10

11   **Abstract**

12   Lysosomal exocytosis is involved in many key cellular processes but its spatio-temporal regulation is
13   poorly known. Using total internal reflection fluorescence microscopy (TIRFM) and spatial statistics, we
14   observed that lysosomal exocytosis is not random at the adhesive part of the plasma membrane of RPE1
15   cells but clustered at different scales. Although the rate of exocytosis is regulated by the actin
16   cytoskeleton, neither interfering with actin or microtubule dynamics by drug treatments alters its spatial
17   organization. Exocytosis events partially co-appear at focal adhesions (FAs) and their clustering is
18   reduced upon removal of FAs. Changes in membrane tension following a hypo-osmotic shock or
19   treatment with methyl-β-cyclodextrin was found to increase clustering. To investigate the link between
20   FAs and membrane tension, cells were cultured on adhesive ring-shaped micropatterns, which allows to
21   control the spatial organization of FAs. By using a combination of TIRFM and fluorescence lifetime
22   imaging microscopy (FLIM) microscopy, we revealed the existence of a radial gradient in membrane
23   tension. By changing the diameter of micropatterned substrates, we further showed that this gradient as
24   well as the extent of exocytosis clustering can be controlled. Together, our data indicate that the spatial
25   clustering of lysosomal exocytosis relies on membrane tension patterning controlled by the spatial
26   organization of FAs.

27

28

29

1   Introduction

2   Exocytosis is an evolutionary novelty shared among all eukaryotes (i.e. a synapomorphy) (Kloepper et al.,
3   2007). It relies on the SNARE machinery probably inherited from an archaeal ancestor (Neveu et al.,
4   2020). In addition to Golgi-derived vesicles along the secretory pathway, late endosomes, lysosomes and
5   lysosome-related organelles also undergo exocytosis. Lysosomal exocytosis (referred to the secretion
6   from late endosomes/lysosomes) is involved in the secretion of enzymes (Samie and Xu, 2014) and
7   exosomes (Kowal et al., 2014). It supports plasma membrane repair (Andrews and Corrotte, 2018) as
8   well as the remodeling of the microenvironment. Besides these general functions, lysosomal exocytosis
9   fulfills specific roles in several cell types, such as the growth of neurites (Arantes and Andrews, 2006),
10   axonal myelination (Chen et al., 2012), cell communication through ATP release in astrocytes (Dou et al.,
11   2012), pseudopode formation in phagocytosis (Huynh et al., 2007), secretion of cytotoxic granules in
12   lymphocytes (Peters et al., 1991), MHC-II antigen presentation (Geuze, 1998) and bone resorption in
13   osteoclasts (Lacombe et al., 2013). It has a fundamental importance in several pathological contexts. For
14   instance, lysosomal exocytosis is exploited by some β-coronavirus for their egress (Ghosh et al., 2020;
15   Chen et al., 2021) or by cancer cells to enhance invasion through the secretion of metalloproteases,
16   especially at invadopodia (Hoshino et al., 2013; Machado et al., 2015). Importantly, impairment of
17   lysosomal exocytosis has been implicated in lysosomal storage disorders (LSDs) (LaPlante et al., 2006).
18   Enhancing lysosomal exocytosis to release undigested lysosomal contents is a promising therapeutic
19   strategy in these diseases (Samie and Xu, 2014).

20   Seminal work on the molecular machinery maintaining exocytosis, particularly vesicular (v-) and target (t-
21   ) SNAREs that are critical for the fusion of secretory vesicles arriving at the plasma membrane (PM)
22   (Novick et al., 1980; Söllner et al., 1993; Fernández-Chacón et al., 2001), uncovered key mechanisms that
23   regulate the frequency of secretory events (Gundelfinger et al., 2003; Kasai et al., 2012). Exocytosis has
24   been known to be polarized toward active zones in neuronal cells for a long time (Südhof, 2012). In
25   recent years, the question has arisen where exocytosis takes place and how cells regulate secretion at
26   specific cellular sites in non-neuronal cells. After some conflicting results (Schmoranzer et al., 2000;
27   Keller et al., 2001), it has been now clearly demonstrated that exocytosis is not random but clustered
28   even in non-polarized cells (Sebastian et al., 2006; Yuan et al., 2015; Urbina et al., 2018; Fu et al., 2019).
29   Evidence also exists that lysosomal intracellular positioning is non-random (Schauer et al., 2010; Ba et al.,
30   2018). Moreover, in polarized epithelial cells, lysosomal exocytosis is targeted to the basolateral
31   membrane (Xu et al, 2012). However, the spatial regulation of exocytosis in non-polarized cells and its
32   mechanisms have not been explored.

33   Lysosomal exocytosis relies on VAMP7 (Martinez-Arca et al., 2000; Proux-Gillardeaux et al., 2007;
34   Verderio et al., 2012), a v-SNARE that is insensitive to tetanus and botulinum neurotoxins (hence its
35   other names TI-VAMP for Tetanus neurotoxin Insensitive Vesicle-Associated Membrane Protein) (Galli et
36   al., 1998). In epithelial cells, VAMP7 interacts with the t-SNAREs syntaxin (STX) 3 (Vogel et al., 2015) and
37   STX4 (Williams et al., 2014) found at the PM and with STX7. Whereas STX3/4 are involved in exocytosis,
38   STX7 is only involved in intracellular endosomal fusion events (Ward et al., 2000; Wade et al., 2001;
39   Bogdanovic et al., 2002).

1   In the present study, we use tools from spatial statistics to analyze live imaging data of fluorescent
2   VAMP7 obtained by TIRFM on RPE1 cells undergoing lysosomal exocytosis. We report that spatial
3   organization of lysosomal exocytosis is regulated by membrane tension gradient that relies on the spatial
4   distribution of FAs.

5

6   **Results**

7
8   **1) Exocytosis from lysosomes is not random**

9   To monitor lysosomal exocytosis, we transfected RPE1 cells with a pHluorin construct of the v-SNARE
10 VAMP7, VAMP7-pHluorin. The pHluorin signal is quenched in the lumen of acidic vesicles but
11 unquenched during exocytosis when protons from the lysosomal lumen are released (F1A). Using
12 dynamic TIRFM imaging, we manually detected exocytosis events characterized by a sudden increase in
13 intensity followed by a decay clearly visualized in kymographs (F1B). The decrease in intensity
14 corresponds to the 2D diffusion of VAMP7-pHluorin in the plane of the PM. Its diffusion kinetic can be
15 fitted by a single decreasing exponential function with a half-life of about 1.69 ± 0.83s (S1A-S1B).
16 Detected exocytosis can be represented by an intensity map where the intensity λ represents the local
17 expected number of event/μm^2 (F1C). RPE1 cells display a high lysosomal exocytosis rate as several
18 hundred exocytosis events in a typical cell could be observed within 5min, corresponding to an
19 exocytosis rate of $39 \times 10^{-5} \pm 31 \times 10^{-5}$ exocytosis/μm^2/s (F1D). VAMP7 has been reported as a marker of
20 the endosomal/lysosomal compartments. However, it substantially colocalizes with Golgi-derived
21 vesicles in some cell types (Chaineau et al., 2009), especially in neuronal cells (Burgo et al., 2012). To
22 confirm that VAMP7 specifically marks lysosomal exocytosis in RPE1 cells, we treated cells with Golgicide
23 A, an inhibitor of the Arf1 GEF (Guanine nucleotide Exchange Factor) GBF1, which induces Golgi
24 apparatus dispersion and inhibits the Golgi-derived vesicles secretion (Saenz et al., 2009). As shown in
25 (F1E), Golgicide A did not significantly alter the exocytosis rate. Contrary, inhibition of the lysosomal V-
26 type ATPase using Bafilomycin A1 significantly reduced the exocytosis rate (F1F). Lysosomal exocytosis
27 can be stimulated by histamine through the G1q-PKC pathway (Verweij et al., 2018). As expected,
28 treating RPE1 cells with histamine significantly increased the exocytosis rate (F1G) immediately after the
29 addition of histamine (S1C). Taken together, these results demonstrate that VAMP7 exocytosis
30 represents *bona-fide* lysosomal exocytosis in RPE1 cells.

31 The obtained exocytosis maps can be visualized as patterns of points (F1C). Such patterns can be the
32 result of an uniformly random process (Complete Spatial Randomness, CSR) or reflects either clustering
33 (i.e. aggregation) or dispersion (i.e. ordering with an inhibition surface around each point of exocytotic
34 event) (Diggle, 1983; Lachuer et al., 2020). We obtained a large dataset of 183 cells showing 32 880
35 exocytosis events to test the CSR hypothesis and to characterize the spatio-temporal properties of
36 lysosomal exocytosis. The observed spatio-temporal characteristics of exocytosis were compared to CSR
37 Monte-Carlo simulations (see methods). First, we found that exocytosis events present a smaller
38 nearest-neighbor distance (NND) than expected in the case of CSR, which indicates clustering at the scale

1 of immediate neighbors (F1H). Moreover, events are more distant to cell borders than expected
2 demonstrating that exocytosis is much less frequent close to cell borders (F1I). Events are also
3 anisotropically distributed in the cells *i.e.* have a preferential direction (F1J). To explore this anisotropy,
4 we seeded cells on rectangular micro-patterns forcing the orientation of cells into two possible
5 directions (left or right) (S1D). Results confirmed anisotropy in exocytosis and showed that the secretory
6 direction correlates with the Golgi-Nucleus axis (S1D).

7 The most pertinent tool to analyze a spatial structure is the Ripley's K function that measures the
8 average number of neighbor events at a given scale. The average curve obtained from observed events
9 significantly deviated from the expected one in case of CSR, indicating clustering of lysosomal exocytosis,
10 even at the scale of several micrometers (F1K). The CSR envelope is not symmetric around 0, reflecting a
11 slight bias introduced by the boundary corrections in the computation of the Ripley's K function. Note
12 that the treatment with Golgicide A, Bafilomycin A1 and histamine did not change the spatial
13 organization of exocytosis (S1E-G), indicating that the rate and spatial patterning of exocytosis are
14 independent features. We noticed a slight correlation between exocytosis rate and clustering (S1H). This
15 correlation is not due to a bias in the measure, because Ripley's K function is independent on the
16 number of events (Baddeley et al., 2015) and indeed, conserving an arbitrary percentage of the recorded
17 events does not affect the Ripley's K function (S1I). We conducted a similar analysis for the temporal
18 distribution of exocytosis events. The temporal Ripley's K function demonstrates a temporal clustering
19 (S1J). However, a Fourier analysis revealed that this clustering is not due to a periodicity in the exocytosis
20 rate (S1K). Lastly, we quantified the coupling between spatial and temporal dimensions using the spatio-
21 temporal Ripley's K function (S1L), which provides information about the independency of the temporal
22 and spatial coordinates. This analysis revealed that a substantial proportion of cells presents a spatio-
23 temporal coupling and among cells with a significant coupling, 82.7% have a positive coupling *i.e.* events
24 that are close in space are also more likely to be close in time. Together, our analysis confirmed that
25 lysosomal exocytosis is a non-random process in space and time.

26

27 **2) Lysosomal exocytosis is coupled to internal focal adhesions in a cytoskeleton-independent**
28 **manner.**

29 To investigate the mechanisms underlying the spatial clustering of lysosomal exocytosis events, we first
30 tested whether the t-SNAREs interacting with VAMP7 show clustering, as proposed previously (Xu et al.,
31 2012). Therefore, we analyzed the spatial patterns of STX3 and STX4 (S2A-C). Although STX3/4 presented
32 a significant clustering, it was much weaker than the one of exocytosis events, and did not recapitulate
33 several features of VAMP7 exocytosis such as low frequency close to cell borders and a short scale
34 clustering. Next, we focused on FAs, shown to be targeted by a subpopulation of lysosomes that were
35 characterized to be the MAPK scaffoled complex p14-MP1 (p14-MP1+) (Schiefermeier et al., 2014) as
36 well as by Golgi-derived RAB6+ vesicles (Fourriere et al., 2019). We quantified the co-appearance of
37 VAMP7-pHluorin with FAs using the FA protein paxillin (Paxillin-mCh) as a marker in co-transfected cells
38 (F2A-B). The co-appearance index was significantly higher than expected from CSR Monte-Carlo
39 simulations (F2B). Interestingly, VAMP7 lysosomal exocytosis only appeared at internal FAs, consistent

4

1 with the observation that exocytosis frequency is low close to cell borders (F2A). To further test the role
2 of FAs, we cultured cells on Poly-L-Lysine (PLL) substrates to inhibit the formation of FAs (S2D). Under
3 this condition, the clustering of lysosomal exocytosis decreased significantly (F2C), indicating a role of
4 FAs in the spatial organization of exocytosis. We noticed that exocytosis rate was significantly enhanced
5 on PLL substrate, probably due to a smaller adhesive surface under this condition (S2E).

6 FAs are closely linked to both microtubules (MT) (+) ends (Stehbens and Wittmann, 2012; Stehbens et
7 al., 2014; Seetharaman and Etienne-Manneville, 2019), and the cortical acto-myosin cytoskeleton
8 (Miklavc and Frick, 2020). Surprisingly, MT depolymerization by nocodazole treatment did not reduce
9 clustering (F2D) nor the exocytosis rate (F2E). Depolymerisation of F-actin by a low dose of cytochalasin
10 D significantly reduced the exocytosis rate (F2G), however did not reduce lysosomal clustering (F2F). This
11 suggested a role of actin in facilitating fusion of lysosomes with PM but not in the organization of
12 exocytosis patterning. Moreover, myosin-2 (MYH9) inhibition by para-nitro-blebbistatin treatment
13 affected neither exocytosis clustering nor exocytosis rate (F2H-I). Taken together, these results
14 demonstrate that FAs regulate lysosomal exocytosis patterns in a cytoskeleton-independent manner.
15 Moreover, they confirm a targeting of lysosomal secretion events to internal FAs and exclusion from
16 external ones.

17

18   3) **Exocytosis clustering depends on membrane tension**

19 We tested the role of physical parameters, such as membrane tension, known to regulate the exocytosis
20 rate (Gauthier et al., 2011; Wen et al., 2016; Kliesch et al., 2017; Shi et al., 2018; Wang and Galli, 2018;
21 Wang et al., 2018). We applied a hypo-osmotic shock and monitored VAMP7 exocytosis 15min after the
22 shock. Hypo-osmotic shock causes cell swelling leading to an increased membrane tension. VAMP7+
23 exocytosis has been reported to be less frequent after hyper-osmotic shock (Wang et al., 2018) and
24 hypo-osmotic shock decreased exocytosis rate in experimental and theoretical models (Zwiewka et al.,
25 2015; Mao et al., 2021). Surprisingly, the hypo-osmotic shock significantly reduced the exocytosis rate in
26 RPE1 cells (F3B). However, hypo-osmotic shock significantly increased the clustering of lysosomal
27 exocytosis (F3A). It also increased the co-appearance between exocytosis events and FAs (F3C). To
28 further confirm these results, we treated cells with methyl-β-cyclodextrin that depletes cholesterol from
29 the PM, and thus has been proposed to affect membrane tension (Hissa et al., 2017; Biswas et al., 2019;
30 Cox et al., 2021). Cyclodextrin treatment significantly increases clustering, similarly to hypo-osmotic
31 shock treatment (F3D). Moreover, cyclodextrin treatment also decreases exocytosis rate (F3E) and
32 increases the co-appearance between exocytosis events and FAs (F3F).

33 Next, we directly measured membrane tension using the Fluorescence Lifetime Imaging Microscopy
34 (FLIM) probe Flipper-TR (Colom et al., 2018). The Flipper-TR intercalates in membranes, where the
35 membrane microenvironment favors one of two possible molecular conformations of the Flipper-TR
36 (planar or orthogonal). The two conformations display different fluorescence lifetimes. Higher local
37 membrane tension leads to higher fluorescence lifetimes. We quantified fluorescence lifetime in living
38 cells using a TIRF-FLIM device under different experimental conditions. We observed that the membrane

1   tension at the ventral part of the cell is not homogeneous in cells seeded on fibronectin-coated surface.
2   Interestingly, we found that membrane tension presents variability compatible with the micrometer
3   scale of exocytosis clustering (F3G). Surprisingly, no major variation in the Flipper-TR fluorescence
4   lifetime was observed following a hypo-osmotic shock or treatment with cyclodextrin (S3A-B). Because
5   lysosomal clustering is regulated by FAs, we next quantified fluorescence lifetime in living cells seeded on
6   PLL-coated surface. Despite their difference in exocytosis clustering, the average lifetime was again
7   similar in these two conditions (F3H). Together, these results indicate that global membrane tension
8   does not regulate clustering of exocytosis. However, cells grown on fibronectin showed clustering of
9   similar lifetime values at several regions, whereas these values appeared more homogeneously
10   distributed in cells on PLL (F3G). Thus, we measured the spatial auto-correlation using the Moran's index,
11   which increases in case of clustering of pixels values. Moran's index was indeed significantly higher in
12   cells plated on fibronectin than on PLL (F3I). This suggests that the spatial organization of lysosomal
13   exocytosis is controlled by regional heterogeneity in membrane tension rather than the global tension at
14   the whole cell level. Moreover, our results indicate that the presence of FAs favors a
15   compartmentalization of membrane tension.

16

17   ### 4) Intracellular coupling between exocytosis probability and membrane tension

18   A simultaneous observation of the Flipper-TR signal and exocytosis events is technically very challenging.
19   Therefore, to correlate membrane tension and exocytosis events, we normalized RPE1 cell geometries
20   using adhesive ring-shaped micropatterns. An advantage of micropatterned cells is the possibility to
21   standardize the adhesive surface and FA distribution. On ring-shaped micropatterns (F4A), FAs are
22   formed at the inner and outer borders of the ring mimicking the inner and peripheral FAs found in non-
23   patterned cells (S4A-B). Using the Ripley's K function, we found that the clustering of lysosomal
24   exocytosis also occurs in patterned cells, although significantly weaker than in non-patterned cells (F4B).
25   Plotting the radial average density of exocytosis events demonstrated that cells exhibit an enrichment of
26   events at half of the cell radius as the density deviated there from the expected CSR case (F4C).
27   Moreover, exocytosis events are less frequent at cell borders similarly to non-patterned cells. Using the
28   same micropatterns, we then measured membrane tension by TIRF-FLIM. Interestingly, cells displayed a
29   radial gradient of membrane tension with lowest membrane tension values at the extreme cell border
30   and in the center, and a linear increase in membrane tension for the center to the periphery (F4D-E). The
31   Moran's index is lower in patterned cells than in non-patterned cells despite the presence of the
32   gradient (S4C). Taken together with the PLL experiments, this result points out a correlation between
33   clustering/compartmentalization of membrane tension and clustering of exocytosis. The cross-
34   correlation between the normalized lifetime and the exocytosis probability demonstrates that the
35   exocytosis probability increases with the membrane tension in a monotonous however non-linear
36   manner (F4F). Note that the exocytosis probability is defined as the probability of exocytosis at a given
37   place knowing that an event will occur. Therefore, it does not reflect the exocytosis rate but only its
38   spatial distribution. The above results together indicate that exocytosis is favored at regions with high
39   local membrane tension, and that these regions are spatially organized leading to clustering in these
40   regions.

1

5) Strength of membrane tension gradient regulates clustering of lysosomal exocytosis

To further investigate the role of membrane tension in the spatial regulation of exocytosis, we established exocytosis and membrane tension maps of cells cultured on ring-shaped micropatterns of different sizes (F5A). The average membrane tension was found to be similar on all pattern sizes (S5A). However, the membrane tension gradient varied according to the pattern size (F5B), except for cells plated on small patterns that did not display any gradient. Consistently, the Moran's index increased from small to large micro-patterns (S5B). Interestingly, the absence of a gradient in the smallest size micropatterns correlates with a lower level of clustering of exocytosis events, whereas the presence of a gradient in the largest cell size correlates with higher clustering (F5C). On the other hand, the exocytosis rate (normalized to cell surface) was not significantly different regardless of the pattern sizes (S5C). These results confirm a role of the membrane tension gradient in the regulation of spatial exocytosis patterns.

4 ## Discussion

5 Our data demonstrate that lysosomal exocytosis is not random (*i.e.* CSR) but clustered in space and time
6 with a positive coupling between spatial and temporal dimensions (Fig1). Lysosomal exocytosis occurs
7 close to internal FAs and it is almost absent at cell borders. In agreement with this result, cells seeded on
8 PLL, which inhibits the formation of FAs, display a decreased clustering of exocytic events (Fig2). Previous
9 work described a targeting of lysosomes to FAs but exocytosis at these points was not demonstrated
10 (Schiefermeier et al., 2014). Our data suggest that clustering does not rely on an intact cytoskeleton as
11 the spatial pattern of lysosomal exocytosis was not perturbed upon treatment with drugs affecting the
12 cytoskeleton (Fig2). The underlying mechanism supporting clustering of exocytotic events from
13 lysosomes at FA is likely different from the exocytosis of Golgi-derived vesicles. Indeed, clustering of
14 Golgi-derived vesicles was shown to be inhibited by both actin and microtubule depolymerization (Yuan
15 et al., 2015). However, interfering with the actin cytoskeleton inhibits VAMP7-mediated exocytosis rate
16 in neuronal cells (Gupton and Gertler, 2010). The involvement of the cytoskeleton in clustering of
17 lysosomal and Golgi-derived exocytosis will then require further investigation in different cell types.

18 We found that interfering with membrane tension by hypo-osmotic shock and methyl-β-cyclodextrin
19 treatments impact clustering of exocytosis, revealing for the first time a role of membrane tension in the
20 spatial organization of exocytosis (Fig3). Our results complement previous data illustrating the role of
21 membrane tension on the exocytosis rate (Wen et al., 2016; Kliesch et al., 2017; Shi et al., 2018; Wang
22 and Galli, 2018; Wang et al., 2018; Cohen and Shi, 2020).

23 A previous study reported that in addition to changing total membrane tension, methyl-β-cyclodextrin
24 treatment increases its heterogeneity (Biswas et al., 2019). In addition, transmembrane proteins such as
25 FAs have been proposed to behave as obstacles to the lipid flow that equilibrates membrane tension
26 (Cohen and Shi, 2020). Cells seeded on PLL reveal a more uniform membrane tension, confirming the
27 role of FAs as obstacles. Together, our data suggest that an inhomogeneity of membrane tension
28 induced by FAs leads to the accumulation of secretory events at these regions. This hypothesis is
29 supported by experiments performed on micropatterns, which show that the symmetric arrangement of
30 FAs leads to a well-defined gradient of membrane tension (Fig.4). Moreover, changing the micropattern
31 diameter increases the strength of membrane tension gradient and exocytosis clustering (Fig.5).
32 Interestingly, a gradient in membrane tension has been already observed in moving keratinocytes (Lieber
33 et al., 2015). Such a gradient could result from the friction between plasma membrane and either actin
34 treadmilling or the adhesion substrate (Schweitzer et al., 2014). In our experiments performed on non-
35 migratory cells constrained by adhesion on micropatterns, only actin retrograde flow could potentially
36 cause friction. Yet, experiments in non-patterned cells revealed that clustering is independent of the
37 actin cytoskeleton. Thus, the above result could indicates that the diffusion of lipids in the plasma
38 membrane is very slow, resulting in a stable gradient of membrane tension at the time scale of our

1   experiments, similarly to what was previously observed in non-neuronal cells (Shi et al., 2018). Finally,
2   the experiments on micropatterns revealed a positive coupling between exocytosis probability and
3   membrane tension (Fig. 4). Of note, the absence of gradient in membrane tension observed in cells
4   grown on small micropatterns does not totally abolish exocytosis clustering. This suggests that other
5   mechanisms regulate clustering, such as for instance clustering of syntaxins. In conclusion, we propose
6   that the spatial clustering of lysosomal exocytosis relies on the spatial organization of membrane
7   tension, which is regulated by the presence and localization of FAs.

Figures Legend

Figure 1. Lysosomal exocytosis is not random but clustered. A. Schematic representation of the exocytosis of a VAMP7-pHluorin+ vesicle: the low pH of the acidic lumen quenches the fluorescence of pHluorin. During exocytosis, protons are released and pHluorin starts to emit light. An exocytosis event is followed by the 2D diffusion of VAMP7-pHluorin at the plasma membrane. **B.** TIRFM image of VAMP7-pHluorin in a transfected RPE1 cell. The inset represents the field in the white square showing one exocytosis event at different time points, t=0 represents the beginning of the exocytosis event. A kymograph is plotted along the dashed white line and arrowheads indicate several observed exocytosis events. **C.** Exocytosis intensity map of the cell in B acquired during 5min. Black dots represent exocytosis events. The color code represents the estimation of the local intensity $\hat{\lambda}$ expressed in exocytosis/µm². **D.** Normalized exocytosis rate in RPE1 cells from n=183 cells (and 32.880 exocytosis events) from 34 independent experiments. ($3.9 \times 10^{-4} \pm 3.1 \times 10^{-4}$ exocytosis/s/µm²). **E.** Exocytosis rate before and after Golgicide A (10µM, 30min) treatment; n=14 cells from 3 independent experiments. **F.** Exocytosis rate before and after bafilomycin A1 (100nM, 60min) treatment; n=16 cells from 3 independent experiments. **G.** Exocytosis rate before and after histamine (100µM, no incubation) treatment; n=17 cells from 3 independent experiments. **In E-G**, significance has been evaluated with paired Wilcoxon test, ns p>0.05 and ***p<0.001. **H.** Relative Nearest Neighbor Distance (NND$_{observed}$/NND$_{simulated}$) of basal exocytosis observed in D. **I.** Relative distance to cell borders (distance$_{observed}$/distance$_{simulated}$) of basal exocytosis observed in D. **J.** Relative anisotropy index (anisotropy$_{observed}$/anistropy$_{simulated}$) of basal exocytosis observed in D. 90% of the cells have a relative anisotropy index superior to 1. **In H-J**, the red dotted line represents expected value under CSR hypothesis and the significance of the deviation to CSR has been computed using a t-test. ***p<0.001. **K.** Average centered Ripley's K function (K(r)-πr²) of 183 cells (and 32.880 exocytosis events) observed in D. Green curve represents the experimental results ± SEM and the red dotted line the expectation under CSR hypothesis. Red shade represents envelope containing 95% of CSR simulations.

Figure S1. A. Exocytosis kinetics monitored by the normalized average fluorescence intensity (± SEM) at exocytosis event localization. Intensity has been normalized to 1 at t=0 observed at the beginning of the exocytosis event. The kinetic has been fitted by a single exponential function ($I(t) = Ae^{-\frac{t}{t_{1/2}}} + B$) represented by the black dashed line. The half-life extracted from this fit is t$_{1/2}$ = 1.48s. **B.** Half-life t$_{1/2}$ measured by the same fitting but cell by cell. Average half-life is 1.69 ± 0.83s. **C.** Average cumulative exocytosis events after histamine addition: the y-axis represents the fraction of exocytosis events observed at a given time over the total number of exocytosis events recorded. Time is normalized between 0 and 1 and histamine (100µM) is added at 0.5 corresponding to the dashed black line. Green curve represents results before histamine and the blue one after histamine addition. Experimental curves are averages ± SEM; n=17 cells from 3 independent experiments. **D.** Anisotropy assay. VAMP7-pHluorin/mCh-RAB6A co-transfected cells are seeded on rectangular micropattern (visualized by fibrinogen Alexa647). Exocytosis axis was established by TIRFM and compared to the nucleus-Golgi axis. Histogram presents the percentage of cells with co-polarization and anti-polarization; n=42 cells from 4

1 independent experiments. Binomial test, *p<0.05. **E.** Average spatial Ripley's K function ± SEM before
2 (green) and after (blue) Golgicide A (10µM, 30min) addition; n=14 cells from 3 independent experiments.
3 **F.** Average spatial Ripley's K function ± SEM before (green) and after (blue) bafilomycin A1 (100nM,
4 60min) addition; n=16 cells from 3 independent experiments. **G.** Average spatial Ripley's K function ±
5 SEM before (green) and after (blue) histamine (100µM, no incubation) addition; n=17 cells from 3
6 independent experiments. **E-G**. The significance of the difference between Ripley's K functions has been
7 evaluated using a permutation test (see method) and red-dashed line represents expectation under CSR
8 hypothesis. **H.** Correlation between the exocytosis rate and the clustering measured as the area under
9 the Ripley's K function curve between 0µm and 8µm in control cells. Correlation has been evaluated
10 using Pearson correlation (r=0.29) and t-test (p=4.279x10^{-5}) for correlation. **I.** Average Ripley's K function
11 by keeping 25, 50, 75 and 100% of the events for each cell (artificial thinning). Curves represent averages
12 ± SEM and red-dashed line represents expectation under CSR hypothesis. **J.** Average centered temporal
13 Ripley's K function (K(t)-2t). Green curve represents the experimental average ± SEM and the red dashed
14 line the expectation under CSR hypothesis. Red shade represents envelope containing 95% of CSR
15 simulations. **K.** Fourier analysis of the temporal distribution of exocytosis events. Curve represents the
16 average modulus of FFT. **L.** Median spatio-temporal Ripley's K function (K(r,t)) subtracted by the product
17 of the spatial and the temporal Ripley's K function (K(r) and K(t)). An independency test has been made
18 cell by cell. Among significant cells, 82.7% present a positive spatiotemporal coupling (and 62.8% among
19 all cells). In **A-B** and **H-L**, 183 cells from 34 independent experiments were analyzed.

20

21 **Figure 2. Lysosomal exocytosis is coupled to internal focal-adhesions in a cytoskeleton-independent**
22 **manner. A.** Merge from TIRFM live cell imaging of a paxillin-mCh/VAMP7-pHluorin co-transfected RPE1
23 cell: the gray scale image represents snapshot of paxillin-mCh intensity and green dots represent
24 exocytosis events localization. **B.** Co-appearance index between exocytosis events and FAs. Red dashed
25 line represents expected co-appearance in the case of CSR. The significance of the deviation to CSR has
26 been computed using a t-test, ***p<0.001; n=49 cells from 4 independent experiments. **C.** Average
27 spatial Ripley's K function ± SEM for cells seeded on fibronectin (green curve) and PLL (blue curve); 36
28 cells on PLL and 183 cells on fibronectin were analyzed from 3 and 34 independent experiments,
29 respectively. **D.** Average spatial Ripley's K function ± SEM before (green) and after (blue) incubation with
30 nocodazole (10µM, 60min). **E.** Exocytosis rate before and after nocodazole treatment (10µM, 60min). **D-**
31 **E**: n=19 cells analyzed from 4 independent experiments. **F.** Average spatial Ripley's K function ± SEM
32 before (green) and after (blue) cytochalasin D treatment (500nM, 60min). **G.** Exocytosis rate before and
33 after incubation with cytochalasin D (500nM, 60min). **F-G**: 19 cells analyzed from 3 independent
34 experiments. **H.** Average spatial Ripley's K function ± SEM before (green) and after (blue) para-nitro-
35 blebbistatin treatment (20µM, 15min). **I.** Exocytosis rate before and after para-nitro-blebbistatin
36 treatment (20µM, 15min). **H-I**: n=13 cells from 3 independent experiments were analyzed. In **C, D, F** and
37 **H**, the significance of the difference between Ripley's K functions has been evaluated using a
38 permutation test (see methods) and red-dashed line represents expectation in the case of CSR. In **E, G**
39 and **I**, the significance has been evaluated using a paired Wilcoxon test, ns p>0.05, *p<0.05.

40

1 **Figure S2. A.** STX3/4 immunofluorescence of representative fixed cells seeded on ring-shaped
2 micropattern. **B.** Average Ripley's K function ± SEM of STX3 segmented spots from 28 cells. **C.** Average
3 Ripley's K function ± SEM of STX4 segmented spots from 30 cells. In **B** and **C,** red-dashed line represents
4 expected curve in the case of CSR, and the red shade represents the envelope containing 95% of CSR
5 simulations. **D.** Bright-field and TIRFM images of paxillin-mCh transfected cells seeded on fibronectin or
6 PLL substrate. The cell counters of transfected cells are marked by white dashed lines. **F.** Exocytosis rate
7 for cells seeded on fibronectin or PLL substrate. 36 cells on PLL and 183 cells on fibronectin were
8 analyzed from 3 and 34 independent experiments, respectively. The significance has been evaluated
9 using a t- test, ***p<0.001.

10

11 **Figure 3. Membrane tension regulates lysosomal exocytosis clustering. A.** Average spatial Ripley's K
12 function ± SEM before (green) and after (yellow) hypo-osmotic shock (1:1 dilution, 15min). **B.** Exocytosis
13 rate before and after hypo-osmotic shock. In **A** and **B**, 22 cells from 4 independent experiments were
14 analyzed. **C.** Co-appearance index between exocytosis spots and FAs before and after hypo-osmotic
15 shock. 15 cells analyzed in 3 independent experiments. **D.** Average spatial Ripley's K function ± SEM
16 before (green) and after (dark-red) β-methyl-cyclodextrin addition (5mM, 15min). **E.** Exocytosis rate
17 before and after β-methyl-cyclodextrin addition. In **D** and **E**, 20 cells from 3 independent experiments
18 were analyzed. **F.** Co-appearance index between exocytosis spots and FAs before and after β-methyl-
19 cyclodextrin; 19 cells from 3 independent experiments were analyzed. In **A** and **D**, the significance of the
20 difference between Ripley's K functions has been evaluated using a permutation test (see method) and
21 red-dashed line represents expected curve in the case of CSR. In **B, C, E** and **F**, significance has been
22 evaluated using paired Wilcoxon test, **p<0.01 and **p<0.001. **G.** TIRF-FLIM images of each 4
23 representative cells seeded on either fibronectin or PLL substrate, and incubated with Flipper-TR. The
24 color code represents the Flipper-TR fluorescence lifetime. **H.** Average fluorescence lifetime per cell
25 seeded on fibronectin and PLL substrate. **I.** Moran's I index per cell seeded on fibronectin and PLL
26 substrate. In **H** and **I**, significance has been evaluated using t-test, ns p>0.05 and **p<0.01, 75 cells have
27 been analyzed on fibronectin-coated surface, and 80 cells in PLL-coated, from 3 independent
28 experiments.

29

30 **Figure S3. A.** TIRF-FLIM images of 4 representative cells in each condition: control, hypo-osmotic shock
31 (1:1 dilution, 15min) and β-methyl-cyclodextrin (5mM, 15min), all incubated with Flipper-TR. The color
32 code represents the Flipper-TR fluorescence lifetime. **B.** Average fluorescence lifetime per cell in 3
33 conditions: control, hypo-osmotic shock and β-methyl-cyclodextrin. The significance has been evaluated
34 using Kruskal-Wallis test and a *post-hoc* Dunn's test, *p<0.05, 67 cells were analyzed in control condition,
35 43 in hypo-osmotic shock condition, and 41 cells in β-methyl-cyclodextrin, from 5, 3 and 3 independent
36 experiments, respectively.

37

13

1   **Figure 4. Coupling between membrane tension gradients and exocytosis probability. A.** Representative
2   epifluorescence image of a 37µm diameter ring-shaped micropattern stained with fibrinogene-Alexa647
3   and a TIRFM image of VAMP7-pHluorin transfected cell cultured on it accompanied by the average
4   exocytosis map from 42 cells. The color code represents the probability to observe exocytosis knowing
5   that one event occurred. **B.** Average spatial Ripley's K function ± SEM of exocytosis in cells seeded on
6   ring-shaped micropattern (blue) and non-patterned cells (green, same data as in F1K). The significance of
7   the difference between Ripley's K functions has been evaluated using a permutation test (see method).
8   **C.** Average radial-density ± SEM of exocytosis in cells seeded on ring-shaped micropattern. The modulus
9   (distance to pattern center) is normalized to the cell radius, setting cell border at R=1. The gray rectangle
10 represents the average position of the adhesive part of the micropattern ± SEM. The inset represents the
11 same data but as a cumulative density function instead of probability density. **A-C**: 42 cells were
12 analyzed from 9 independent experiments. In **B-C**, the red-dashed line represents expected curve in the
13 case of CSR and red shade represents envelope containing 95% of CSR simulations. **D.** TIRF-FLIM image of
14 a representative cell seeded on a ring-shaped micropattern and incubated with Flipper-TR, and average
15 fluorescence lifetime map from TIRF-FLIM images of 15 cells. The color code represents Flipper-TR
16 fluorescence lifetime. **E.** Radial average ± SEM of the Flipper-TR fluorescence lifetime. Fluorescence
17 lifetime is presented under a Z-score form (see methods) and the modulus is normalized to the cell
18 radius setting cell border at R=1. In **D** and **E**, 15 cells analyzed in 1 independent experiment. **F.** Coupling
19 between exocytosis probability and membrane tension using data from **C** and **E**. The estimation of
20 exocytosis probability at a given modulus R is based on the number of events normalized by the
21 corresponding surface, contrarily to **C**. The color code corresponds to the normalized modulus R. Each
22 point is associated to SEM for both axes.

23

24 **Figure S4. A.** Representative epifluorescence image of a 37µm diameter ring-shaped micropattern
25 stained with fibrinogene-Alexa488 and a TIRFM image of paxillin-mCh transfected cells. Arrowheads
26 show internal FAs. On the right, average paxillin signal (from 19 cells) after denoising. **B.** Average paxillin
27 radial intensity ± SEM. The modulus is normalized to the cell radius setting cell border at R=1. The
28 intensity is normalized to obtain a total equal to 1, 19 cells were analyzed. **C.** Moran's index for cells
29 seeded on micropattern or non-patterned fibronectin coated classical culture, 15 cells from one
30 independent experiment and 42 cells from 9 independent experiments were analyzed, respectively. The
31 significance has been evaluated using unpaired Wilcoxon test, *p<0.05.

32

33 **Figure 5. Strength of membrane tension gradient regulates clustering of lysosomal exocytosis. A.**
34 Representative images of cells seeded on ring-shaped micropattern of different diameters (classified as
35 small ~ 25µm, medium ~ 35µm and large ~ 45µm) and incubated with Flipper-TR visualized by TIRF-FLIM
36 (upper panel). The color code represents the Flipper-TR fluorescence lifetime. Average fluorescence
37 lifetime maps for cells seeded on different diameters (middle panel), maps are an average of FLIM
38 images from n=16 (small), n=29 (medium) and n=15 (large) cells from 4 independent experiments. Color
39 code represents Flipper-TR fluorescence lifetime. Average exocytosis maps (lower panel) from n=15

1 (small), n=51 (medium) and n=24 (large) cells from 11 independent experiments. The color code
2 represents the probability of exocytosis. **B.** Radial averages ± SEM of the Flipper-TR fluorescence lifetime
3 (data from **A**). Lifetime is presented under a Z-score form (see methods) and the modulus is normalized
4 by the cell radius setting cell border at R=1 for the 3 conditions. **C.** Average spatial Ripley's K functions ±
5 SEM of exocytosis in cells seeded on ring-shaped micropatterns with different diameters, small in dark
6 red, medium in orange and large in yellow (data from **A**). The significance of the differences between
7 Ripley's K functions has been evaluated using a permutation test (see methods) and p-values were
8 corrected using Benjamini-Hochberg procedure. The red-dashed line represents expected curve under
9 CSR hypothesis.

10

11 **Figure S5. A.** Average Flipper-TR fluorescence lifetimes per cell seeded on ring-shaped micropatterns
12 with different diameters: small, medium and large. Significance has been evaluated using Kruskal-Wallis
13 test, ns p>0.05. **B.** Correlation between the Moran's index per cell and the cell radius (cell seeded on
14 ring-shaped micropatterns). Correlation has been evaluated using Pearson correlation (r=0.27) and t-test
15 (p=0.0217) for correlation. In **A** and **B**, 60 cells from 5 independent experiments were analyzed. **C.**
16 Correlation between the exocytosis rate per cell and the cell radius (cell seeded on ring-shaped
17 micropatterns). Correlation has been evaluated using Pearson correlation (r=-0.08) and t-test (p=0.47)
18 for correlation. 90 cells were analyzed from 11 independent experiments.

19

20

21

22

23

24

25

1 Materials and Methods

2 **Cell culture:** hTERT-immortalized retinal pigment epithelial cell line (hTERT RPE-1) were cultivated in
3 DMEM/F12 media (Gibco, catalog # 21041-025) complemented with 10% Fetal Bovine Serum (Eurobio,
4 catalog # CVFSVF00-01) (without antibiotics). Cells were maintained at 37°C with 5% CO2 in a humidified
5 incubator.

6 **Transfection:** Cells were transfected with the following constructs: VAMP7-pHluorin (Chaineau et al.,
7 2008), mCh-Rab6A and Paxillin-mCh (Fourriere et al., 2019). Cells are transfected with 800ng of DNA (or
8 2x400ng for co-transfection) using the JetPrime kit (Polyplus). Cells were imaged 24h after transfection.

9 **Drug treatments:** Cells were treated with the following drugs with the given concentration and
10 incubation time: Golgicide A 10µM 30min (Merck, catalog # G0923), Bafilomycin A1 100nM 1h
11 (MedChemExpress, catalog # HY-100558), Histamine 100µM no incubation (Merck, catalog # H7125),
12 Nocodazole 10µM 1h (Merck, catalog # M1404), Cytochalasin D 500nM 1h (Merck, catalog # C8273),
13 Para-nitroblebbistatin 20µM 15min (Cayman Chemical Company, item 24171), β-methyl-cyclodextrin
14 5mM 15min (Merck, catalog # C4555). Hypo-osmotic shocks were made by adding water in the media
15 with a volume ratio of 1:1 and cells were imaged 15min after. For all drug conditions, a paired design has
16 been used: the same cell is imaged before and after the treatment.

17 **Micropatterning:** We followed the photolithography micropatterning protocol from Azioune *et al.*
18 (Azioune et al., 2010). Briefly, coverslips (1.5H ThorLabs, Catalog # CG15XH1) were oxidized by plasma-
19 cleaner (Harrick Plasma) during 5min. Coverslips were PEG-coated by incubating them on a drop of PLL-
20 g-PEG (Surface Solutions, PLL(20)-g[3.5]- PEG(2)) (0.1mg/ml diluted in water, 10mM HEPES, pH=7.4) in a
21 moiety chamber during 1h. After coating, patterns were printed using a deep UV lamp (Jelight Company
22 Inc, catalog # 342-220) with radiation passing through a photomask (DeltaMask) during 5min. Finally,
23 patterns were fibronectin-coated by incubating coverslips on a drop of fibronectin (Merck/Sigma, catalog
24 # F1141) (50µg/ml diluted in water) and fibrinogen-Alexa647 (Molecular Probes, Invitrogen, catalog #
25 F35200) (or fibrinogen-Alexa488) (5µg/ml) in a moiety chamber during 1h. Coverslips were conserved at
26 4°C in PBS.

27 Cell seeding on micropatterns was described in Lachuer *et al.* (Lachuer et al., 2020). Briefly, coverslips
28 were maintained in magnetic chamlides for live imaging or kept in a P6 wells for fixation. ~200 000
29 trypsinized (Thermo Ficher, catalog # 12605010) cells were added in the chamlide chamber. After 10min
30 incubation in 37°C incubator, cells were attached to the substrate. Cells were washing using DMEM/F12
31 media with 20mM HEPES (Gibco, catalog # 15630-056) (+ 2% penicillin/streptomycin (Gibco, catalog #
32 15140-122) if cells were used for lived-imaging). Cells were incubated at least 3h in the incubator until
33 full spreading on the micropattern. Cells were imaged the same day.

34 Different geometries of micropatterns were used. In figure 4 and S2, ring-shaped micropatterns with a
35 diameter of 37µm were employed. In figure 5, 3 sizes of ring-shaped micropatterns were used, with
36 diameters of 25µm, 35µm and 45µm. For all sizes, the thickness of the adhesive ring was 7µm. Figure 5
37 also includes data of figure 4. Despite these theoretical sizes, a variation in the measured cell diameter
38 was observed likely due to UV diffraction during the printing. The actual dimensions were systematically

1   measured. During analysis, cells with diameter inferior to 20µm were categorized as "Small", between
2   20µm and 38µm as "medium" and superior to 38µm as "large". In figure S1, rectangular micropattern
3   has dimensions of 9x40µm.

4   **Microscopy:**

5   *TIRFM:* Non-patterned cells were seeded in fluorodishes (World Precision Instrument) coated with
6   fibronectin (or PLL (Merck P4707)). DMEM/F12 media + 20mM HEPES was used for imaging. Patterned
7   cells were prepared as described. Acquisition was made using an inverted Nikon TIRFM equipped with an
8   EMCCD camera (efficiency 95%) with a 100x objective (pixel size = 0.160µm). The following lasers were
9   used 491nm, 561nm and 642nm. Time-lapse of VAMP7-pHluorin was acquired with a frame rate of 1
10   image every 300ms during 5min. Frame rate was set according to the half-life of exocytosis events. Due
11   to microscopic device delay, the actual frame rate was computed using the computer time of saved files.

12   *TIRF-FLIM:* Images were acquired on a homemade setup based on a x100 1.49 Nikon Objective (Blandin
13   et al., 2009; Marquer et al., 2011). A 2MHz supercontinuum laser source (SC450 HE-PP Fianium) was
14   filtered (Excitation filter 482-18, Dichroic Di01-R488, Emission filter Long Pass 488, Semrock) within the
15   microscope cube to match the dye excitation/emission spectra. The average power in the back focal
16   place of the objective was between 30 and 100 µW depending on the experiment. The TIRF angle was
17   finely controlled thanks to a motorized stage which allows one to adjust the pulsed beam focalization in
18   the back focal plane of the TIRFM objective. Fluorescence images were detected thanks to a time-
19   resolved detection based on the use of a high-rate imager (Kentech Ltd., UK) optically relayed to a
20   charge-coupled device camera (ORCA AG, Hamamatsu, binning 2x2). This intensifier was synchronized
21   with the laser pulse through a programmable delay line (Kentech, precision programmable 50 Ω delay
22   line), which enables us to open temporal gates with 1 ns width at different times after the pulse, thus
23   sampling the fluorescence decay. Each time gated image corresponds to an average of 10 images (10 x
24   250 ms). FLIM maps were thus produced by recording a series of 17 time-gated fluorescence intensity
25   images and fitting the data for each image pixel to a single exponential decay model by use of a standard
26   nonlinear least-squares fitting algorithm.

27   *Flipper-TR*: Cells were prepared as for classical TIRFM. 15min before acquisition, Flipper-TR was added in
28   the media (Spirochrome, Catalog # SC020) (Colom et al., 2018) at a concentration of 1µM. If used, drugs
29   were added with Flipper-TR. Cells were not washed as recommended. Due to the high variability of the
30   fluorescence lifetime, a z-score transformation was applied when specified. For each cell, the average µ
31   and standard-deviation σ of the fluorescence lifetime was computed. Then, each lifetime pixel x_i value
32   was reduced and centered:

$$z_i = \frac{x_i - \mu}{\sigma}$$

33   **Immunofluorescence:** Cells were fixed with 4% PFA (Euromedex, catalog # 15710) during 15min and
34   quenched with a 50mM NH4Cl solution. After PBS washing, cells were permeabilized (and blocked) with
35   a PBS Saponin (MP Biomedicals, catalog # 102855) (0.5g/l) BSA (Merck, catalog # 10735094001) (1g/l).
36   Coverslips were incubated during 1h in a moiety chamber at RT with primary antibodies diluted in a PBS

1   2% BSA solution. After PBS washing, coverslips were incubated with a secondary antibody (400x)
2   conjugated with a fluorophore following the same protocol. Finally, coverslips were mounted with
3   Mowiol (Biovaley, catalog # MWL4-88-25) and DAPI (Merck, catalog # D8417). The following primary
4   antibodies were used: Syntaxin 3 (100x) (Merck/Sigma, catalog # S5547), Syntaxin 4 (1000x) (BD
5   Transduction Laboratories, Material # 610439). The following secondary antibodies were used: Mouse
6   A488 (Interchim 715-545-151) and Rabbit A488 (Interchim, 711-545-152).

7   Sample were imaged using an inverted videomicroscope with deconvolution (Delta Vision – Applied
8   Precision) equipped with Xenon lamp. Acquisition was made at 100x (pixel size = 65nm). Images acquired
9   were deconvolved using softworx (enhanced ratio method).

10   **Statistical analysis:** All statistical analysis were made with R (R Core Team (2021)) with the help of the
11   following packages: spatsat (Baddeley et al., 2015), raster, viridis, ggplot2, dunn.test, ape (Paradis and
12   Schliep, 2019), imager, pracma, circular, ggpur, evmix (Hu and Scarrott, 2018), splancs, OpenImageR,
13   minpack.lm.

14   *Hypothesis testing*: The number of cells and the number of independent repetition is indicated in the
15   legend. Since our cells are mostly isolated when imaged, we performed only single cells analysis, each
16   cell is considered as independent, setting the sample size. The statistical test used is indicated in the
17   legend. Tests are always conducted in a two-sided manner and a multiple comparison correction is
18   applied when needed. We mainly used non-parametric test (Wilcoxon test, Kruskal-Wallis test), and a
19   parametric test (Student t-test) only when the sample size was high (n>30). Paired tests were used for all
20   experiments where the same cell is imaged before and after treatment. Finally, correlation was
21   measured by Pearson correlation coefficient and tested with a t-test.

22   *Intensity map:* The intensity function λ is defined by:

$$E[x \in S] = \int_S \lambda(u)du$$

23   With x a pattern of points, u coordinates, S a region of the observation window, and E[x∈n] the expected
24   number of points in S. The intensity map was computed using spatstat function density() with Jones-
25   Diggle improved edge correction. The intensity map can be interpreted and normalized as a density map
26   by dividing it by the total number of points.

27   *Monte-Carlo CSR simulations*: Monte-Carlo simulations were used for 3 purposes: i) normalization and ii)
28   generation of CSR 95% envelopes.

29   i) Several measures used depend on the cell geometry and the number of exocytosis events. Therefore,
30   we normalized observed values by CSR simulated values. For each cell, a high number (n=100) of Monte-
31   Carlo simulations was run to generate CSR exocytosis maps associated with the same number of
32   exocytosis events and the same cell geometry. The ratio between observed and average simulated
33   values allows classifying cells in two categories: more extreme or less extreme than CSR compared to the
34   observed measure.

1   ii) Monte-Carlo simulations were used to generate CSR envelopes. Some measures (mainly Ripley's K
2   function) were averaged over a population of cells; therefore CSR simulations were run in the same way:
3   Monte-Carlo CSR simulations were run for the full population of cells and the evaluated quantity is
4   averaged over the different simulated cells. This procedure was repeated a high number of times
5   (n=100). The CSR envelope contains 95% of these simulations.

6   *Nearest Neighbor Distance:* The Nearest Neighbor Distance (NND) of a given exocytosis event is the
7   distance to the closest exocytosis event. These distances give information on the short scale spatial
8   structure. NND was used to test CSR hypothesis according to the procedure presented in Lachuer *et al.*
9   (Lachuer et al., 2020) and detailed in the Monte-Carlo section. Simulated average NND are compared to
10 the observed NND. This allowed to classify the cell as clustered ($NND_{observed} < NND_{simulated}$), or dispersed
11 ($NND_{observed} > NND_{simulated}$). Note that temporal NND were treated similarly to spatial NND, just by reducing
12 the dimension of the analysis.

13 *Ripley's K function:* For a point pattern X={x_1, x_2, …, x_n} where each x is point coordinates observed in an
14 area |**S**|, the Ripley's K function (Ripley, 1976; Dixon, 2014) is defined as:

$$K(r) = \frac{|\Omega|}{n(n-1)} \sum_{i=1}^{n} \sum_{j \neq i} 1_{|x_i - x_j| \leq r}$$

15 This function quantifies the average number of points in a disk of radius r centered on one point. In case
16 of CSR, this function should be close to πr^2. Therefore we always substrate πr^2 to K(r), a positive value
17 indicates clustering whereas a negative value indicates dispersing. The spatial Ripley's K function was
18 computed using spatstat function Kest() with the best edge correction possible. Ripley's K function was
19 computed between 0 and a quarter of the cell size to avoid edge effects. All Ripley's K functions plotted
20 are an average of a population of Ripley's K functions (+/- SEM). A permutation test (with 999
21 permutations) based on a Studentized distance is used to compare populations thanks to the sptatstat
22 function studpermu.test() (Hahn, 2012). Finally, a CSR 95% envelope was computed with Monte-Carlo
23 simulations (see corresponding section).

24 Temporal Ripley's K function K(t) is the reduction of the 2D spatial Ripley's K function in 1D. Therefore
25 the expected value under CSR hypothesis is 2t. K(t) was computed by our own function using the Ripley's
26 edge correction following (Yunta et al., 2014). Temporal Ripley's K function was treated in the same way
27 as the spatial one to generate the CSR 95% envelope and for the averaging.

28 Spatio-temporal Ripley's K function K(r,t) is the 3D extension of the spatial Ripley's K function that
29 evaluates the number of neighbors in a cylinder of a radius r and a half height t (Diggle et al., 1995). K(r,t)
30 was computed using the splancs function stkhat(). The median K(r,t) was computed (averaging is avoided
31 due to the generation of aberrant values by splancs). In absence of spatio-temporal coupling (*i.e.*
32 independency of the temporal and spatial point coordinates):

$$D = K(r,t) - K(r)K(t) = 0$$

1 Thereby the independency can be evaluated by the D statistics. It can be statistically tested using a
2 permutation test (1000 permutations) using the splancs function stmctest().

3 *Distance to cell border*: Distance to cell border was computed using imager function
4 distance_transform(). For each cell, the distance to cell border at exocytosis sites was measured. The
5 distribution was computed using Kernel Density Estimation (KDE). The distribution depicted is a
6 distribution averaged over multiples cells +/-SEM. The 95% CSR envelope was computed by Monte-Carlo
7 simulations (see corresponding section). The solid blue line represents the average of the simulated
8 densities.

9 The significance at the single cell level was accessed using Monte-Carlo simulations (see corresponding
10 section). Observed cell border distances were divided by the average simulated cell border distances
11 allowing a classification of the cells into two categories: borders-avoiding (ratio<1) or borders-linking
12 (ratio>1).

13 *Anisotropy:* The cell was cut in 30 angular sections (from the center of mass). An angle θ_i was associated
14 to each section. The number of exocytosis event was computed in each section and divided by the
15 surface of the corresponding section giving a coefficient w_i (normalized by the sum of the coefficients).
16 The anisotropy/polarization measurement is based on the average resultant length computed as:

$$R = \frac{1}{n}\sqrt{\left(\sum_{i=1}^{30} w_i cos(\theta_i)\right)^2 + \left(\sum_{i=1}^{30} w_i sin(\theta_i)\right)^2}$$

17 This polarization index ranged between 0 and 1. The significance was accessed using Monte-Carlo
18 simulations (see corresponding section). Observed average resultant lengths were divided by the
19 average simulated resultant length allowing a classification of the cells into two categories: polarized
20 (ratio>1) or non-polarized (ratio<1).

21 *Exocytosis-FA co-appearing index:* The average paxillin fluorescence intensity was measured at the
22 locations of exocytosis event. The significance was accessed using Monte-Carlo simulations (see
23 corresponding section). The comparison of the observed average intensity with simulated ones allows
24 classifying cells with a colocalization index (I_{obs}/I_{sim}) under two categories: co-appearing (I_{obs}/I_{sim}>1), no-
25 co-appearing (I_{obs}/I_{sim}<1).

26 *Modulus distribution:* On micropatterns, exocytosis events were described with polar coordinates (with
27 the origin at the center of the pattern). The modulus is the distance between an event and the center
28 (normalized by the cell radius). For each cell a modulus distribution was computed using Kernel Density
29 Estimation (KDE). To avoid boundary effects, an asymmetric beta kernel was used (Chen, 1999) using the
30 evmix function dbckden(). The depicted modulus distribution is an average over the population +/- SEM.
31 This distribution can be compared to the expected distribution in case of CSR:

$$p_{CSR}(r) = 2r$$

1   The 95% CSR envelope was computed using Monte-Carlo simulations (see corresponding section).
2   Despite beta edge correction, the simulations do not fit perfectly p_{csr}. In order to avoid any bias due to
3   kernels, we also conducted the same analysis using empirical cumulative distributions. The empirical
4   cumulative distribution P_{CSR} under CSR hypothesis is:

$$P_{CSR}(r) = \int_0^1 p_{CSR}(x)\,dx = r^2$$

5   *Fourier analysis:* Fourier analysis was conducted using Fast Fourier Transform function fft(). The
6   spectrum of modulus was computed for each cell between 0 and Nyquist frequency. Modulus spectrum
7   were averaged over the cell population.

8   *Moran'I:* Moran's I evaluates the spatial auto-correlation (Moran, 1950). We used it to evaluate the
9   spatial structure of lifetime measurement. For an image of N pixels, the Moran's I is defined as:

$$I = \frac{N}{\sum_{i=1}^N \sum_{j=1}^N w_{i,j}} \frac{\sum_{i=1}^N \sum_{j=1}^N w_{i,j}(x_i - \bar{x})(x_j - \bar{x})}{\sum_{i=1}^N (x_i - \bar{x})^2}$$

10 With x_i the ith pixel value, $\bar{x}$ the average pixel values, and w_{ij} the inverse of the Euclidian distance
11 between pixel i and j. This index is superior to -1/(N-1) in case of pixel clustering and inferior to in case of
12 regular spacing (*i.e.* pixels with similar values are regularly separated). A decreased of the Moran's I
13 should be perceived as a spatial decorrelation *i.e.* pixels are less clustered. Moran's I index was
14 computed using ape function Moran.I() using a random subsample of pixels (Monte-Carlo random
15 sampling scheme) to keep a decent computation time.

16 **Image analysis:**

17 *Exocytosis detection*: Exocytosis events were detected manually (because automatization failed to reach
18 our exigency level). However some events were probably missed (false negative). This is not a problem,
19 because Ripley's K function is invariant under random thinning (Baddeley et al., 2015). It is also likely that
20 some events did not correspond to exocytosis (false positive). Due to the superposition principle
21 (Baddeley et al., 2015), the experimental Ripley's K function is the sum of the exocytosis Ripley's K
22 function and the one of false annotation. Therefore, under the assumption that these false annotations
23 are random, possible false annotations could only slightly underestimates clustering.

24 *Half-life*: Fluorescence intensity was measured at exocytosis event localizations in a window of 1.12μm
25 centered on the event through time. The intensity was divided by the intensity at the beginning of the
26 event normalizing the exocytosis peak at 1. The intensity profile of all events in a cell was averaged. The
27 intensity was fitted on this averaged profile over 20 frames (~8s) with a single exponential function:

$$I(t) = Ae^{-t/t_{1/2}} + B$$

28 With $t_{1/2}$ the half-life. The fitting was performed with the minpack.lm function nlsLM(). The profile
29 depicted is the average over multiple cells. The half-life obtained from this average curve is close to the
30 lifetime averaged over multiple cells.

1 *Segmentation*: Cell segmentation to obtain mask or segmentation of syntaxin patches was perforled
2 using manual thresholding with ImageJ software.
