In sum, these results support the notion that humans can adaptively direct attention to reward and punishment information to selectively elicit Pavlovian biases in line with their action plans.

Current theories often emphasize the "hardwired" nature of Pavlovian biases (Boureau et al., 2015; Dayan et al., 2006) that allow for fast, but inflexible responding. Under the assumption that these

biases embody environmental statistics on an evolutionary time scale, they should lead to the correct

response in most situations. Normative models assign a dominant role to these biases in contexts that

cannot be controlled (yet) by instrumental knowledge about action-outcome relationships (Dorfman &

Gershman, 2019). However, once an environment is controllable, biases should disappear. Frequent

action slips reveal that Pavlovian biases continue to interfere with goal-directed behavior and require

active suppression (Cavanagh et al., 2013; Swart et al., 2018). These cases of interference seem to

question their putatively adaptive nature, warranting an update on previous theories.

Here, we suggest that a strong Pavlovian system can be adaptive, even in well-known

environments, when it is actively brought into alignment with the goals of other (instrumental) systems.

Pavlovian and instrumental control do not need to operate in a strict parallel fashion and merely interact

at the output stage. Instead, we show that instrumental control can determine the input to Pavlovian

control by selectively steering attention to (potentially unrelated) reward or punishment information. In

this way, it sets the Pavlovian system on an "ballistic" track that will eventually lead to the intended

response. Having such an auxiliary mechanism that will trigger the intended response might be

particularly adaptive in real-life contexts in which the implementation of actions unfolds over time and

is prone to interruption by distractors. By "aligning" Pavlovian with instrumental control, action

selection becomes more robust against interference. Such an faciliatory effect of Pavlovian control is

in line with our finding of better performance in participants with stronger attentional shaping of

responses.

Beyond the context of Pavlovian biases, our results extend previous literature on the upstream

determinants (rather than downstream consequences) of attention allocation. Previous studies have

found that, at least early in the choice process, attention appears to be randomly allocated to choice

options in a way that is independent of their value (Manohar & Husain, 2013; Westbrook et al., 2020).

In contrast, recent Bayesian accounts of "active sensing" have proposed that attention should be actively

driven by the value and uncertainty of choice options in order to gather the maximal amount of

information (Callaway et al., 2021; Jang et al., 2021; Sepulveda et al., 2020). We highlight yet another

role of attention allocation: to stabilize (or even speed up) action implementation in face of delays and

distraction. This role stipulates that (visual) attention is at least partly under control of ongoing motor

processes—as proposed by the premotor-theory of attention (Olivers & Roelfsema, 2020; Rizzolatti et

al., 1987; Sheliga et al., 1997)—as well as recent accounts highlighting that vision and visual working

memory primarily serve action (Heuer et al., 2020; van Ede, 2020).

The idea of Pavlovian biases being recruited by instrumental action plans extends such accounts

into the domain of value-based decision-making. It provides a potential explanation for why humans

seek out a choice option right before selecting it, even when this will not reveal new information on

what is the optimal choice (Hunt et al., 2016; Kaanders et al., 2021). Fixating an (appetitive) option

might trigger Pavlovian biases that ensure its selection in face of distractors. Even more so, after

participants have made the decision to select an option, its collection and consumption (potentially in

face of competitors) might require further motor actions that can benefit from invigoration via these

biases. Hence, the role of Pavlovian biases in invigorating motor programs might potentially explain

phenomena of human (and animal) curiosity and information seeking (Cervera et al., 2020; Vasconcelos

et al., 2015) even after the decision process is finished.

Our results also shed new light on the potential mechanisms by which attention to different

choice options affects their eventual choices. Past research has not yet provided evidence on how

fixating a choice option (e.g., a well-known food item like a Snickers) helps its evaluation or affords

more information about it. Some accounts have proposed that value-based decisions are made by

retrieving goal-relevant information or "preferences" from memory (Shadlen & Shohamy, 2016).

Attention to an option could potentially facilitate the retrieval of value-related information about this

option (Callaway et al., 2021). Other studies have observed effects of attention also on perceptual

choices that might not require memory retrieval, suggesting that attention can also affect visual stimulus

processing directly (Smith & Krajbich, 2021; Tavares et al., 2017). In contrast to all of these studies,

our results suggest that attentional effects might be uncoupled from any features of the choice option

and instead be "Pavlovian" in nature: attending to (any) positive information disinhibits motor cortex

and facilitates selection, while attending to (any) negative information inhibits motor cortex and leads

to rejection—regardless of whether this information is related to the choice option or not.

Crucially, in our paradigm, positive and negative information was unrelated (and orthogonal) to the

action that needed to be selected, and thus should not be incorporated into the choice process. However,

even this unrelated information did bias choice. To dissociate whether attentional effects are truly driven

by increased knowledge about an option's features rather than a simple (dis-) inhibitory effect of its

valence, future research should systematically manipulate the relevance of positive and negative option

features to the eventual choice.

There are a few important considerations when generalizing our findings to real world

situations. First, possible outcomes of a choice are often not explicitly presented to an agent. Rather,

agents must make a selection among many potentially relevant pieces of information on what they deem

important. Our task tried to mimic such situations by allowing agents to freely choose how much to

attend to information about rewards and punishments at stake. Still, attention allocation differed from

"naturalistic" free viewing settings in two important ways. Participants were not completely free to

attend to the stakes, but were incentivized to do so by the secondary catch task. Furthermore, only two

pieces of potential information—exemplary of positive and negative aspects of the situation—were

presented, which is a drastic simplification of our information-dense environment. Future extensions of

this research should provide participants with a larger set of information to select from, allowing them

complete freedom to seek out any information during action preparation.

Second, in real life situations as well as in this task, people might initiate an action plan, but

then change their mind. We only had access to the participants' ultimate response, which does not allow

us to disentangle situations in which they maintained a determined action plan throughout the trial from

situations in which actions plans were changed based on reward/ punishment information.

Neuroimaging techniques with high temporal resolution such as EEG and MEG could shed light on the

dynamic interactions between motor processes and how these change as a function of attentional focus.

Third and finally, exploratory analyses suggested that participants whose ultimate response

relied more strongly on attentional inputs showed higher performance. This result corroborates the

postulated adaptive nature of a strong Pavlovian system that can be harnessed by instrumental systems.

In contrast, the degree to which responses were shaped by the stakes magnitudes (i.e., larger magnitudes

resulting in stronger Pavlovian biases) was associated with lower performance. This—at first perhaps

surprising—dissociation likely arose from our task design in which stakes magnitudes were orthogonal

to action requirements. When participants performed substantially above chance, stakes magnitudes had

a greater potential to disturb action selection on "incongruent" trials (where the required action and the

action triggered by the net stakes difference mismatched) than to facilitate it on "congruent" trials. In

contrast, in many real-world contexts, it is adaptive to take into account the size of available rewards or

punishments when choosing whether and how vigorously to respond.

Still, even if stakes magnitudes and attention to stakes are both meaningful contributors to

choices in real-world settings, it is noteworthy that both had different consequences for performance in

our task, suggestive of dissociable behavioral phenotypes. While relying on stake magnitudes might be

linked to "sign-tracking" behavior previously observed in animals and humans (Flagel et al., 2009,

2010; Schad et al., 2019) and suggested to constitute a risk factor for addiction (Chen et al., 2021;

Garbusow et al., 2016; T. E. Robinson & Berridge, 1993), relying on attention might be a "novel"

phenotype reflecting a strategic recruitment of Pavlovian biases. To conclusively demonstrate the

adaptive nature of using attention to invigorate Pavlovian biases, future studies would need to causally

manipulate participants' strategies. Such studies could for example train participants to strategically

seek out reward or punishment information under a certain action plan. The ability to strategically up-

or down-regulate Pavlovian biases could then be relevant for future interventions in psychopathologies

characterized by aberrant biases, such as depression (Huys et al., 2016) or alcohol addiction (Chen et

al., 2021; Garbusow et al., 2016; Schad et al., 2019; Sommer et al., 2017).

In sum, our results suggest a broadening of the current view of Pavlovian control: In addition

to providing sensible "default" actions in novel or uncontrollable environments, a strong Pavlovian

system can be adaptive even in well-known environments when its robust, almost "ballistic" nature is

recruited to ensure that an action plan is implemented even in face of distraction.

Context of this research

Much literature on Pavlovian biases has focused on situations in which these biases are

maladaptive, investigating how they can be suppressed via top-down control (Cavanagh et al., 2013;

Swart et al., 2018). However, stronger biases have been found predictive of better recovery from

depression (Huys et al., 2016). Furthermore, initial theoretical considerations have proposed that biases

could be evaded by mentally reframing a given situation (Boureau & Dayan, 2011) rather than recruiting

top-down control. We pursued this line of reasoning experimentally, testing whether humans use

attention to reward/ punishment cues to create a "Win"/ "Avoid" situation that helps them pursue their action goals. This perspective highlights that instrumental and Pavlovian control might more often work on concert rather than oppose each other.

864 **Supplemental Material 1:**

865 **Results overview full sample**

866 Here, we report an overview over all major statistical results reported in the main text and the

867 supplementary material. These results are based on all participants in both samples. For details on how

868 mixed-effects regression were performed, see the Methods section of the main text.

	DV	IV	Sample	b	SE	χ²(1)	p
Task performance	Go/ NoGo	Required action	1	1.075	0.097	53.191	< .001
			2	1.265	0.091	89.190	< .001
Effect of stake valence and magnitude on action (i.e., Pavlovian bias)	Go/ NoGo	Stake difference	1	0.117	0.027	15.320	< .001

[1]Controlling for first fixation and the stake difference. All effects are significant with required action/ Q-value difference as sole predictor.

Supplemental Material 2:

Results overview: Participants not significantly above chance excluded

We report an overview over all major statistical results as reported in the main text and the

supplementary material, but excluding the five (seven) participants in Sample 1 (2) that did not perform

significantly above chance level, i.e., did not learn the task. For details on how mixed-effects regression

were performed, see the Methods section of the main text. These analyses led to the same conclusions

as the analyses based on the full samples reported in S01.

[1]Controlling for first fixation and the stake difference. All effects are significant with required action/ Q-value difference as sole predictor.

903   **Supplemental Material 3:**

904   **Effects of stake magnitudes on responses and reaction times**

905   Given that stake differences (reward minus punishment stake) affected both Go/ NoGo responses and

906   reaction times, we additionally tested for separate effects of the reward and punishment stake magnitude

907   on responses and reaction times using in mixed-effects logistic regressions (for Go/ NoGo responses)

908   and linear regressions (for reaction times). We coded reward and punishment stake magnitudes as

909   separate regressors (instead of as their difference).

910   The effect of reward stake magnitude on responses was significant in both samples (Sample 1:

$b = 0.14$, 95% CI [0.08 0.19], $\chi^2(1) = 20.79$, $p < .001$; Sample 2: $b = 0.08$, 95% CI [0.03 0.13], $\chi^2(1) =$

8.15, $p = .004$; Fig. S03A), while the effect of punishment stake magnitude was only significant in

Sample 2 (Sample 1: $b = -0.05$, 95% CI [-0.10 0.001], $\chi^2(1) = 3.30$, $p = .069$; Sample 2: $b = -0.06$, 95%

CI [-0.12 -0.01], $\chi^2(1) = 4.71$, $p = .030$; Fig. S03B). In contrast, for RTs, higher reward stake magnitude

predicted faster responses only in Sample 1 (Sample 1: $b = -0.03$, 95% CI [-0.06 -0.001], $\chi^2(1) = 3.98$,

$p = .046$; Sample 2: $b = -0.01$, 95% CI [-0.03 0.01], $\chi^2(1) = 0.03$, $p = .861$; Fig. S03C), while higher

punishment stake magnitude consistently predicted slower responses (Sample 1: $b = 0.03$, 95% CI

[0.001 0.07], $\chi^2(1) = 4.01$, $p = .045$; Sample 2: $b = 0.03$, 95% CI [0.01 0.05], $\chi^2(1) = 7.31$, $p = .006$; Fig.

S03D). Note that RTs are only available for Go responses; hence, the amount of data (and resulting

statistical power) are lower compared to the Go/ NoGo response data.

921   In conclusion, effects of stake magnitude on driving Pavlovian biases reported in the main

922   manuscript were driven by variations in both the reward and the punishment stake. These effects

923   resemble effects of Pavlovian biases reported before, but in this study emerged in a graded fashion, i.e.,

924   more and faster Go responding the larger the reward stake was, and less and slower Go responding the

925   larger the punishment stake was.

926   In addition, we tested whether the effect of stake difference on responses (i.e., the Pavlovian

bias) became weaker over time. For this purpose, we used mixed-effects logistic regression models

including stake difference, time, and their interaction. As time, we either used a) trial number across

the whole task (1–264), b) trial number within each block (1–88), c) cue repetition number (1–22), or

d) block number (1–3). A significant interaction would indicate that the Pavlovian bias changes over

time. However, we did not find any significant interaction, neither a) for trial number across the task

(Study 1: b = -0.04, 95% CI [-0.10 0.02], $\chi2(1)$ = 2.55, p = .110; Study 2: b = -0.03, 95% CI [-0.07

0.01], $\chi2(1)$ = 1.49, p = .222) nor b) for trial number within blocks (Study 1: b = -0.02, 95% CI [-0.08

0.04], $\chi2(1)$ = 0.61, p = .433; Study 2: b = -0.02, 95% CI [-0.06 0.02], $\chi2(1)$ = 1.11, p = .293), nor c) by

cue repetition number (Study 1: b = -0.02, 95% CI [-0.07 0.04], $\chi2(1)$ = 0.27, p = .597; Study 2: b = -

0.02, 95% CI [-0.07 0.02], $\chi2(1)$ = 0.89, p = .345), nor d) for block number (Study 1: b = -0.03, 95% CI

[-0.09 0.03], $\chi2(1)$ = 1.14, p = .286; Study 2: b = -0.02, 95% CI [-0.06 0.02], $\chi2(1)$ = 0.56, p = .455).

Numerically (but not significantly), the bias got weaker with time, which is to be expected given that

people make less errors over time, while errors are necessary to detect the presence of a Pavlovian bias.

In sum, we found no evidence that the Pavlovian bias vanishes over time.

Of note, in our pre-registration, we mentioned under "exploratory analyses" that we would fit

reinforcement-learning drift diffusion models (RL-DDMs) to jointly analyze the effects of stakes/ dwell

times on choices and RTs. We decided to not report the results from these models because data

simulated from them was markedly different from the empirical data. We suspect that DDMs cannot

capture data from this task due to i) the tight response deadline (600 ms), leading to overall fast (but

regularly incorrect) responses while preventing late responses, and ii) the absence of RTs for the NoGo

responses, which can be computationally dealt with, but which implies a lack of constraint on the

parameters (especially the starting point bias term). Lastly, enforcing a strict response threshold is not

possible in the DDM framework. Potentially, evidence accumulation frameworks in which the response

thresholds decrease and eventually become zero at the response deadline might be able to accommodate

such data, but likelihood functions for such models are not readily available. We encourage other

researchers to reanalyze this data with more suitable modeling frameworks that might arise in the future.

Figure SI03. Effect of stake magnitudes on responses and reaction times. A higher reward stake magnitude led to a higher proportion of Go responses (**A**; significant in both studies), while a higher punishment stake magnitude led to a lower proportion of Go responses (**B**; only significant in Study 2). Similarly, a higher reward stake magnitude tended to speed up reaction times (**C**; significant only in Study 1), while a higher punishment stake magnitude tended to slow down reaction times (**D**; significant in both studies).

Supplemental Material 4:

Effect of action plans on attentional measures

As our first key prediction, we tested whether attention allocation to reward and punishment stake was

affected by action requirements. For this purpose, we regressed attention measures (first fixation and

dwell time difference) on participants' trial-by-trial action plans (required action and Q-value

differences) using mixed-effects logistic (first fixation) and linear (dwell time difference) regression.

Results are reported in the main text as well as in S01. First fixations were more likely on rewards when

a Go action was required/ Q-values favored Go over NoGo. Similarly, participants looked overall longer

at the reward (compared to the punishment) stake when a Go action was required/ Q-values favored Go

over NoGo. Taken together, all these results suggest that attention to rewards/ punishments was

synchronized to participants' action plans.

Figure SI04. Effect of action plans on attention measures. Action requirements, i.e., whether participants should make a Go or a NoGo response based on the cue they see, biases participants' attention during the stakes phase: A Go compared to a NoGo requirements led to a higher proportion of first fixations on the reward stake (**A**) and longer dwell time on rewards (compared to punishments) (**C**). The same finding was obtained when fitting a Rescorla-Wagner model to participants' responses and using the Q-values based on responses from past trials to predict what participants should do on the current trial (**B** and **D**).

977   **Supplemental Material 5:**

978   **Effect of dwell times on responses and reaction times**

Given that dwell time differences (reward minus punishment dwell times) affected both Go/ NoGo

responses and reaction times, we additionally tested for separate effects of reward and punishment dwell

times (instead of the difference in dwell times) on responses and reaction times using in mixed-effects

logistic (for Go/ NoGo responses) and linear (for reaction times) regressions. Dwell time on rewards

predicted a higher proportion of Go responses significantly only in Sample 2 (Sample 1: $b = 0.04$, 95%

CI [-0.03 0.10], $\chi^2(1) = 0.95$, $p = .331$; Sample 2: $b = 0.07$, 95% CI [0.01 0.13], $\chi^2(1) = 4.62$, $p = .032$;

Fig. S04A). Dwell time on punishments significantly predicted a lower proportion of Go responses in

both samples (Sample 1: $b = -0.19$, 95% CI [-0.26 -0.11], $\chi^2(1) = 18.04$, $p < .001$; Sample 2: $b = -0.28$,

95% CI [-0.36 -0.20], $\chi^2(1) = 35.08$, $p < .001$; Fig. S04B). Reward dwell time did not significantly

predict RTs in either sample (Sample 1: $b = -0.03$, 95% CI [-0.09 0.02], $\chi^2(1) = 1.62$, $p = .203$; Sample

2: $b = -0.01$, 95% CI [-0.04 0.02], $\chi^2(1) = 0.76$, $p = .384$; Fig. S04C), but punishment dwell time

predicted slower RTs in Sample 2 (Sample 1: $b = 0.03$, 95% CI [-0.03 0.08], $\chi^2(1) = 0.94$, $p = .333$;

Sample 2: $b = 0.04$, 95% CI [0.01 0.07], $\chi^2(1) = 7.67$, $p = .006$; Fig. S04D). Note that RTs are only

available for Go responses; hence, the amount of data (and resulting statistical power) are lower

compared to Go/ NoGo response data.

994   Interestingly, stake magnitudes and dwell times exerted highly similar effects on both responses

and reaction times, with higher reward stake magnitude as well as more attention to them increased Go

responding and speeded responses, while higher punishment stake magnitude as well as more attention

to them decreased Go responding and slowed responses. Given that stake magnitudes and dwell times

exerted such highly similar effects, one might expect them to operate through the same underlying

mechanism. One consequence following from such a shared architecture is that the effects might

influence each other, predicting an interaction effect. We hence performed exploratory analyses testing

for such an interaction effect, reflecting whether effects of longer vs. shorter attention to the reward

(punishment) stake were amplified when participants saw many vs. few potential rewards

(punishments) or vice versa. The interaction between the stake difference and the dwell time difference

on responses was not significant in either study (Sample 1: $b = -0.008$, 95% CI [-0.06 0.04], $\chi^2(1) =$

0.10, p = .755; Sample 2: b = -0.04, 95% CI [-0.08 0.002], $\chi^2(1)$ = 3.42, p = .064), and neither was the

case for RTs (Sample 1: b = 0.04, 95% CI [-0.01 0.08], $\chi^2(1)$ = 2.25, p = .133; Sample 2: b = -0.003,

95% CI [-0.02 0.02], $\chi^2(1)$ = 0.03, p = .856), providing no evidence for attention amplifying effects of

stake magnitudes or vice versa.

In conclusion, longer dwell time on rewards led to more and faster responding while longer

dwell time on punishments led to less and slower responding. However, effects on reaction times were

only significant in the punishment domain. We did not find evidence for an interaction between stake

magnitudes and dwell times, yielding no conclusive evidence whether both effects rely on the same

underlying mechanism or not.

Figure SI05. Effect of dwell times on responses and reaction times. Higher absolute dwell time on rewards led to a higher proportion of Go responses (**A**; only significant in Study 2), while higher absolute dwell time on punishments led to a lower proportion of Go responses (**B**; significant in both studies). Similarly, higher dwell time on rewards tended to speed up reaction times (**C**; though not significant in either study), and higher dwell time on punishment tended to slow down reaction times (**D**; only significant in Study 2).

Supplemental Material 6:

Supplementary online study manipulating attention to reward and punishment stakes

In the results from our eye-tracking studies reported in the main text, we observed an effect of

(manipulated) action requirements on eye-gaze (first fixation and dwell time) and an effect of

(measured) eye-gaze on the ultimate response. Given that both action requirements and eye-gaze

predicted the ultimate response, on might wonder whether the link between eye-gaze and the ultimate

response was spurious, induced by action plans as a "common cause" (an instance of the "third variable

problem"). Note that all analyses regressing responses onto dwell time reported in the main text

controlled for the action plans. In addition, we tested for a causal effect of attention to reward/

punishment information on responses in a separate online study in which we manipulated attention.

This study was performed as a thesis project for Bachelor students at the beginning of the COVID-19

pandemic.

Participants and Exclusion Criteria

We collected data from 34 participants (M_{age} = 22.4, SD_{age} = 2.1, range 19–27; 18 female, 31

right-handed). Data collection and analyses were pre-registered (https://osf.io/kzdhm). Data was

collected under a stopping rule of N = 55 as maximal sample size or May 10, 2020 as final data

collection date (set by financial/ time constraints). As pre-registered, we conducted all analyses in two

ways, once including all participants and once excluding participants who a) guessed the research

hypotheses (zero participants) or b) did not significantly perform above chance (based on a per-

participant logistic regression with response as dependent and required action as independent variable,

with $p < .05$ as cut-off; three participants). Both ways led to identical conclusions.

We recruited participants via the SONA Radboud Research Participation System of Radboud

University. Participants were required to be at least 18 years old, understand English at a sufficient level

(self-reported), not be color-blind, perform the experiment on a PC with a keyboard (no phones or

tablets) and complete the study within a maximum of 90 minutes (i.e., 1.5 times the expected completion

time). The experiment was administered via the Gorilla platform (Anwyl-Irvine, Dalmaijer, Hodges, &

Evershed, 2020). After providing informed consent and demographic information on age, gender, and

handedness, participants completed the "reversed-dot-probe" version of the Motivational Go/ NoGo

Task for 30-40 minutes (see below). Afterwards, they filled out the brief (13-item) version of the Self-

Control Scale (SCS) (Tangney, Baumeister, & Boone, 2004) and the Behavioral Activation/ Behavioral

Inhibition System Scales (BIS/BAS) (Carver & White, 1994). Additionally, participants completed two

vignettes (measuring omission bias) in which they rated the experienced regret and responsibility of

two football coaches who won/ lost a match, afterwards changed/ kept their match plan, and then lost

the next game (adapted from (Zeelenberg, van den Bos, van Dijk, & Pieters, 2002). Finally, participants

performed a debriefing questionnaire asking them to a) guess the hypotheses of the experiment, b) report

any (non-instructed) strategies they used, and c) guess whether the additional instructions helped them

perform the task better. Participants were then debriefed about the purposes of the study. In

compensation for participation, participants received 1 hour of course credit. Furthermore, participants

with at least 60% accuracy in the Go/ NoGo task received tickets (proportional to performance) for a

lottery featuring two 20€ gift card vouchers. Research was approved by the local ethics committee of

the Faculty of Social Sciences at Radboud University (proposal no. ECSW-2018-171).

Task

Participants performed an adapted version of the Motivational Go/ NoGo learning task termed

"reverse-dot-probe version" (Fig. S06A). On each trial, they first saw how many points they could win

for a correct response (printed in green font with a "+") or lose for an incorrect response (printed in red

font with a "-", termed "stakes"). Stakes varied between 10 and 90 points drawn from a uniform

distribution. Reward and punishment stake were presented on the left/ right side of the screen, with

positions counterbalanced across blocks. Participants were instructed to attend to the stakes because

these were relevant for a catch task implemented on some of the trials (see below). After 500 ms, in

addition to the stakes, one out of four action cues (letter from the Agathodaimon alphabet) appeared on

the screen, which required either a Go response (space bar press) or a NoGo response (no button press).

Participants had to learn the correct response from trial-and-error and respond within 1,500 ms. The

action cue was presented in close proximity to either the reward stake or the punishment stake, nudging

participants to direct more attention to one of the two stakes. Cue position was counterbalanced across

trials and orthogonal to action requirements. After a brief fixation cross screen (700 ms), participants

received the outcome (either the reward or the punishment stake previously shown) displayed for 1,500

ms. Feedback was probabilistic in that 86% (12 out of 14) trials were "valid" with a correct response

winning points and an incorrect response losing points, while the remaining 14% of trials were "invalid"

with a correct response losing points and an incorrect response winning points. Trials ended with a

variable inter-trial interval (uniform distribution from 1,100 ms till 1,900 ms in steps of 100 ms).

1078   On 12 trials within the first two blocks, after the outcome phase, a catch task occurred. Reward

and punishment stake magnitudes were presented together with a "decoy" number (all numbers printed

in white font on black boxes without +/- signs, random assignment of numbers to positions). Participants

had to indicate the "other" outcome they could have received (i.e., points-to-be-won in case they lost

points, points-to-be-lost in case they won points) by clicking on it with the mouse within 20 seconds.

The catch task required participants to memorize the exact stake magnitudes seen earlier in the trial,

incentivizing attention to them. For the latter two blocks, we did not include any catch trials to not

interfere with participants applying the additional instructions (see below).

1086   After the second block, participants received additional instructions that explicitly encouraged

1087   them to look at the reward stake in case they planned to perform a Go response, and look at the

1088   punishment stake in case they planned to perform a NoGo response. In this way, we aimed to test

1089   whether participants could voluntarily align their attention with their action plans and in this way reduce

1090   the effect of the action cue's position on responses.

1091   Participants completed 224 trials split into four blocks à 56 trials, each blocks featuring four

1092   novel cues with 14 repetitions. Trial features (action cue identity, action requirement, stake magnitudes

1093   and positions, ITI) were controlled by one of ten pseudo-randomly drawn "spreadsheets" (preventing

1094   cue to repeated on more than two consecutive trials) randomly allocated to participants.

Data Preprocessing

1096   In line with the pre-registration, we excluded reaction times shorter than 300 ms from all

analyses (as those are too fast to be induced by the presented cue). Using 200 ms as alternative cut-off

(as used in our eye-tracking samples) did not change the conclusions.

Analyses

We analyzed participants' responses (Go/ NoGo) using mixed-effects logistic regression models and

their reaction times using mixed-effects linear regression as implemented in the lme4 package in R

(Bates, Mächler, Bolker, & Walker, 2015). For all categorical independent variables, sum-to-zero

coding was used. Continuous dependent and independent variables were standardized such that

regression weights can be interpreted as standardized regression coefficients. We included all possible

random intercepts, slopes, and correlations to achieve a maximal random effects structure (Barr, Levy,

Scheepers, & Tily, 2013). *P*-values were computed using likelihood ratio tests with the package afex

(Singmann, Bolker, Westfall, & Aust, 2018). We considered *p*-values smaller than α = 0.05 as

statistically significant.

As pre-registered (https://osf.io/kzdhm), firstly, we tested whether the action cue position (i.e.,

the cue being closer to the reward stake or to the punishment stake) as a proxy for participants' induced

attention affect their Go/ NoGo responses and reaction times, expecting a main effect of cue position.

Secondly, we tested whether instructing people to attend to stake that matched their action plan reduced

the effect of cue position, expecting an interaction between cue position and instructions. We tested

both hypotheses in a single model (a logistic regression model for responses, a linear regression model

for reaction times) featuring the regressors required response (Go/ NoGo), cue position (on the reward/

punishment side), and instructions (before /after) as well as all possible interactions. As mentioned in

the pre-registration, we also report the interaction between required action and instructions as well as

the three-way interaction between required action, cue position, and instructions.

Furthermore, we specified two exploratory analyses in our pre-registration. Firstly, we tested

whether the difference in stakes (reward minus punishment stake) affected participants' responses and

reaction times, expecting more positive differences to lead to more and faster Go responses. For this

purpose, we fitted a model with stake difference as sole regressor. Secondly, we calculated participants'

mean score on the self-control scale (SCS), BIS and BAS scales and regret judgements and tested

whether these scores modulated participants' cue position effect. For this purpose, we fitted a new

model for each score featuring cue position, the respective score, and their interaction.

1126

Figure SI06. Task design and results from the online study manipulation attention to reward and punishment information **A.** Task design. On each trial, participants saw many points they could win for correct responses or lose for incorrect responses ("stakes"). After 500 ms, a Go/ NoGo action cue was displayed either next to the reward or the punishment stake, nudging participants to direct more attention to the respective stake. Participants learned whether a cue required a Go or NoGo response from trial-and-error. Outcomes are delivered in a probabilistic manner (86% feedback validity). On catch trials, participants indicated which other stake (i.e., the one they did not receive as an outcome) they had seen before. **B.** Proportion of Go responses as a function of action requirement and cue position. Participants performed significantly more Go responses to Go cues than NoGo cues and when cues were presented next to the reward stake compared to the punishment stake. **C.** Reaction times as a function of action requirement and cue position. Participants showed significantly faster responses to Go cues than NoGo cues and when cues were presented next to the reward stake compared to the punishment stake. **D.** Proportion of Go responses as a function of stake difference (reward minus punishment stake). As net stakes became more positive, participants performed significantly more Go responses. **E.** Reaction times as a function of stake difference (reward minus punishment stake). As net stakes became more positive, participants became faster, but this effect was not significant.

Results

Overall, participants learned the Go/ NoGo task (% correct: $M = 79.0$, $SD = 12.0$, range 52.7–

94.2), performing significantly more Go responses to Go cues than NoGo cues (main effect of required

action: $b = 1.60$, 95% CI [1.33 1.88], $\chi^2(1) = 54.53$, $p < .001$). Three participants did not perform

significantly above chance (per-participant logistic regression with response as dependent and required

response as independent variable, which is significant for accuracy levels of at least 56%). In line with

our pre-registration, we report results with and without these participants. Performance in the catch task

was above chance (3 response options imply a chance level of 33.3%; a one-sided binomial test based

on 12 trials is significant for 63% accuracy and higher) in only 25 out of 34 participants. Also, the

group-level performance was hardly above chance (% correct: $M = 66.4$, $SD = 18.6$, range 25.0–81.7),

likely reflecting that this task was very demanding.

1138   Firstly, in line with our pre-registration, we tested whether the cue position (action cue on the

reward/ punishment side) affected participants' Go/ NoGo responses. Participants performed more Go

responses when the action cue was on the side of the reward stake compared to the side of the

punishment stake (main effect of cue position: $b = 0.19$, 95% CI [0.09 0.29], $\chi^2(1) = 10.90$, $p < .001$;

Fig. S06B), suggesting that increased attention to rewards (compared to punishments) induced more Go

responses. Similarly, participants performed faster Go responses when the action cue was on the side

of the reward stake compared to the side of the punishment stake (main effect of cue position: $b = -0.03$,

95% CI [-0.04 -0.02], $\chi^2(1) = 25.70$, $p < .001$; Fig. S06C). These results suggested that more attention

directed to reward/ punishment stake causally affects participants' responses and reaction times in the

fashion of Pavlovian biases.

1148   Secondly, in line with our pre-registration, we tested whether the effect of cue position became

smaller after participants were instructed to attend to the stake that matched their action plan. The

interaction effect between cue position and instructions was not significant ($b = -0.03$, 95% CI [-0.10

0.04], $\chi^2(1) = 0.55$, $p = .458$), providing no evidence for responses becoming less affected by the cue

position once participants tried to voluntarily deploy their attention. In fact, the sign of the effect

suggested the effect of cue position to become stronger (instead of weaker) after additional instructions

were administered. However, there was a significant interaction between required action and

instructions ($b = -0.38$, 95% CI [-0.50 -0.25], $\chi^2(1) = 29.28$, $p < .001$), suggesting that participant overall

performed better after receiving instructions. In absence of a control group, this effect cannot be

disentangled from an increase in performance over time, providing inconclusive evidence for whether

instructions affected participants' responses or not. The three-way interaction effect between required

action, cue position, and instruction was not significant ($b = 0.01$, 95% CI [-0.06 0.07], $\chi^2(1) = 1.78$, p

$= .182$). Apart from responses, also the effect of cue position on reaction times was not significantly

changed by instructions ($b = 0.01$, 95% CI [-0.003 0.02], $\chi^2(1) = 1.65$, $p = .199$), and neither was the

interaction between required action and instructions ($b = 0.001$, 95% CI [-0.01 0.01], $\chi^2(1) = 0.04$, $p =$

$.840$) nor the three-way interaction effect between required action, cue position, and instruction ($b = -$

0.0003, 95% CI [-0.01 0.01], $\chi^2(1) = 0.004$, $p = .948$) significant.

Thirdly, as part of the exploratory analyses mentioned in the pre-registration, we tested whether

the difference in stakes (reward minus punishment stake) affected participants' responses or reaction

times. As expected, as the difference in stakes increased (relatively more points to win than to lose),

participants performed significantly more Go responses ($b = 0.08$, 95% CI [0.03 0.12], $\chi^2(1) = 8.15$, p

$= .004$; Fig. S06D), suggesting that the difference in available rewards/ punishments biased their

responses in the fashion of Pavlovian biases. Reaction times were not significantly affected by the stake

difference ($b = -0.004$, 95% CI [-0.01 0.004], $\chi^2(1) = 1.01$, $p = .316$; Fig. S06E).

Fourthly, as part of the exploratory analyses mentioned in the pre-registration, we tested

whether the effect of cue position on responses was predicted by participants' score on the self-control

scale (SCS), the BIS and BAS scales, or the regret and responsibility ratings in the omission bias

vignettes. We did not find any significant modulation of the cue position effect by SCS scores ($b = -$

0.03, 95% CI [-0.09 0.06], $\chi^2(1) = 0.70$, $p = .403$), BAS Drive scores ($b = -0.04$, 95% CI [-0.11 0.03],

$\chi^2(1) = 1.03$, $p = .310$), BAS Reward Responsiveness scores ($b = -0.01$, 95% CI [-0.08 0.05], $\chi^2(1) =$

0.10, $p = .756$), rated regret for changing the match plan after a previous football win ($b = -0.02$, 95%

CI [-0.10 0.07], $\chi^2(1) = 0.14$, $p = .710$), rated responsibility asymmetry when changing/ keeping the

match plan after a previous football win ($b = 0.02$, 95% CI [-0.04 0.08], $\chi^2(1) = 0.39$, $p = .532$), rated

regret for changing the match plan after a previous football defeat ($b = -0.01$, 95% CI [-0.07 0.05], $\chi^2(1)$

$= 0.10$, $p = .750$), or rated responsibility asymmetry when changing/ keeping the match plan after a

previous football defeat ($b = -0.004$, 95% CI [-0.09 0.08], $\chi^2(1) = 0.01$, $p = .933$). However, the cue

position effect was significantly modulated by BIS scores ($b = -0.07$, 95% CI [-0.13 -0.01], $\chi^2(1) = 4.32$,

$p = .038$) with participants with higher BIS scores showing weaker cue position effects, and by BAS

Fun Seeking scores ($b = -0.07$, 95% CI [-0.14 -0.01], $\chi^2(1) = 4.64$, $p = .031$) with participants with

higher BAS scores showing again weaker cue position effects. Given the sample only comprised 34

participants and several between-participants analyses were run, these results should be interpreted with

caution.

We repeated all analyses while excluding three participants who did not perform significantly

above chance in the Go/ NoGo task. Firstly, still, participants performed more ($b = 0.18$, 95% CI [0.08

0.29], $\chi^2(1) = 10.13$, $p = .001$) and faster ($b = -0.03$, 95% CI [-0.05 -0.02], $\chi^2(1) = 26.84$, $p < .001$) Go

responses when the action cue was on the side of the reward stake compared to side of the punishment

stake. Secondly, the effect of cue position on responses was again not significantly different after

compared to before additional instructions were administered ($b = -0.02$, 95% CI [-0.10 0.06], $\chi^2(1) =$

0.24, $p = .623$), but the effect of required action was again stronger after compared to before responses

($b = -0.41$, 95% CI [-0.55 -0.27], $\chi^2(1) = 23.39$, $p < .001$), with again no significant three-way interaction

($b = 0.01$, 95% CI [-0.07 0.09], $\chi^2(1) = 0.06$, $p = .800$). Regarding reaction times, again, neither the

effect of cue position ($b = 0.01$, 95% CI [-0.003 0.02], $\chi^2(1) = 1.98$, $p = .159$) nor the effect of required

action ($b = 0.003$, 95% CI [-0.01 0.02], $\chi^2(1) = 0.28$, $p = .597$) was significantly modulated by

instructions, and neither was the three-way interaction significant ($b = -0.001$, 95% CI [-0.01 0.01],

$\chi^2(1) = 0.08$, $p = .779$). Thirdly, as the stake difference increased, participants again performed

significantly more Go responses ($b = 0.06$, 95% CI [0.01 0.11], $\chi^2(1) = 5.72$, $p = .017$), but not

significantly faster responses ($b = -0.006$, 95% CI [-0.01 0.002], $\chi^2(1) = 2.33$, $p = .127$). Fourthly, we

again did not find any significant modulation of the cue position effect by SCS scores ($b = -0.04$, 95%

CI [-0.11 0.03], $\chi^2(1) = 1.25$, $p = .264$), BAS Drive scores ($b = -0.02$, 95% CI [-0.09 0.05], $\chi^2(1) = 0.30$,

$p = .582$), BAS Reward Responsiveness scores ($b = -0.01$, 95% CI [-0.08 0.05], $\chi^2(1) = 0.10$, $p = .751$),

rated regret for changing the match plan after a previous football win ($b = 0.02$, 95% CI [-0.07 0.09],

$\chi^2(1) = 0.27$, $p = .603$), rated responsibility asymmetry when changing/ keeping the match plan after a

previous football win ($b = 0.02$, 95% CI [-0.04 0.09], $\chi^2(1) = 0.23$, $p = .632$), rated regret for changing

the match plan after a previous football defeat ($b = -0.004$, 95% CI [-0.07 0.06], $\chi^2(1) = 0.01$, $p = .909$),

or rated responsibility asymmetry when changing/ keeping the match plan after a previous football

defeat ($b = 0.007$, 95% CI [-0.08 0.10], $\chi^2(1) = 0.02$, $p = .877$). The modulation by BIS scores was not

significant any more ($b = -0.06$, 95% CI [-0.13 0.004], $\chi^2(1) = 2.33$, $p = .127$), while the modulation by

BAS Fun Seeking scores was still significant (b = -0.06, 95% CI [-0.13 -0.003], $\chi^2(1)$ = 4.19, p = .041).

Overall, analyses excluding the three participants who did not perform the Go/ NoGo task significantly

above chance led to identical conclusions as analyses including all participants.

Discussion

In this study, we manipulated attention by displaying Go/ NoGo action cues next to either the

reward or punishment stake, nudging participants to pay relatively more attention to the stake that we

next to the action cue. We obtained causal evidence that attention to reward information (compared to

punishment information) leads to more Go (compared to NoGo) responses as well as to faster responses.

We did not find evidence for instructions to voluntarily deploy attention in line action plans reducing

the attentional effect. Potentially, the task was too demanding and the trial time course too fast for

participants to voluntarily steer attention in a way that supported their action plans. Future studies might

use different instructions or an altered task design that gives participants more time to deploy attention

before they perform an action.

Furthermore, we found evidence for overall stake differences (reward minus punishment stake)

biasing responses (but not reaction times) in the fashion of Pavlovian biases. These results support the

effect of stake differences on responses reported in the main text. Finally, we did not find any strong

modulation of the attentional effect by self-reported measures such as the Self-Control Scale, the BIS/

BAS scales, or regret and responsibility ratings in two vignettes measuring omission biases. Although

there was some evidence for stronger BIS and BAS Fun Seeking scores predicting weaker attention

effects, these results should be treated with caution given the limited sample size and the higher number

of tests. Future studies should test for such links in larger samples. In sum, the core conclusion is that

the results of this study support a causal effect of attention on Go/ NoGo responses.

Supplementary Material 7:

Effects of stake magnitudes and dwell times on responses predict interindividual

differences in task performance

Both stakes and dwell times affected Go/ NoGo responses (and reaction times) in a similar way, i.e., a

higher reward stake as well as more attention to it increased Go responding and speeded responses,

while a higher punishment stake as well as more attention to it decreased Go responding and slowed

responses. Given such highly similar effects, one might expect them to operate through the same

underlying mechanism. First, one consequence following from such a shared architecture is that effects

should influence each other, i.e., the presence of a higher stake could alter the impact of dwell times on

responses, or vice versa, which predicts an interaction effect. However, we observed no evidence for

such an interaction effect (see S05), tentatively suggesting that effects operate independently of each

other (though curiously with highly similar consequences).

An alternative way of assessing how comparable these effects are is to probe their consequences

for task performance across participants: Does letting responses be strongly guided by stake differences

(reward minus punishment stake magnitudes) vs. strongly guided by dwell time differences (reward

minus punishment dwell times) have similar or different consequences for overall performance in the

Go/ NoGo task? For this purpose, we re-fitted regression models across both samples, extracted per-

participant regression coefficients (fixed-effect plus participant-specific random effect), and correlated

these coefficients with participant overall performance (% correct responses).

Performance was significantly lower in those participants in which stake difference more

strongly shaped their responses (Figure S08A, B). This finding was in stark contrast to significantly

higher performance in those participants in which dwell time differences (reward minus punishment

dwell time) more strongly affected response. It is noteworthy that the stake differences are

experimentally controlled, and thus purely "bottom-up", while in contrast, dwell time differences were

under participants' control and synchronized to action plans, both directly (effect on dwell time

difference) and indirectly (effect on first fixations).

We performed control analyses to exclude the possibility that the association between

attentional effects on responses and task performance was driven by better performing participants

showing higher eye-tracking data quality. First, we computed the number of trials with any (opposed to

no) fixation on any of the two stakes. This number was significantly positively correlated with

performance, $r(97) = 0.23$, 95% CI [0.03, 0.41], $p = .025$, but not with the attentional effect on

responses, $r(97) = 0.13$, 95% CI [-0.07, 0.32], $p = .208$. When using both task performance and number

of trials with any fixation to predict attention effects in a multiple linear regression, the effect of task

performance was still strongly significant, $t(96) = 4.79$, $p < .001$. Second, we calculated the total time

(in ms) that people attended to any of the two stakes objects. This number was neither significantly

correlated with performance, $r(97) = 0.09$, 95% CI [-0.11, 0.28], $p = .389$, nor with the attentional effect

on responses, $r(97) = 0.13$, 95% CI [-0.07, 0.32], $p = .183$, and when using both task performance and

total fixation time to predict attention effects in a multiple linear regression, the effect of task

performance was still strongly significant, $t(96) = 4.90$, $p < .001$. In sum, it is unlikely that the

correlation between performance and attentional effects on responses is driven by more accurate

participants providing higher-quality eye-tracking data.

Furthermore, we performed control analyses checking whether performance, being associated

with how many rewards (rather than punishments) participants received, was associated with

differential fixation patterns (more first fixations or longer fixations) to reward vs. punishment stakes.

It is possible that performance affects information search: high performing participants can reasonably

expect to receive rewards most of the time, so they might be more interested in and attend more to

reward stakes. Vice versa, lower performing participants might expect occasional punishments and thus

also attend to punishment stakes. There was no significant correlation between task performance and

the number of first fixations on rewards vs. punishments, $r(97) = -0.11$, 95% CI [-0.30, 0.09], $p = .298$

and the association between task performance and the attentional effect on responses remained

significant when controlling for the number of first fixations, $t(96) = 4.97$, $p < .001$. There was however

though a significantly negative correlation between task performance and overall dwell time difference

(dwell time on reward stakes minus dwell time on punishment stakes), $r(97) = -0.27$, 95% CI [-0.44, -

0.08], $p = .007$: participants with higher performance showed a more variable (i.e., less biased towards

reward stakes) gaze pattern and attended relatively more to punishments compared to participants with

low performance. The association between task performance and the attentional effect on responses

remained significant when controlling for the this overall dwell time difference, $t(96) = 5.20$, $p < .001$.

In sum, we found no evidence for high performing participants exclusively focusing on reward stakes

and low performing participants also attending to punishment stakes. If anything, we found the opposite

pattern of high performing participants showing a more variable gaze pattern (also attending to

punishment stakes), which chimes with the idea that these participants could rely their response on their

(more adaptive/ flexible) gaze pattern.

Note that all these performance-dependent results are exploratory and should be interpreted

with caution.

Figure SI07. Association between interindividual variability of accuracy and in the effects of stake magnitudes and dwell times on responses. Participants' mean accuracy correlated significantly negatively with their respective effect of stake differences on responses (**A**), also when two outliers removed (**B**), which was driven both by a negative correlation with the effect of the reward stake (**C**; note that these effects tend to be positive) as well as a positive correlation with the effect of the punishment stake (**D**; note that these effects tend to be negative, i.e., participants with stronger negative effects showed worse performance). These correlations suggest that participants with strong stake difference effects showed poor performance. The opposite pattern

occurred for the effect of dwell time on responses: This effect correlated significantly positively with accuracy, both for the difference between reward and punishment dwell times (**E**) as well as the relative dwell time (ratio) on rewards (**F**). Again, this effect was driven by reward dwell times (**G**) rather than punishment dwell times (**H**). These correlations suggest that participant with strong attention effects showed high performance.
