19

20 Abstract

21 Domestication is an excellent model for studying adaptation processes, involving 22 recent adaptation and diversification, convergence following adaptation to similar 23 conditions, as well as degeneration of unused functions. Geotrichum candidum is a 24 fungus used for cheese-making and is also found in other environments such as soil 25 and plants. By analyzing whole-genome data from 98 strains, we found that all 26 strains isolated from cheese formed a monophyletic clade. Within the cheese clade, 27 we identified three differentiated populations and we detected footprints of 28 recombination and admixture. The genetic diversity in the cheese clade was high, 29 indicating a lack of strong bottleneck. Commercial starter strains were scattered 30 across the cheese clade, thus not constituting a single clonal lineage. The cheese 31 populations were phenotypically differentiated from other populations, with a slower 32 growth on all media, even cheese, a prominent production of attractive cheese 33 flavors and a lower proteolytic activity. Furthermore, one of the cheese populations 34 displayed footprints of a more advanced state of domestication, with much lower 35 genetic diversity, denser and fluffier colones and excluding more efficiently cheese

36 spoiler fungi. Cheese populations lost two beta lactamase-like genes, involved in 37 xenobiotic clearance, and displayed transposable element expansion, likely due to 38 relaxed selection. Our findings suggest the existence of genuine domestication in *G.* 39 *candidum*, which led to diversification into different varieties with contrasted 40 phenotypes. Some of the traits acquired by cheese strains indicate convergence with 41 other, distantly related fungi used for cheese maturation.

42

43 Introduction

44 Understanding how populations adapt to their environment is a key question in 45 evolutionary biology. Domestication, the change in the genetic and phenotypic make-46 up of populations under human artificial selection, is an excellent model for studying 47 adaptation processes, as it involves recent adaptation events under strong selection 48 on known traits and rapid diversification. Numerous studies have documented the 49 specific traits acquired in domesticated animals (dog, horse, pig, cow) (Diamond, 50 2002; Frantz et al., 2015; Petersen et al., 2013; Warmuth et al., 2011) and plants 51 (cabbage, corn, wheat) (Hufford et al., 2012; Mabry et al., 2021; Peng et al., 2011), 52 as well as their genetic differentiation from wild populations and their adaptive 53 genomic changes. For example, domesticated animals (dog, horse and cattle) have 54 been selected for coat color, size, rapidity and docility (Liu et al., 2022; Plassais et 55 al., 2022; Qanbari et al., 2014). In plants too, similar traits have been selected in 56 different lineages, such as bigger grains with more nutrients and lack of dormancy 57 (Cornille et al., 2014; Hufford et al., 2012; Peng et al., 2011; Purugganan, 2019). On 58 the other hand, functions essential in wild environments but unused in anthropic 59 environments have often degenerated due to relaxed selection, for example, 60 reductions in defense mechanisms in plants (Cornille et al., 2014; Hufford et al., 61 2012). Domestication also often leads to strong reduction in genetic diversity due to 62 bottlenecks in animals (e.g. dog) (Marsden et al., 2016) and annual plants (e.g. rice) 63 (Zhu et al., 2007).

Humans have domesticated several fungi for the fermentation of foods (e.g. beer,
bread, wine, dry-cured meat and cheese), to produce secondary metabolites used in
pharmaceutics (e.g. penicillin), or for their nutritional and gustatory values (e.g.
button and shiitake mushrooms) (Steensels et al., 2021). Fungi are excellent models

68 for studying evolution and adaptation in eukaryotes, given their many experimental 69 assets (Gladieux et al., 2014): fungi have relatively small genomes, many are easy 70 to culture in laboratory conditions, and spores can survive long periods in the 71 freezer. However, despite their economic and industrial importance, and their utility 72 as biological models for studying adaptive divergence, the fungi used by humans 73 have yet been little studied. An exception is the budding yeast Saccharomyces 74 cerevisiae used in the production of beer, wine and bread (Bai et al., 2022; Duan et 75 al., 2018; Fay and Benavides, 2005; Gallone et al., 2016; Lahue et al., 2020; Legras 76 et al., 2018; Libkind et al., 2011; Liti et al., 2009; Peter et al., 2018), and to a lesser 77 extent the filamentous fungus Aspergillus oryzae used to ferment soy and rice 78 products in Asia (Galagan et al., 2005; Gibbons et al., 2012; Machida et al., 2005) 79 and the *Penicillium* species used for cheese ripening, e.g. *P. camemberti* for soft 80 cheeses (Ropars et al., 2020), and P. roqueforti for blue cheeses (Cheeseman et al., 2014; Dumas et al., 2020; Ropars et al., 2015). Phenotypic traits beneficial for food 81 82 production have been acquired in fungal domesticated populations, being different 83 from wild populations. The domestication having led to P. camemberti occurred in 84 several steps, with the successive differentiation of several lineages displaying 85 decreasing diversity and increasing beneficial traits for cheese maturation, from the wild P. fuscoglaucum, to P. biforme and then the two clonal P. camemberti varieties, 86 87 caseifulvum and camemberti (Ropars et al., 2020b). Domesticated populations of 88 fermented food microorganisms can for example better assimilate the carbon 89 sources present in the anthropic environment, e.g. lactose for Penicillium cheese 90 fungi (Ropars et al., 2015) and maltose for S. cerevisiae sourdough strains (Bigey et 91 al., 2021). Furthermore, volatile organic compounds crucial for cheese flavor are 92 more appealing in cheese populations compared to wild populations in *P. roqueforti* 93 (Caron et al., 2021).

94 The genomic processes involved in adaptation to human-made environments in 95 domesticated fungi include gene family expansion for specific metabolism pathways, 96 gene gain, inter-specific hybridization, introgression and horizontal gene transfer 97 (Almeida et al., 2014; Barros Lopes et al., 2002; Borneman et al., 2016; Cheeseman 98 et al., 2014; Gallone et al., 2016; Libkind et al., 2011; Machida et al., 2005; Naumova 99 et al., 2005; Novo et al., 2009; Ropars et al., 2015). Domesticated fungi also have 100 lost parts of genes no longer useful in the food environment; for example a cheese 101 P. roqueforti population and P. camemberti var. caseifulvum are no longer able to produce some of their toxins due to deletions in the corresponding genes (Gillot et al., 2017; Ropars et al., 2020b). Such losses are likely due to relaxed selection in terms of competition ability in cheese, in which desired fungi are often inoculated in large quantities compared to possible competitors. Bottlenecks and degeneration have also been documented in domesticated fungi, with reduced fertility and genetic diversity in the cheese fungi *P. roqueforti* and *P. camemberti* (Dumas et al., 2020; Ropars et al., 2020b).

109 While several cheese-making fungi have been studied recently, it is important to add 110 study cases in additional lineages, as it allows addressing the question of whether 111 adaptation to a similar medium leads to convergent traits. In the case of cheese-112 making fungi, one can expect convergence for example for more or less rapid growth 113 on cheese, higher proteolysis and lipolysis abilities, higher competitive abilities and 114 greater production of positive volatile compounds (Ropars et al., 2020a, 2020b). 115 Geotrichum candidum (teleomorph Galactomyces candidus) is a dimorphic fungus 116 (i.e., able to grow as a yeast or a mycelial form), commonly used for cheese-making, 117 but also thriving in other environments such as soil, plants and fruits. Geotrichum 118 candidum is naturally present in raw milk and is also often added as a starter culture 119 for the production of semi-hard, mold-ripened, smeared soft cheeses, fresh goat and 120 ewe cheeses. Analyses based on genetic markers have revealed genetic 121 differentiation between cheese and wild strains (Alper et al., 2013; Jacques et al., 122 2017; Perkins et al., 2020; Tinsley et al., 2022). Phenotypic diversity within G. 123 candidum has been reported in terms of carbon and nitrogen assimilation, lipolysis 124 and proteolysis (Boutrou and Gueguen, 2005; Perkins et al., 2020). However, it has 125 not been tested whether G. candidum cheese populations have evolved specific 126 traits that could be beneficial for cheese-making.

127

128 By analyzing the genomes of 98 strains isolated from different kinds of cheeses and 129 other environments, we confirmed the genetic differentiation between cheese and wild strains. Within the cheese clade, we identified three differentiated cheese 130 131 populations, including one with all goat cheese strains, as well as footprints of 132 recombination and admixture. The genetic diversity in the cheese clade remained 133 high indicating a lack of strong bottlenecks. Commercial strains were scattered within 134 the cheese clade, some corresponding to hybrid strains. We found phenotypic 135 differentiation between cheese and wild populations, and between cheese

populations, in terms of growth, proteolysis and volatile compounds. We revealed the loss, in the cheese clade, of two tandem beta lactamase-like genes involved in xenobiotic clearance. Altogether our findings suggest the existence of genuine domestication in *G. candidum*, resulting in both the genetic and phenotypic differentiation of cheese strains from their wild counterparts, and their convergence with other domesticated cheese fungi. We also found diversification within the cheese clade, with three genetic clusters with contrasted traits and levels of diversity.

144 Results

145 Genetic differentiation between wild and cheese strains in 146 *Geotrichum candidum*

147 We collected and sequenced the genomes of 88 G. candidum strains with Illumina 148 technology and included in our analyses ten available genomes (Illumina and 149 PacBio) (Perkins et al., 2020). Our dataset included 61 strains isolated from different 150 kinds of cheeses (semi-hard, mold-ripened, smeared soft and fresh goat cheeses), 151 16 industrial strains used for cheese-making, seven strains from dairy products, four 152 strains from other food substrates (e.g., sausage or vegetables) and all the 10 wild strains available in public collections worldwide (isolated for exemple from soil or 153 154 plant) (Table S1). We identified 699,755 SNPs across the 98 strains by mapping against the CLIB 918 reference genome (cheese strain, NCBI accession: 155 156 PRJEB5752).

The maximum likelihood tree, principal component analysis (PCA) and neighbor-net 157 158 (SplitsTree) analyses all identified the same three clades (Figure 1A), with one 159 containing mostly wild strains (corresponding to the GeoC group identified previously based on genetic markers) (Perkins et al., 2020), one composed of strains of varying 160 161 origins (i.e. dairy products and other environments, corresponding to the group 162 previously named GeoB) and one containing mostly cheese and dairy strains (previously named GeoA). The larger sampling and the genome sequencing of the 163 164 present study further revealed genetic subdivision in the cheese clade, with three 165 clearly differentiated populations and several admixed strains (Figure 1B).

We performed an admixture analysis by inferring *K* populations, *K* ranging from two to ten. At *K*=3, the cheese, mixed-origin and wild clades were separated (Figure S1). At *K*=5, the cheese clade was divided into three genetic clusters, corresponding to monophyletic groups in the maximum likelihood tree and well-separated genetic clusters in the PCA and the neighbor-net (Figure 1 B, D). At higher K, new populations inferred were either too small (two individuals) or not monophyletic.

172 Some cheese strains could not be assigned to any genetic cluster with the admixture analysis and were placed on the PCA between the three well-delimited cheese 173 174 genetic clusters (Figure 1C-D), suggesting that they resulted from admixture events. 175 To test this hypothesis, we investigated whether these strains had mosaic genomes, 176 with different genomic regions assigned to distinct clusters. We calculated pairwise identity between unassigned strains and the other strains, computing mean identity 177 178 to the different genetic clusters along scaffolds using sliding windows. For all 179 unassigned strains in the cheese clade, we observed shifts in identity values along 180 scaffolds, confirming that these strains are the results of admixture between clusters 181 (Figure S2). In contrast, the three unassigned strains outside of the cheese clade did 182 not show changes in similarity level to the different clusters along their genome; 183 these strains may belong to yet additional genetic clusters that could not be distinguished by the analyses because too few strains belonged to these clusters in 184 185 the sampling (Figure 1B).

186 We found no particular cheese type distribution among the three cheese populations, 187 except that all strains from goat cheeses clustered in the Cheese 1 population. The 188 wild clade was the most differentiated population from all other G. candidum 189 populations with F_{ST} values above 0.70 (Table S2). Its differentiation level was 190 similar to that found between the domesticated P. camemberti mold and its wild 191 closest relative species, *P. fuscoglaucum* ($F_{ST} = 0.83$; $d_{xy} = 6E-03$), and much higher 192 than the differentiation between the cheese Roquefort population and the lumber/food spoiler population in *P. roqueforti* ($F_{ST} = 0.27$). The percentage of private 193 194 SNPs in the five populations was also high (Table S3). F3 tests based on the 195 number of shared sites (Table S4) supported the differentiation between these 196 populations.

High nucleotide diversity within cheese populations andfootprints of recombination

199 The overall diversity in the cheese clade (π =2.82E-3) was higher than in the wild 200 population (π =2.12E-03). Each of the three cheese populations of G. candidum had 201 however reduced nucleotide diversities compared to wild and mixed-origin 202 populations (Table S5), by at least a factor of two. The Cheese 2 population showed 203 the lowest genetic diversity (π =4.82E-04), by a factor of four compared to the two 204 other cheese populations (Table S5), being of the same order of magnitude as in the 205 Roquefort P. roqueforti population (Dumas et al., 2020). The Cheese 1 population 206 had a nucleotide diversity (π =1.26E-03) similar to that in the domesticated cheese 207 species *P. biforme* (π =1.09E-03), whereas the Cheese 3 population (π =1.92E-03) was genetically as diverse as *P. fuscoglaucum* (π =1.93E-03), the closest wild 208 209 relative of the clonal lineage P. camemberti (Ropars et al., 2020b).

210 Geotrichum candidum is a heterothallic fungus, meaning that sexual reproduction 211 can only occur between two haploid cells carrying different mating types. Two mating 212 types have been described in G. candidum (Morel et al., 2015): MATA, encoded by a 213 HMG box gene homolog to the MATA2 Kluyveromyces lactis allele, present in CLIB 214 918 (sequence id: HF558448.1), and MATB, encoded by an alphabox gene homolog 215 to the MATa1 S. cerevisiae allele, present in the strain CBS 615.84 (sequence id: 216 HF558449.1). In the Cheese 2 population, we found a significant departure from the 217 1:1 mating-type ratio expected under regular sexual reproduction; all the 12 strains 218 carried the MATB allele, suggesting that this population is at least partly clonal 219 (Table S6). The absence of linkage disequilibrium decay with physical distance 220 between two SNPs (Figure S3), together with the absence of reticulation in the 221 neighbor-net (Figure 1), are also consistent with a lack of recombination in the 222 Cheese 2 population. However, pairwise homology index (PHI) tests, testing with 223 permutations the null hypothesis of no recombination by looking at the genealogical 224 association among adjacent sites, were significant in all the G. candidum populations 225 (Table S7); this indicates that recombination did occur at least in a recent past in the 226 Cheese 2 population.

We did not detect any accumulation of nonsense or missense mutations in any population compared to silent mutations (Felsenstein, 1974; Table S8), while degeneration can be expected to be particularly strong in clonally replicated

15 oRxiv preprint doi: https://doi.org/10.1101/2022.05.17.492043; this version posted August 12, 2022. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted bioRxiv a license to display the preprint in perpetuity. It is made available under aCC-BY-NC-ND 4.0 International license.

populations as recombination allows more efficient selection. None of the genes that presented nonsense mutation had predicted functions that could be detected as specific either to the wild or cheese environments (Figure S4). This also suggest that the absence of sexual reproduction in the Cheese_2 population may be too recent to observe degeneration.

In contrast to the Cheese_2 population, we found both mating-type alleles in balanced proportions in both Cheese_1 and Cheese_3 populations (Table S6) and we observed sharp decays in linkage disequilibrium (LD) with genomic distance, although LD levels remained higher than in the mixed-origin and wild populations (Figure S3). We observed reticulations in the neighbor-net network within populations and, to a lesser extent, between populations (Figure 1A).

241

242 As previously mentioned, the 16 commercial starter strains in our G. candidum 243 dataset were scattered in the maximum likelihood tree (in yellow, Figure 1B.a.) and 244 we detected above footprints of recombination in the Cheese 1 and Cheese 3 245 populations (Figure 1A, Figure S3). We nevertheless detected a few groups of 246 clonemates, by the lack of branches in the trees and the presence of fewer than 247 1,200 SNPs between strains (Figure 1; Table S1, clonal group column). As strains within these clonal lineages were isolated from different cheeses, it indicates that 248 249 some lineages may be clonally cultivated for cheese-making; some of the 250 commercial starter strains indeed clustered within these clonal groups ("\$" symbol on 251 Figure 1B). Within the admixed cheese strains, 19 out of 23 were part of clonal 252 lineages, suggesting that hybrid lineages may have been selected for beneficial traits 253 for cheese-making, as in other domesticated fungi (e.g. S. pastorianus; Gallone et 254 al., 2018).

255 Copy number variation: loss of two tandem beta lactamase-like 256 genes in the cheese populations and repeat expansion

Expansions of gene families involved in specific metabolism pathways, of transposable elements and loss of genes no longer required in the new environment can be involved in adaptation to new environments. For example, variations in gene copy number were associated with the adaptation of *S. cerevisiae* to beer making, with duplications of genes involved in maltose and maltotriose metabolism specifically in domesticated beer strains (Gallone et al., 2016; Giannakou et al., 1 DioRxiv preprint doi: https://doi.org/10.1101/2022.05.17.492043; this version posted August 12, 2022. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted bioRxiv a license to display the preprint in perpetuity. It is made available under aCC-BY-NC-ND 4.0 International license.

263 2020; Gonçalves et al., 2016). We therefore looked for gene copy-number variation 264 (CNV) that differentiated wild and cheese populations, using 500 bp sliding windows 265 and two reference genomes, belonging to the Cheese 3 and the wild populations, respectively (Table S9). Using the Cheese 3 reference, we found 61 CNV regions 266 267 (mean length of 1515 bp and 45 non-genic CNVs), encompassing in total 16 genes. 268 half having predicted functions, none being obviously related to cheese adaptation 269 (e.g. methylglyoxal reductase and tRNAs, Table S9). Using the wild genome 270 reference, we found 132 CNV regions (mean length of 1664 bp and 105 non genic 271 CNVs), encompassing 29 genes (seven with unknown functions).

272 One of these regions, 20 kb long, included only two genes, both matching the Pfam 273 hidden markov model for beta-lactamases; these two genes (g5112 and g5113) were absent from all cheese populations, and were present in most wild strains 274 275 (except one that had partially the region) and in four strains belonging to the mixed-276 origin population (Figure 2). The nucleotide identity between the two beta lactamase-277 like genes was 93%. A third beta lactamase-like gene (g5111) was found 278 immediately next to this CNV region in all G. candidum strains, and displayed a 279 nucleotide identity of 87% with the two other beta lactamase-like genes within the 280 CNV. Surrounding these different genes, we found several Tc1/mariner, a LINE/Tad1 and other DNA transposons, that may have contributed to the beta-281 282 lactamase-like gene deletion (Figure 2). Fungal beta lactamase-like genes are 283 known to contribute to hydrolysis of microbial and plant xenobiotics, and thus may be 284 important in the wild environment to compete with other microorganisms (Gao et al., 285 2017). The cheese populations may have lost these two copies of the beta-286 lactamase genes due to relaxed selection; indeed, these functions may not be useful 287 in the cheese environment if G. candidum is inoculated in high quantity compared to 288 potential competitors.

289

290 *De novo* detection of repeats using the wild strain LMA-244 yielded a library 291 containing 107 types of repeated elements (including 15 types of DNA transposons 292 and 11 of retroelements and 3 rolling-circles). We identified 14 types of repeated 293 elements present in at least one other *G. candidum* genome with five times more 294 copies than in the LMA-244 wild strain (this threshold was set based on the fat tail of 295 the distribution; Figure S5). Among these 14 types of repeated elements, several 296 DNA transposons of the Tc1/*mariner* repeat family showed a cheese-clade specific 19 Rxiv preprint doi: https://doi.org/10.1101/2022.05.17.492043; this version posted August 12, 2022. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted bioRxiv a license to display the preprint in perpetuity. It is made available under aCC-BY-NC-ND 4.0 International license.

expansion (Table S10, Figure 3). Several unidentified, *Tad1* and *Helitron* repeat types also showed expansions in the cheese clade, alongside a milder expansion in the mixed origin clade. Such transposable element expansions in the cheese clade could be due to relaxed selection (Baduel et al., 2019).

301 Genomic footprints of adaptation: genomic islands of 302 differentiation in cheese populations and genes under positive 303 selection

304 We looked for genomic regions with a greater differentiation or a lower genetic diversity than the genomic background when comparing each of the three cheese 305 306 populations to the wild population, to detect footprints of divergent selection and 307 recent selective sweeps, respectively. We scanned the whole genome using-non-308 overlapping windows and explored the windows with the 1% highest d_{xy} (high 309 differentiation) or 5% lowest π (low diversity) values. Regions of high differentiation 310 appeared as outliers in the distribution of d_{xy} values, representing a small peak of 311 high d_{xy} values (Figure S6), and were often located in non-genic or in low gene-312 density regions (Figure S7). We however detected 69 genes in the high-313 differentiation regions across the three cheese populations, including 26 genes with predicted functions. Two of them encoded proteases, one of them being an ADAM 314 315 metalloprotease which was an enriched function in the high-differentiation regions 316 when compared to the rest of the genome, and the only one (Table S11). Proteases 317 are important in cheese-making as the breakdown of milk caseins greatly contributes 318 to cheese texture and decreases water activity by degrading proteins into molecules 319 with free carboxyl and amino groups (McSweeney, 2004). Geotrichum candidum is 320 prevalent during the amino-acid catabolism ripening step of Pelardon fresh cheese 321 (Penland et al., 2021), suggesting that G. candidum plays an important role in 322 proteolysis in cheese-making.

In the 198 windows representing the pooled set of the 5% lowest π values in the three cheese populations, we detected 497 genes, 323 of which had predicted functions Among the 323 annotated genes, five predicted proteases or lipases. Although these functions were not enriched compared to the rest of the genome (Table S11), this could still represent footprints of selection on some of these individual genes. Lipases are key enzymes for cheese flavor as they enable the breakdown of milk fats through fatty acid production (Collins et al., 2003), and arethus crucial for cheese-making.

331 We searched for genes evolving under positive selection in terms of high rates of non-synonymous substitutions by performing McDonald and Kreitman (MK) tests 332 333 (Table S12), comparing the mixed-origin population to each cheese population and 334 to the cheese clade as a whole. We detected 25 genes as evolving under positive 335 selection in at least one cheese population (9 for Cheese 1, 18 for Cheese 2, two in 336 Cheese 3 and one in all three cheese populations at once; Table S12). Among 337 them, a metalloendopeptidase evolved under positive selection in all three cheese 338 populations, likely playing a role in casein degradation through cell lysis (Dugat-Bony 339 et al., 2015; KUMURA et al., 2002). A Glucan 1,3-beta-glucosidase was also 340 detected as evolving under positive selection in the Cheese 2 population; this 341 enzyme could be involved in fungal inhibition through fungal cell degradation (Adams, 2004). The other genes under positive selection had either no predicted 342 343 function or putative functions that could not be related to cheese adaptation (Table 344 S12).

³⁴⁵ Phenotypic differentiation between cheese and wild populations

346 Denser mycelial growth and/or faster proteolysis in cheese populations347 of *Geotrichum candidum*

348 Strains selected by humans are expected to display specific traits beneficial for 349 cheese-making, such as faster growth in cheese at cave temperature or colonies of 350 attractive aspect or color. For example, the P. camemberti strains used for soft 351 cheese production were selected for their white and fluffy aspect, to make cheeses 352 more attractive to consumers compared to the blue-grey crust produced by the P. 353 *camemberti* ancestor (Pitt et al., 1986). In contrast, the ability to grow in harsh 354 conditions may have been lost in cheese strains due to relaxed selection, as often 355 reported for unused traits in human-made environments in domesticated organisms 356 (Gallone et al., 2018; Price, 2002; Ropars et al., 2015).

We therefore measured colony radial growth of 31 strains from the five *G. candidum* populations on different agar media (cheese, rich and poor media) at different temperatures. Wild populations grew faster than cheese populations on all media at all temperatures, with a more pronounced difference at 25°C (Table S13, Figure S8). This may result from trade-offs with other traits, such as a fluffier mycelium, i.e. more vertical growth at the expense of less radial growth.

363 To test whether cheese populations had a denser mycelium or had become whiter 364 and/or fluffier, we compared the opacity of populations on cheese agar at cave 365 temperature (10°C), which integrates the brightness and fluffiness of a colony. The 366 Cheese 1 and Cheese 3 populations were not more opaque than wild populations 367 (Figure 4B). The Cheese 2 population had a significantly higher opacity than all other G. candidum populations, except the mixed-origin population (post-hoc Tukey 368 369 test in Table S13). This represents a convergence with *P. camemberti* var. 370 *camemberti*, with independent evolution of similar phenotypes in two distantly related 371 cheese fungi.

372 Lipolysis and proteolysis are crucial biochemical processes during cheese ripening, 373 that influences flavor and texture of the final product; lipolysis and proteolysis 374 contribute to energy and nutrient uptake, and they affect the production of volatile 375 compounds, which are key flavor factors in cheeses (McSweeney, 2004). All 376 populations of G. candidum had similar lipolysis rates. The wild and mixed-origin 377 populations had degraded a significantly higher amount of proteins than the cheese 378 populations and we did not detect any proteolysis in the Cheese 2 population in our 379 experiment (Figure S9; Table S14).

380 No adaptation to high salt concentration or milk origin in cheese381 populations

382 Cheese is a salty medium, with the percentage of salt varying from 0.5 g / 100 g for 383 Emmental to 3 g / 100 g for Roguefort. Salt is added on the surface of cheeses to 384 prevent the growth of contaminants, and cheese populations of G. candidum may 385 thus have adapted to high salt concentrations. Cheeses display a wide range of salt 386 concentrations so we tested four cheese media: unsalted, 1% salt as St Nectaire and 387 cream cheeses, 2% as Camembert and goat cheeses and 4% as Roquefort blue 388 cheeses. Wild populations grew faster than cheese populations in all salt 389 concentrations tested, as on YPD and minimal media (Figure S10A ;Table S13).

390 Because all strains sampled from goat cheeses belonged to the Cheese_1 391 population, we tested whether this population was able to grow faster on goat 392 cheese medium (1% salt) compared to other populations. We however found no 393 significant interaction between population and media on radial growth effects, i.e. no 25 Rxiv preprint doi: https://doi.org/10.1101/2022.05.17.492043; this version posted August 12, 2022. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted bioRxiv a license to display the preprint in perpetuity. It is made available under aCC-BY-NC-ND 4.0 International license.

394 specific adaptation to any particular kind of milk by the different populations (Figure395 S10B).

396 Contrasting volatile compound production between wild and cheese 397 populations

398 Cheese ripening fungi, including G. candidum, contribute to cheese flavor through 399 the production of volatile compounds (McSweeney, 2004). Flavor is a crucial 400 criterion for cheese consumers and the cheese populations may have been selected 401 for desirable and specific volatile compounds. We grew 14 G. candidum strains on a sterilized Camembert curd for 21 days at 10°C, *i.e.*, the ripening conditions of a 402 403 Camembert. On average across compounds, the wild population produced five times 404 higher quantities of volatiles than cheese populations. In order to compare the 405 relative proportions of the different compounds, which is also an important aspect for 406 flavor, we standardized the values by dividing all compound quantities by the total 407 quantity of volatiles per sample. The PCA indicated a differentiation between wild 408 and cheese strains in terms of volatile relative proportions (Figure 4D). The wild 409 population thus produced combinations of volatile compounds different from cheese 410 populations, with a high proportion of ethyl esters and ethyl acetates (Figure S10C). 411 known to be key compounds in fermented beverages such as wine and beer. 412 However, the impact of ethyl acetate on flavor is rather negative because it brings 413 solvent type notes. In cheese, these esters are never predominant (Liu et al., 2004; 414 Urbach, 1997). Ethyl esters are involved in anaerobic metabolism and may be 415 important for survival in the wild. By contrast, cheese strains produced many 416 alcohols, ketones, aldehydes and sulfur compounds (Figure S10C), known for 417 producing attractive flavors such as buttery, cheesy, fermented and aldehydic notes 418 (Curioni and Bosset, 2002). These volatile compounds, attractive in cheese, were 419 present in similar absolute quantities in wild strains but were in minor proportions 420 compared to other volatile compounds (Table S13), suggesting that cheese 421 populations evolved a lower production of undesirable and unused volatiles. The 422 overall balance between different volatile compounds is as important as volatile 423 absolute quantities for flavor perception (Liu et al., 2004). The dimethyl sulfone, a 424 compound previously reported to be produced during the catabolism of L-methionine 425 in G. candidum, is actually specifically produced by the cheese populations 426 (Bonnarme et al., 2001; Penland et al., 2021).

427 Cheese populations inhibit more the growth of food spoilers than wild 428 populations

429 Cheese is a protein- and fat-rich medium, where many microorganisms, including 430 desired microbes, but also spoilers, can thrive and thus compete for nutrients; for 431 example, iron is limiting in cheese (Mayo et al., 2021; Monnet et al., 2015, 2012). 432 Cheese G. candidum populations may have been selected for excluding competitors 433 by inhibiting their growth (Boutrou and Gueguen, 2005). This fungus is known to 434 inhibit fungal and bacterial food spoilers, such as Aspergillus species and Listeria 435 monocytogenes, but these inhibitory activities have only been investigated in cheese 436 G. candidum strains so far (Dieuleveux et al., 1998; Nielsen et al., 1998; Omeike et 437 al., 2021). We therefore tested whether cheese populations displayed better growth 438 inhibition abilities than the wild population, using common fungal food spoilers as 439 competitors: Debaryomyces hansenii, Penicillium biforme, P. roqueforti and 440 Scopulariopsis asperula. We also tested whether growth inhibition of challengers 441 occurred via secreted and/or volatile compounds.

442 Inhibition by a mycelium lawn - In the first experiment, we grew challengers in a 443 central spot for 24h, alone or after spreading out G. candidum to let it grow as a lawn; growth inhibition could occur in this setting by secreted molecules in the 444 445 medium, volatile compounds and/or a physical barrier to reach nutrients and grow. 446 The growth of D. hansenii was completely inhibited by all populations of G. 447 candidum. Penicillium roqueforti was strongly inhibited by G. candidum, in particular 448 by the Cheese 2 population that completely prevented *P. roqueforti* growth (Figure 449 5; Table S13). The growth of Scopulariopsis asperula and P. biforme was also inhibited by G. candidum, with a significant difference between competitor growth 450 451 when spread alone or on a G. candidum lawn; the Cheese 2 population again 452 inhibited better competitors than any other population (Figure 5; Table S13). The 453 Cheese 2 population was the most opaque population on cheese and had a beta-454 glucanase gene under positive selection, suggesting that challenger inhibition would 455 be due to either mycelium density as a physical barrier or degradation of competitor 456 cell wall.

Inhibition by volatile compounds - In a second experiment, we used splitted Petri dishes (the two parts being separated by a plastic barrier) to test whether cheese populations inhibited competitors to a greater extent than the wild population when only volatile compounds can reach challengers. No significant growth difference was

461 observed between the growth alone and at the side of *G. candidum* for neither *S.* 462 *asperula* nor *P. roqueforti* (Figure 5B, Table S13). Only *P. biforme* showed a 463 significant growth inhibition by *G. candidum* in this setup (Table S13); such a growth 464 inhibition by *G. candidum* from an isolated Petri dish compartment indicates that 465 volatile compounds produced by *G. candidum* are able to impair the growth of some 466 competitors.

467 The two sets of experiments enabled us to assess by which mechanism G. 468 candidum can inhibit competitors: P. biforme growth was inhibited by G. candidum in 469 the splitted Petri dishes, suggesting that volatile compounds are able to impair its growth. On the contrary, P. roqueforti and S. asperula were only inhibited by G. 470 471 candidum when molecules could diffuse in their medium and G. candidum mycelium 472 could form a physical barrier. The Cheese 2 population had a stronger inhibition 473 ability than the other G. candidum populations only when molecules could diffuse in 474 the medium and the mycelium could act as a barrier.

475

476 Discussion

477 Analyzing the genomes of 98 G. candidum strains isolated from different kinds of cheeses, other food substrates and other environments revealed three monophyletic 478 479 clades, corresponding to strains isolated from cheese, mixed-origins (dairy and other 480 environments) and the wild, respectively. Within the cheese clade, we found three 481 distinct clusters and several admixed strains. In terms of genetic diversity, the mixed-482 origin clade contained the highest diversity level, followed by the wild clade and then 483 the distinct cheese populations. However, the nucleotide diversity within each of the 484 cheese populations was still relatively high compared to other cheese fungi. Indeed, the Cheese 2 population, while being four times less diverse than the two other 485 486 cheese populations, was as diverse as the Roquefort P. roqueforti cheese 487 population. The low diversity, the presence of a single mating type, a high level of 488 linkage disequilibrium and the absence of reticulation in the neighbor-net network 489 indicated a lack of recombination in the Cheese 2 population, that may thus 490 correspond to a clonally cultivated line for cheese-making. Additional, less 491 widespread clonal lineages may be cultivated for cheese-making, as we found 492 clonemates in all cheese populations, even in the clusters of intra-specific hybrids,

493 and including some commercial starter strains. This presence of commercial starter 494 strains in the clusters of intra-specific hybrids suggests that hybrid lineages may 495 have been selected for beneficial traits for cheese-making, as in other domesticated fungi (e.g. Saccharomyces pastorianus used for the production of lager beer) but this 496 497 needs further investigation (Rainieri et al., 2006). The Cheese 1 population was as 498 diverse as the domesticated cheese species P. biforme and the Cheese 3 499 population as its wild relative *P. fuscoglaucum*. The genetic diversity of the cheese 500 clade as a whole was even higher than that in the wild population, which may be due 501 to the relatively low number of wild strains available and to the diversification of the 502 cheese clade into three varieties.

503 The genetic relationships between G. candidum populations and their contrasting 504 levels of diversity suggest that domestication occurred in several steps, with an ancient domestication event separating the mixed-origin and the wild clades, then 505 the cheese and the mixed-origin clades, and yet more recently the three cheese 506 507 clusters. The domestication of *P. camemberti* similarly occurred in several steps, the 508 last steps involving the selection of a white and fluffy clonal lineage (Ropars et al., 509 2020b). Considering the genetic diversity, the situation in *G. candidum* is however 510 very different from that of P. camemberti and P. roqueforti, for which a single or a 511 few clonal lineages are sold by spore producers for all kinds of cheeses (Ropars et 512 al., 2020b). The domestication of G. candidum did not involve strong bottlenecks that 513 occurred in other domesticated cheese fungi, such as P. camemberti, P. roqueforti 514 and S. cerevisiae, perhaps because it is more abundant spontaneously in raw milk 515 and because there has been a diversification into three genetically differentiated 516 varieties. It may also be that the domestication of the three G. candidum varieties is 517 more recent or has not involved a selection as strong as in other cheese fungi, 518 except perhaps in the Chhese 2 lineage. Sampling further cheese types, geographic regions and wild environnements may reveal further genetic clusters. 519

520 521

522 We found evidence of phenotypic adaptation to cheese-making in *G. candidum* 523 cheese populations, with a slower growth on all media, even cheese, a prominent 524 production of attractive cheese flavors and a lower proteolytic activity compared to 525 the wild population. The slower growth and proteolysis activity may allow to prevent 526 a too fast degradation of products during maturation, as found in the Roquefort *P*. *roqueforti* population (Dumas et al. 2020). The lack of adaptation to salt was also found in the Roquefort *P. roqueforti* population and in dry-cured meat *Penicillium* fungi and may be due to evolutionary constraints (Lo et al., 2022). We also found genomic footprints of adaptation to cheese, with the presence of genomic islands of differentiation in cheese populations and the loss of genes no longer required in the human-made environment, i.e. tandem beta lactamase-like genes. This may correspond to a first step of domestication.

- 534 The Cheese 2 population appeared to represent a more advanced state of 535 domestication than the other cheese populations, with much lower genetic diversity, 536 a fluffier mycelium, a higher competitive ability and a complete lack of proteolysis 537 activity. Denser mycelial growth leading to a fluffy aspect at the expense of less rapid radial growth has also been selected in *P. camemberti* var. camemberti (Ropars et 538 539 al., 2020b), thus representing a convergent phenotype between two distantly related 540 cheese fungi. Geotrichum candidum is increasingly inoculated in milk in the place of 541 *P. camemberti* for industrial soft cheese production, as it provides the fluffy desired 542 aspect without the disadvantage of P. camemberti that browns the surface of 543 Camembert cheeses at the end of the ripening process (Carreira et al., 2002). 544 Proteolysis activity was also found lower in the Roquefort P. roqueforti population, 545 which may be beneficial to obtain not too degraded cheeses (Dumas et al. 2020). 546 The volatile proportions produced by cheese strains corresponded to attractive flavor 547 for cheese-making, in contrast to wild strains, as also documented in P. roqueforti 548 (Caron et al., 2021; Dumas et al., 2020). Geotrichum candidum is able to efficiently 549 inhibit the growth of common food spoilers, in particular P. biforme and P. roqueforti, 550 and the clonal Cheese 2 population is the most efficient competitor.
- 551

552 Our study shows that it is of fundamental importance to study further domestication 553 in various cheese fungi as it allows assessing whether independent adaptation 554 events to similar media and usage lead to evolutionary convergence, as this is an 555 important question in evolutionary biology (Alberto et al., 2018; Cresko et al., 2004; 556 Dyer et al., 2012; Elmer et al., 2014, 2010; Lin et al., 2012; Macías et al., 2021; O'Quin et al., 2010; Thorpe et al., 2015). We found here both similarities 557 558 (convergence) and differences in the adaptation of G. candidum to cheese compared 559 to other cheese fungi. One of the most striking convergence was the evolution of a 560 fluffy and white mycelium as in *P. camemberti* with a trade-off with radial growth 35 oRxiv preprint doi: https://doi.org/10.1101/2022.05.17.492043; this version posted August 12, 2022. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted bioRxiv a license to display the preprint in perpetuity. It is made available under aCC-BY-NC-ND 4.0 International license.

(Ropars et al., 2020b). The higher competitive ability and lower proteolysis activity,
as well as the greater production of positive volatile compounds, also represent
interesting convergence events between multiple very distant fungal lineages,
indicating that evolution can be repeatable.

565

566 Our findings also have industrial implications, as they reveal high genetic diversity 567 and subdivision in a fungus widely used in the cheese industry, and the existence of 568 different varieties, *i.e.*, genetically and phenotypically different populations used for 569 cheese-making, with specific and contrasted traits beneficial for cheese-making. The 570 most fluffy and most competitive cheese population corresponded to a clonal lineage 571 which may represent the most recent selection event. The occurrence of 572 recombination between cheese strains is highly relevant for cheese producers as it opens possibilities for further improvement for the agrofood sector. It is crucial to 573 574 maintain the larger genetic diversity in cheese G. candidum populations as genetic 575 diversity is essential in domesticated organisms for variety improvement and 576 diversification and to avoid degeneration (Harlan et al., 2012).

577

578 Material and Methods

579 Sampling

580 We isolated 53 strains from different kinds of cheeses (e.g. Camembert, Brie, Saint 581 Nectaire, Ossau Iraty, comté, bleu de chèvre) from five European countries, Canada 582 and the USA. Cheese crusts were left in the freezer for 24h to kill acarians. Then, we 583 diluted a piece of each crust in sterile water and spread 50 uL of the suspension on a 584 malt agar Petri dish. When colonies appeared on the Petri dish, typically after three days, we isolated the different morphotypes with a sterile toothpick and inoculated 585 586 them on new Petri dishes. After seven days of growth, we performed monospore 587 isolation by several dilution steps, in order to obtain separated colonies arising each 588 from a single spore. We identified the species of these pure strains after DNA 589 extraction by sequencing the 5' end of the nuclear ribosomal large subunit (LSU 590 rDNA) using the LROR/LR6 oligonucleotide primers (Vilgalys and Hester, 1990). We 591 also gathered 24 strains from INRAE, isolated from cheeses but also other

37 ioRxiv preprint doi: https://doi.org/10.1101/2022.05.17.492043; this version posted August 12, 2022. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted bioRxiv a license to display the preprint in perpetuity. It is made available under aCC-BY-NC-ND 4.0 International license.

environments (e.g. sand, hay, rainforest) and 15 strains from a French spore seller.
We gathered all the wild strains available in public collections. For each strain, single
spore cultures were generated to ensure the presence of a single genotype before
DNA extraction.

596 The LMA-244 strain were inoculated on Yeast Extract Glucose (YEG) agar plates 597 (10 g.L-1 of yeast extract (Fischer Scientific), 10 g.L-1 of D-glucose (EMD 598 Chemicals) and 15 g.L-1 of Bacto agar (BD Diagnostics)) directly from 15% glycerol 599 (v/v) stock cultures stored at -80°C. The plates were incubated in the dark for five 600 days at 25°C.

601 DNA extraction, genome sequencing, assembly, annotation and 602 mapping

We used the Nucleospin Soil Kit (Macherey-Nagel, Düren, Germany) to extract DNA from 88 *G. candidum* strains cultured for five days on malt agar. Sequencing was performed with Illumina HiSeq 3000 paired-end technology (Illumina Inc.), 2x150 bp. For the eight LMA strains, sequencing was performed using the Illumina HiSeq paired-end technology.

All Illumina reads were trimmed and adapters cleaned with Trimmomatic v0.36 (Bolger et al., 2014). Leading or trailing low quality or N bases below a quality score of three were removed. For each read, only parts that had an average quality score higher than 20 on a four base window are kept. After these steps, only reads with a length of at least 36 bp were kept.

613 Cleaned Illumina reads were assembled with SPAdes v3.15.3 not using unpaired 614 reads with "--careful" parameter.

For the LMA-244 strain, Genomic DNA was extracted using the Fungi/Yeast Genomic DNA Isolation Kit (Norgen Biotek Corp.) with the following modifications. Thirty milligrams of frozen grounded mycelium were thawed and homogenized in 500 μL of a 0.9% NaCl solution. The elution buffer was replaced by a Tris 10 mM buffer (pH 8). Following the extraction step, gDNA suspensions were purified and concentrated using Agencourt AMPure XP magnetic beads (Beckman-Coulter), according to the manufacturer's protocol.

39 Rxiv preprint doi: https://doi.org/10.1101/2022.05.17.492043; this version posted August 12, 2022. It is made available under aCC-BY-NC-ND 4.0 International license.

DNA concentration and purity were measured using a NanoDrop ND-1000
spectrophotometer (Thermo Fisher Scientific Inc., Wilmington, U.S.A.) and a Qubit
Fluorometer 3.0 (Thermo Fisher Scientific Inc., Wilmington, U.S.A.).

The DNA library was prepared following the Pacific Biosciences 20 kb template 625 626 preparation using BluePippin Size-Selection System protocol and the Pacific 627 Biosciences Procedure & Checklist – Preparing Multiplexed Microbial Libraries Using 628 SMRTbell Express Template Prep Kit 2.0 protocol. No DNA shearing was performed. 629 The DNA damage repair, end repair and SMRT bell ligation steps were performed as 630 described in the template preparation protocol with the SMRTbell Template Prep Kit 631 1.0 reagents and the SMRTbell Express Template Prep Kit 2.0 reagents (Pacific 632 Biosciences, Menlo Park, CA, USA). The DNA library was size selected on a BluePippin system (Sage Science Inc., Beverly, MA, USA) using a cut-off range of 633 634 10 kb to 50 kb. The sequencing primer was annealed at a final concentration of 0.83 635 nM and the P6 v2 polymerase was bound at 0.50 nM while the sequencing primer 636 was annealed with sequencing primer v4 at a final concentration of 1 nM and the 637 Sequel 3.0 polymerase was bound at 0.5 nM.. The libraries were sequenced on a PacBio RS II instrument at a loading concentration (on-plate) of 160 pM using the 638 639 MagBead OneCellPerWell loading protocol, DNA sequencing kit 4.0 v2, SMRT cells 640 v3 and 4 hours movies.

641

Raw PacBio reads were corrected using Illumina reads already available and 642 643 described in a previous article (Perkins et al., 2020), with the default parameters of 644 the LoRDEC software and trimmed with Canu v1.6 (Koren et al., 2017; Salmela and 645 Rivals, 2014). Corrected and trimmed PacBio reads were then assembled using 646 Canu v1.6. Illumina polishing of the Canu assembly was performed using Pilon v1.22 647 (Walker et al., 2014). A final assembly step was then performed with the hybrid assembler SPAdes v3.11.1 using the trimmed PacBio reads, the Illumina reads and 648 649 the Pilon corrected assembly as trusted contigs (Antipov et al., 2016; Prjibelski et al., 650 2020). Additionally, the CLIB 918 assembly (Bioproject PRJEB5752) was used as a 651 reference in the SPAdes script for the assembly of each G. candidum genome (Morel et al., 2015). Scaffolds were filtered using the khmer software with a length 652 653 cut-off of 1,000 bp (Crusoe et al., 2015).

655 The LMA-244 PacBio assembly and reads have been deposited in GenBank: 656 nbPROJECT. To annotate short read assemblies and the LMA-244 genome, gene 657 prediction was performed using Augustus v3.4.0 (Stanke et al., 2008). The training annotation file "saccharomyces" was used, with parameters as follows: "--gff3=on", 658 659 "--protein=on". "--codingseg=on", "--exonnames=on", "--cds=on" "__ and uniqueGeneId=true". The output of Augustus and the CLIB 918 gff was provided to 660 661 Funannotate v1.8.9 (ref DOI:10.5281/zenodo.4054262) for functional annotation. InterProscan was used under Funannotate pipeline locally (Blum et al., 2021). 662 663 Funannotate then searched in the Pfam database v34.0 and dbCAN database version 10.0 with Hmmer v3.3.2 (Eddy, 2011; Huang et al., 2018; Mistry et al., 2021), 664 665 in database UniProt version 2021 03 and database MEROPS version 12.0 with 666 diamond blastp v2.0.11 (Rawlings et al., 2018; The UniProt Consortium et al., 2021), eggNOG-mapper v2 on the database eggNOG 5.0 (Cantalapiedra et al., n.d.; 667 668 Huerta-Cepas et al., 2019).

- 669 Cleaned reads were mapped on the reference genomes CLIB 918 and LMA-244 670 using Bowtie2 v2.4.2 (Langmead and Salzberg, 2012). Maximum fragment length 671 was set to 1000 and the preset "very-sensitive-local" was used.
- 672 SAMtools v1.7 (Li et al., 2009) was used to filter out duplicate reads and reads with a
 673 mapping quality score above ten for SNP calling and above one for CNV analyses.
 674

In total, we have a dataset of 98 genomes, 88 being sequenced, eight from the
University of Laval (LMA strains: Bioproject PRJNA482576, PRJNA482605,
PRJNA482610, PRJNA482613, PRJNA482616, PRJNA482619, PRJNA490507,
PRJNA490528), one strain CLIB 918 from the Collection de Levures d'Intérêt
Biotechnologique (Bioproject PRJEB5752), and one of the strain Phaff72-186 from
the 1000 Fungal Genomes project (Bioproject PRJNA334358 NCBI).

681 SNP calling

Single nucleotide polymorphisms (SNPs) were called using GATK v4.1.2.0 682 HaplotypeCaller, which provides one gVCF per strain (option -ERC GVCF). GVCFs 683 684 combined GATK CombineGVCFs, were using genotypes with GATK GenotypeGVCFs, SNPs were selected using GATK SelectVariants (option -select-685 type SNP). SNPs were filtered using GATK VariantFiltration and options QUAL < 30, 686 DP < 10, QD < 2.0, FS > 60.0, MQ < 40.0, SOR > 3.0, QRankSum < -12.5, 687

4 BoRxiv preprint doi: https://doi.org/10.1101/2022.05.17.492043; this version posted August 12, 2022. ReadPosRankSum < -8.0. All processes from cleaning to variant calling were
performed with Snakemake v5.3.0 (script available at
https://github.com/BastienBennetot/Article_Geotrichum_2022).

691 Phylogenetic analysis

We inferred phylogenetic relationships among the 98 isolates using the dataset of 693 699,755 SNPs in a maximum likelihood framework using IQ-Tree2 v2.1.1 (Minh et al., 2020). The tree has been midpoint rooted. The best-fit model chosen according 695 to Bayesian information criterion (BIC) was TVMe+R2. Branch supports are ultrafast 696 bootstrap support (1000 bootstrap replicates, Minh et al., 2013).

697 Genetic structure

We used the dataset of 699,755 SNPs to infer population structure based on the 698 699 mapping on the CLIB 918 reference genome. We used Splitstree v4.16.2 (Huson 700 and Bryant, 2006) for the neighbor-net analysis. We used the R package Ade4 701 (Bougeard and Dray, 2018; Chessel et al., 2004; Dray et al., 2007; Dray and Dufour, 702 2007; Thioulouse et al., 2018) for principal component analyses (PCA, centered and 703 unscaled). We used NGSadmix v.33 (Jørsboe et al., 2017) from the ANGSD 704 (Korneliussen et al., 2014) package (version 0.933-110-g6921bc6) to infer individual ancestry from genotype likelihoods based on realigned reads, by assuming a given 705 706 number of populations. A Beagle file was first prepared from bam using ANGSD with 707 the following parameters: "-uniqueOnly 1 -remove bads 1 -only proper pairs 1 -GL 1 -doMajorMinor 1 -doMaf 1 -doGlf 2 -SNP pval 1e-6". The Beagle file was used to 708 709 run NGSadmix with 4 as the minimum number of informative individuals. Given the 710 high number of strains genetically highly similar among cheese strains (that may 711 represent clonal lineages), we randomly sampled one of the individuals for each 712 group of clonemates identified on the ML tree as having fewer than 90,000 SNPs 713 and filtered out the other strains (N=64 strains kept) to avoid biasing the analysis. 714 The analysis was run for different K values, ranging from 2 to 10. A hundred 715 independent runs were carried out for each number of clusters (K).

The nucleotide diversity π (Nei's Pi; Hudson et al., 1992; Nei and Li, 1979), the Watterson's θ (Watterson, 1975), the fixation index $F_{s\tau}$ (Hudson et al., 1992) and the absolute divergence d_{XY} (Nei and Li, 1979) were calculated using the *popgenome* package in R (Pfeifer et al., 2014). Fixed, private and shared sites were counted 45 oRxiv preprint doi: https://doi.org/10.1101/2022.05.17.492043; this version posted August 12, 2022. It is made available under aCC-BY-NC-ND 4.0 International license.

720 using custom scripts available at 721 https://github.com/BastienBennetot/fixed shared private count, with bcftools 722 version 1.11 (using htslib 1.13+ds). F3 tests were computed using the admixr 723 package v0.9.1. The pairwise homology index (PHI) test was performed using 724 PhiPack v1.1 and CLIB 918 genome as reference.

Linkage disequilibrium was calculated using vcftools v0.1.17 with the --hap-r2
parameter and a minimum distance between SNPs of 15,000 bp. Values were
averaged when SNPs had the same distance.

Pairwise identity between an admixed strain and each non-admixed strain was calculated using overlapping sliding windows of 30 kb span and 5 kb step. Admixed clusters are indicated in Table S1. The custom script is available on https://github.com/BastienBennetot/Article_Geotrichum_2022

732 Copy number variation and identification of premature stop codons in733 CDS

734 Copy number variation (CNV) was analyzed using Control-FREEC v11.6 with the following parameters: ploidy was set to 1, non-overlapping windows of 500 bp, 735 telomeric and centromeric regions were excluded, expected GC content was set 736 737 between 0.25 and 0.55, minimum of consecutive windows to call a CNV set to 1. 738 This analysis was performed using as references the CLIB 918 (cheese 3) and 739 LMA-244 (wild) genome sequences. CNVs were classified in different groups when 740 the median of copy number was different between populations. We defined three 741 groups: regions for which copy number was different between wild and cheese 742 populations, between mixed-origin and cheese populations and when at least one 743 cheese population differed from another population. For each InterPro term present 744 in these regions, we performed enrichment tests, i.e., a fisher exact test comparing 745 the number of a particular InterPro term found in these regions and the whole 746 genome (Table S9).

747

We used snpeff (Cingolani et al., 2012) to assess how each SNP affected the coding sequence of predicted proteins, in the vcf file containing all SNPs and all genomes of our dataset. We detected premature stop codons in the 7,150 CDS of the CLIB 918 genome and the 5,576 CDS of the LMA-244 genome using a custom script and bcftools v1.11.

753 Analyzing the repeat landscape

754 In order to *de novo* detect repeats within *G. candidum*, RepeatModeler (v2.0.2; Flynn 755 et al., 2020), using the ncbi engine (-engine ncbi) and the option -LTRStruct, was run 756 on the pacbio genome assembly of LMA 244 generating a library of 176 repeats. The 757 repeat redundancy was reduced using cd-hit-est, as described in Goubert et al., 758 giving a final library of 108 repeats (Goubert et al., 2022). To estimate the per strain 759 copy number of each repeat, illumina reads were aligned using bwa mem (v0.7.17; Li, 2013) to the repeat library and the median coverage for each repeat was then 760 761 normalized by the LMA 244 genome wide median coverage.

762 Detecting positive selection

763 The assemblies LMA-317, LMA-77 and LMA-563 have been excluded for this analysis because of a N50 under ten kb. All the 437441 predicted protein sequences 764 765 from the 66 genomes of all cheese clades and mixed-origin clade were searched 766 against each other with BLASTP using diamond v0.9.36 and clustered into 767 orthologous groups using Orthagog v1.0.3 (Ekseth et al., 2014). For these analyses, 768 we only kept single-copy orthologs shared between two populations. We compared 769 the mixed origin population to each cheese population and the cheese clade. 770 Multiple nucleotide sequence alignments with predicted gene sequences were then 771 constructed using MACSE v2.0.3 with default parameters (Ranwez et al., 2018). We 772 performed an approximative MacDonald Kreitman tests using the R package 773 PopGenome (Pfeifer et al., 2014). The approximation comes from the fact that only 774 codons with a single SNP are examined. The assumption of this version of the test is 775 that the probability that two SNPs will appear in the same codon is very low. To 776 identify genes evolving under positive selection in G. candidum genomes, a, i.e. the representation of the proportion of substitutions driven by positive selection was 777 778 used. Genes with an alpha under 0 were filtered out. Of these genes, only those with 779 a Fisher's test p-value under 0.05 were kept.

- 780 Phenotypic characterization
- 781 Sampling and strain calibration

We used 36 *Geotrichum candidum* strains for laboratory experiments: seven from the Cheese_1 population, five from the Cheese_2 population, eleven from the Cheese_3 population, eight from the mixed-origin population and five from the wild population (Table S1). This set encompassed 26 strains isolated from dairies, one from other food environments and nine isolated from environments other than food. Experiments were initiated with spore suspensions calibrated to 1.10⁶ spores/mL with a hemocytometer.

789 Media preparation

All media were sterilized in an autoclave at 121°C for 20 minutes except those with cheese or milk for which the autoclave was run at 110°C for 15 minutes to avoid 49 Rxiv preprint doi: https://doi.org/10.1101/2022.05.17.492043; this version posted August 12, 2022. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted bioRxiv a license to display the preprint in perpetuity. It is made available under aCC-BY-NC-ND 4.0 International license.

792 curdling. Each 94mm-diameter Petri dish was filled with 25mL of the appropriate 793 medium. Cheese medium was prepared as follows for 800mL: 300g of unsalted 794 cream cheese from La Doudou farm in Cheptainville, 16g agar, 8g NaCl dissolved in 795 200mL of deionized water. Deionized water was added to reach 800mL. pH was 796 adjusted to 6.5 and drops of blue food dyes were added to enable fungal colony 797 measures (white medium and white colonies are not distinguable). Yeast Peptone 798 Dextrose (YPD) medium was prepared as follows for 1L: 10g Yeast extract, 10g Bacto Peptone, 10g glucose, 14g agar powder. Minimal medium was prepared as 799 800 described in "Improved protocols for *Aspergillus* minimal medium: trace element and 801 minimal medium salt stock solutions", Terry W. Hill, Rhodes College, Etta Kafer, 802 Simon Fraser University. Tributyrin agar was prepared as follows: Tributyrin medium 33 g/L, neutral Tributyrin 10 g/L, Bacto Agar 15 g/L. Ingredients were bought at Nutri-803 804 Bact company, Québec, Canada. Caseinate agar was prepared according to Frazier 805 and Rupp, modified as follows: Calcium caseinate medium 37.2 g/L, Bacto Agar 15 806 g/L. Ingredients were bought at Nutri-Bact company, Québec, Canada. For yogurt 807 media we used three different types of raw milk, i.e. sheep, goat and cow milks. 808 coming from d'Armenon farm near Les Molières (Esonne, France), Noue farm in 809 Celle les Bordes and Coubertin farm in Saint-Rémy-lès-Chevreuse respectively. Each medium was prepared following the same procedure: 1L of milk was mixed 810 811 with 62.5g of Danone brand yogurt, heated for 5 hour at 43°C and stored in a fridge 812 before use. A subset of 300g of this preparation was used with 16g of agar powder. 813 8g of NaCl, 4 drops of blue food dye and filled up with deionized water to reach 814 800mL.

815 Growth in different conditions and different media

816 Petri dishes were inoculated with 10μ L of the 1.10^6 cells/mL in a 10% glycerol 817 solution. Inoculated Petri dishes were wrapped with plastic film before letting them 818 grow in the dark. A millimeter rule was used to measure two opposite diameters of 819 fungal colonies to estimate their growth. Means of these two measures were used for 820 statistical analyses.

To test media and temperature effect on growth, *G. candidum* strains were grown on minimal, YPD and cheese media. We took pictures and measured their growth at seven, 11 and 14 days for minimal, YPD and cheese media at 10°C (ripening cellar 5 bioRxiv preprint doi: https://doi.org/10.1101/2022.05.17.492043; this version posted August 12, 2022. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted bioRxiv a license to display the preprint in perpetuity. It is made available under aCC-BY-NC-ND 4.0 International license.

temperature), at seven and 11 days for the cheese medium at 15°C and at seven
days for minimal, YPD and cheese media at 25°C (Figure S8).

To test salt tolerance, *G. candidum* strains were grown at 10°C on cheese media of different salt concentrations: unsalted media, 1% salt as St Nectaire and cream cheeses, 2% as Camembert and goat cheeses and 4% as Roquefort blue cheeses. We took pictures and measured colony diameters after 14 days of growth.

To test adaptation of *G. candidum* populations to different milk origins, growth was measured on different yogurt media made from goat, sheep and cow raw milk for seven days at 25°C.

To test lipolytic and proteolytic activities of *G. candidum* populations, we grew strains on tributyrin agar and caseinate agar, respectively. Each strain was inoculated in triplicate Petri dishes that were let grown at 25°C for 14 days. The radius of lysis was measured and the mean between triplicates was used for the analysis.

837

Pictures were taken using a Scan 1200 (Interscience). Petri dishes grown on cheese were analyzed using IRIS (Kritikos et al., 2017) which measured Integral opacity scores, defined as the sum of the brightness values for all the pixels within the colony bounds.

842 Volatile compounds analysis using Gas-chromatography mass-spectrometry (GC-843 MS)

844 Volatile compounds produced by G. candidum were analyzed using gas-845 chromatography mass-spectrometry (GC-MS). Compounds were extracted and 846 concentrated by using a dynamic headspace (DHS) combined with a thermal 847 desorption unit (TDU). Strains were grown for 21 days at 10°C (minimum 848 Camembert ripening time) on a cheese agar medium made with Camembert-type 849 curds. After 21 days, each Petri dish content, with its medium and G. candidum 850 mycelium, was mixed with a fork for one minute, gathered in vials and immediately 851 frozen in liquid nitrogen. For each sample, three grams of frozen cultured media 852 were weighted and stored in vials with septum caps at -80°C. Sixteen hours before 853 analysis, samples were stored at 4°C. The Cheese 2 population was not tested in 854 this experiment because population delineation was not known at this time.

B55 Dynamic headspace (DHS) conditions were as follows: Inert gas: He; Incubation:
B56 30°C for 3min; Needle temperature: 120°C; Trap: nature tenax, 30°C, 450 mL He;

5 BoRxiv preprint doi: https://doi.org/10.1101/2022.05.17.492043; this version posted August 12, 2022. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted bioRxiv a license to display the preprint in perpetuity. It is made available under a CC-BY-NC-ND 4.0 International license.

857 He flow: 30 mL/min; Dry purge : temperature 30°C, 850 mL He, He flow 50 mL/min. 858 Thermal Desorption Unit (TDU) conditions were as follows: inert gas : He; Initial 859 temperature: 30°C, then 60°C/min until 290°C kept for 7 minutes; Transfer temperature: 300°C. Cool Injection System (CIS) conditions were as follows: inert 860 gas : He; Initial temperature: -100°C, then 12°C/s until 270°C kept for 5 minutes. Gas 861 862 chromatograph (brand Agilent 7890B) was used with a polyethylene glycol (PEG) 863 type polar phase column (HP-Innowax, ref. Agilent 19091N-116I, 60mx0.32mm, 0.25µm film thickness). Helium flow was set at 1.6mL/min. Samples were injected in 864 865 splitless mode with a holding time of 1 minute. To optimize separation of 866 compounds, a specific program of the gas chromatography oven was used, with 867 initial temperature at 40°C for 5 minutes, rising temperature from 40°C to 155°C with a slope of 4°C/min, rising temperature from 155°C to 250°C with a slope of 20°C/min 868 869 and then temperature was kept at 250°C for 5 minutes. A single guadrupole mass 870 spectrometer was used to determine m/z of sample molecules (Agilent, référence 871 5977B MSD). Molecules were identified using NIST libraries (NIST 2017 Mass 872 Spectral Library).

873 Competition experiments

874 To test the abilities of G. candidum populations to exclude other fungi by secreting 875 molecules or volatile compounds, we compared the growth of competitors when grown alone and on a lawn of an already grown G. candidum mycelium. We 876 877 inoculated a cheese medium with 150µL of a G. candidum calibrated spore solution (1.10⁶ spores/mL), spread evenly on the Petri dish. After 24h of growth, we 878 879 inoculated 10µL of a competitor spore solution (1.10⁶ spores/mL) in a single spot, in 880 the middle of the Petri dish. We used as competitors the following species and 881 strains: Penicillium biforme (ESE00018, ESE00023, ESE00125, ESE00222), Penicillium roqueforti (ESE00645, ESE00925, LCP06040), Scopulariopsis asperula 882 883 (ESE00044, ESE00102, ESE00835, ESE01287, ESE01324) and *Debaryomyces* hansenii (ESE00284, ESE00561, ESE00576; Table S15). For each competitor, two 884 885 Petri dishes were inoculated without any G. candidum as controls for measuring 886 growth without a lawn.

We took pictures of the Petri dishes at 6 days, when the competitor mycelium grown
alone was near the Petri dishes border; we measured colony size at 7 days for *P. biforme* and *P. roqueforti* and at 19 days for *D. hansenii*, which grows more slowly.

890 To test the abilities of G. candidum populations to exclude other microorganisms by 891 producing volatile compounds, we set up an experiment with splitted Petri dishes 892 where only air can be shared between the two parts. In one part of the Petri dish, we 893 spread 75µL of a G. candidum spore solution (1.10⁶ spores/mL) and let it grow 894 during 24 hours before adding on the other part of the Petri dish a drop of 5µL of a 895 competitor spore solution (1.10⁶ spores/mL). For each competitor, two Petri dishes 896 were inoculated without any G. candidum as controls. We used as competitors the 897 species and strains: Penicillium biforme (ESE00018, ESE00023, following 898 ESE00125, ESE00222, ESE00423), Penicillium roqueforti (ESE00250, ESE00631, 899 ESE00640, ESE00925) and Scopulariopsis asperula(ESE00044, ESE00102, 900 ESE00835, ESE01287, ESE01324; Table S15). Petri dishes were grown at 10°C, 901 measured and pictured at 11 days for P. biforme and P. roqueforti and 19 days for 902 Scopulariopsis asperula.

903 Graphics and statistical analyses

904 Plots and statistical analyses were made using ggplot2 (Wickham, 2016), rstatix and 905 ggpubr packages in the R environment. For ANOVAs, we used standard linear 906 models in which all explanatory variables were discrete, with explained variables 907 being radial growth for growth conditions (for media, temperature, salt content and 908 adaptation to milk experiments), integral opacity score (for opacity experiment), 909 relative proportions of volatiles compounds (for volatile compounds experiment) and 910 radial growth of the competitor (for competition experiments). The explanatory 911 variable common for all analyses was the 'population' of G. candidum. The variables 912 'medium', 'day' and 'temperature' were explanatory variables specific to the growth 913 analysis. The 'competitor species' variable was specific to competition analyses. All 914 variables and all interactions between them were implemented in the ANOVA and 915 non-significant interactions were subsequently removed before performing post-916 ANOVA Tukey's honest significant difference (HSD) tests. The data normality of 917 residuals was checked; when residues deviated from normality (only for the opacity 918 experiment), we also ran non-parametric tests (Wilcoxon ranking tests) using R. Radius of lysis for lipolytic and proteolytic activities experiments was often discrete, 919 920 strains either showing lytic activity or not at all. This is why we decided to transform 921 these data into gualitative discrete data in order to fit a generalized linear model with 922 a binomial function as logit. Growth time (7, 14 and 21 days) and temperature (15

57 ioRxiv preprint doi: https://doi.org/10.1101/2022.05.17.492043; this version posted August 12, 2022. and 25°C) were taken as random variables because no fit could be achieved with
little data and we wanted to test for population effect. Tukey contrasts were used to
compare population means of populations when population effect was significant.

927 Acknowledgments

We thank everyone who sent cheese crusts and Riwanon Lemee for providing 15 strains from Laboratoires STANDA, Caen, France. We thank Laura Prugneau, Jérémy Raynaud, Thomas Mari, Véronique Bougie and Jules Larouche for their help in the laboratory experiments. This work was funded by the Artifice ANR-19-CE20-0006-01 ANR grant to J.R. In addition, a NSERC-Discovery Grant supported the scholarship of V.P and data generation, and is held by S. Labrie. (RGPIN-2017-06388).

935

936 Author contributions

937 J.R. designed and supervised the study, and obtained funding. B.B., V.P., J.R. and 938 A.S. generated the data. C.G. provided strains from the CIRM-Levures INRAE 939 collection. B.B., J.-P.V., R.C.d.I.V. and S.O. analyzed the genomes. B.B., S.H., J.R. 940 and A.S. performed the experiments. B.B. analyzed the data from laboratory 941 experiments. M.H.L. and St.L. supervised the lipolysis and proteolysis analyses. 942 B.B., So.L. and A.-C.P. performed the volatile compound experiment. T.G. 943 contributed to interpretation and writing; B.B. and J.R. wrote the manuscript, with 944 contributions from all the authors.

1485 Figure legends

1486 Figure main:

1487 Figure 1: Phylogenetic relationships and population structure of 98 strains of1488 *Geotrichum candidum,* based on whole-genome data

(A) Neighbor-net analysis based on a single nucleotide polymorphism (SNP)
distance matrix. The scale bar represents 0.01 substitutions per site for branch
lengths.

- 1492 (B) Genetic relationships among strains and population structure in Geotrichum 1493 candidum based on 699,755 SNPs. a) Maximum likelihood tree showing genetic 1494 relationships among the 98 isolates used in this study. All nodes are supported by bootstrap support >98% (bootstrap analysis with 1000 resampled datasets). The 1495 1496 scale bar represents 0.05 substitutions per site for branch lengths. We used the 1497 midpoint rooting method to root the tree. The "\$" symbol pinpoints commercial starter 1498 strains and "*" the PacBio sequences. Genomes used as reference are written in 1499 bold. b) Population subdivision inferred for K = 5. Colored bars represent the 1500 coefficients of membership in the five gene pools based on SNP data.
- 1501 (C) Principal component analysis (PCA) based on 699,755 SNPs and 98 strains. 1502 Genetic clusters are represented by the same colors on all panels: light blue for 1503 Cheese 1, dark blue for Cheese 2, pink for Cheese 3, light grey for the mixed-1504 origin population and dark grey for the wild population. Borders of points were 1505 colored in red when multiple points were overlapping due to clonal lineages (with a 1506 threshold set at <90,000 SNP for defining clonal strains). The shape of points 1507 represents the environment from which strains were sampled: circle for cheese/dairy. 1508 square for food and triangle for wild environment.

(D) PCA based on the 323,385 SNPs when the dataset was restricted to the 78strains from the cheese clade

1511 Figure 2: Synteny of the beta lactamase-like genes lost in the cheese clade of1512 *Geotrichum candidum*

1513 Synteny of the scaffold QQZM01000080.1 of the LMA-244 (wild) assembly against 1514 the scaffold CCBN010000010.1 of the cheese CLIB 918 (Cheese_3) assembly. The 1515 two scaffolds were shortened according to the range of nucleotide position on the 1516 right of each sequence. Beta-lactamase-like genes are annotated in red while other 8 CRXiv preprint doi: https://doi.org/10.1101/2022.05.17.492043; this version posted August 12, 2022. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted bioRxiv a license to display the preprint in perpetuity. genes are displayed in blue. Black triangles indicate positions where repeated
sequences were detected by tandem repeats finder (Benson, 1999). All strains from
the cheese clades and 5 from the mixed-origin populations (LMA-317, ESE00274,
MUCL8652 and ESE00540) carried the 20 kb deletion containing the g5112 and
g5113 genes, both encoding for beta-lactamase like.

1522 Figure 3: Heatmap of different repeats that expanded in the cheese populations1523

1524 From the repeat database based on the LMA 244 (wild) assembly, the copy number 1525 of each repeated element was estimated by aligning illumina reads of each strain. 1526 Only repeated elements that were at least in a 5-fold copy relative to the LMA 244 1527 genome were kept on the heatmap. The total number of copies is written in the 1528 center of each cell and filled with different shadings of grey to red depending on the 1529 relative expansion from the smallest copy number for each type of repeat. The 1530 maximum likelihood (ML) tree from the figure 1 (without admixed strains) was plotted 1531 below strains name to highlight the population's delineation.

1532 Figure 4: Differences in growth, opacity and volatile compounds among the five1533 populations of *Geotrichum candidum*

Each point represents a strain, horizontal dotted lines and vertical lines represent the mean and the standard deviation of the phenotype in the population, respectively. The number *n* at the bottom of plots indicates the number of strains used per population for measuring the corresponding phenotypes. The pairwise Tukey tests performed to assess whether there were mean differences between populations are indicated with brackets and their p-values are given.

(A) Mean radial growth of the three cheeses, mixed-origin and wild populations on
cheese (1% salt), yeast peptone dextrose (YPD) and minimal media at 25°C.

Tot Tot Cheese (17% sail), yeast peptone dextrose (1PD) and minimal media at 25°C.

1542 (B) Differences in opacity between the three cheese populations, mixed-origin and

1543 wild populations on cheese medium (1% salt) at 10°C. Integral opacity is defined as

1544 the sum of the brightness values for all the pixels within the fungal colony bounds1545 and measures the whiteness and density of the mycelium.

1546 (C) Petri dish of a strain (ESE00182) from the Cheese_2 population showing the1547 fluffiness of the colony

1548 (D) Principal component analysis (PCA) of *Geotrichum candidum* strains based on 1549 their relative proportions of the different volatile compounds produced. Strains are 85 Rxiv preprint doi: https://doi.org/10.1101/2022.05.17.492043; this version posted August 12, 2022. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted bioRxiv a license to display the preprint in perpetuity. It is made available under aCC-BY-NC-ND 4.0 International license.

1550 plotted using the first two PCA axes.

(E) Contribution of each volatile compound to the first two PCA axes. Compounds
contributing the most to the differentiation were colored in red and labeled (i.e., those
distant from 0 by an Euclidean distance >=0.1).

1554 Figure 5: Competitive abilities of the different populations of *Geotrichum candidum* 1555 against Penicillium biforme, P. roqueforti and Scopulariopsis asperula challengers. (A) At the top, radial growth abilities of the competitors on lawns of Geotrichum 1556 candidum belonging to different populations (the three cheese, the mixed-origin and 1557 1558 the wild populations). Each point represents a combination of the growth of a 1559 competitor strain on a lawn of a G. candidum strain. Horizontal dotted lines and 1560 vertical lines represent the mean and the standard deviation of the competitor growth 1561 in the population, respectively. The number *n* at the bottom of plots indicates the 1562 number of combinations of competitor-mat used per population. The competitor was 1563 inoculated in a central point 24h later on a lawn of *G. candidum*. At the bottom, from 1564 left to right, are shown pictures of P. biforme ESE00023 on a G. candidum 1565 ESE00186 lawn and without any lawn, P. roqueforti ESE00645 on a G. candidum ESE00186 lawn and without any lawn, and S. asperula ESE01324 on a G. 1566 1567 candidum ESE00198 lawn and without any lawn, all on a salted cheese medium.

1568 B: At the top, radial growth abilities of competitors, with various *G. candidum* strains 1569 belonging to different populations being grown on the other side of splitted Petri 1570 dishes. The competitor was inoculated in a central spot on one side and the G. 1571 candidum strain was spread on the other side of the splitted Petri dish (a picture is 1572 shown as example below the figure). Media is not contiguous between the two sides of Petri dishes, so that inhibition can only occur by volatile compounds. *Penicillium* 1573 1574 biforme and P. roqueforti were grown for 11 days while S. asperula was grown for 19 1575 days at 25°C.

1576 Each point represents a combination of the growth of a competitor strain on a *G*. 1577 *candidum* strain. Horizontal dotted lines and vertical lines represent the mean and 1578 the standard deviation of the competitor growth in the population, respectively. The 1579 number *n* at the bottom of plots indicates the number of combinations of competitor-1580 mat used per population. 87 ioRxiv preprint doi: https://doi.org/10.1101/2022.05.17.492043; this version posted August 12, 2022. 1581 Supplementary Figure:

1582 Figure S1: Population structure of *Geotrichum candidum*.

1583 Population subdivision inferred for K population ranging from two to six. Colored bars 1584 represent the coefficients of membership in the K gene pools based on genomic 1585 data. Each bar represents a strain, its name being indicated at the bottom of the 1586 figure. The new color for each K increment is indicated on the right part. The 1587 second order rate of change in the likelihood (ΔK) peaked at K=6. However the additional population distinguished at K=6 only encompassed two strains that 1588 1589 were not that differentiated in the splistree (MUCL 14462 and CBS 9194; ; FIGURE 1590 1).

1591 Therefore, we chose to set the number of populations to five, the *K* value at which 1592 the structure was the strongest and the clearest, with three cheese populations, 1593 several admixed or hybrid cheese strains, a population of mixed origins and a wild 1594 population. These populations are indicated on the last rows.

Below the admixture plot, two rows are indicating milk from which the strains wassampled and the population delineation.

1597 Figure S2: Pairwise identity between admixed and other strains, averaged by 1598 population of *Geotrichum candidum*.

1599 In order to see traces of introgression from different populations of Geotrichum 1600 candidum in some hybrid strains we computed the pairwise identity along the 1601 genome. Only the first scaffold of the CLIB 918 genome is shown in this figure. 1602 Values were averaged by population and when admixed strains had the same 1603 genetic background (name of strains are above each subplot) across 30 kb 1604 overlapping sliding windows with 5 kb steps. If no introgression happened, we expect 1605 the admixed strain to be equally distant to the different populations along the 1606 genome. Introgression results in genomic regions being atypically closer to a single 1607 population. All admixed strains within the cheese clades had introgression imprints while the other three strains (CBS 9194^T, MUCL 14462 and ESE01080) did not, 1608 meaning that they were either from different genetic backgrounds or introgressed 1609 1610 with genetic backgrounds different from the five populations of *G. candidum*.

1611 Figure S3: Linkage disequilibrium against distance between SNPs for the five1612 *Geotrichum candidum* populations.

1613 The r² (square of the correlation coefficient between two indicator variables) varies

1614 between 0 when two markers are in perfect equilibrium and 1 when they provide 1615 identical information. Under recombination, we expect r^2 to decrease exponentially 1616 with the distance between two SNP while in non recombining lineages linkage 1617 disequilibrium remains flat. All *Geotrichum candidum* populations r^2 decay curve 1618 behaved as recombining populations except the Cheese 2 population.

1619 Figure S4: SNPs inducing a premature stop codon for each *Geotrichum candidum*1620 strain.

In order to keep genes that carried a single nucleotide polymorphism (SNP) inducing 1621 1622 a premature STOP codon in most of a population, we only showed STOP-inducing 1623 SNP that were at least in more than three strains. Columns represent strains and 1624 strains are ordered following the maximum likelihood (ML) tree. Cells are colored in 1625 black when the corresponding SNP induces a premature stop codon, white when 1626 there is no substitution for this site compared to the reference genome and grey 1627 when the SNP status could not be attributed during SNP calling, substitution that induces other effects on the protein sequence were not present in this subset of 1628 1629 STOP-inducing sites. Each row is a site, when multiple SNPs induced stop codons in 1630 the same gene, the corresponding rows were grouped and separated from other 1631 genes by black lines. The analysis was done using either the CLIB 918 (Cheese 3) 1632 genome (A) or the LMA-244 (Wild) genome (B) as a reference.

1633

1634 Figure S5: Density of transposable elements copy number relative to the LMA-2441635 strain

To better show the fat tail distribution, the y-axis (density) was cut at 25%. A red dashed line indicates the threshold of five times more copy number than the LMA-244 strain. This threshold was set to identify repeats expansion related to small peaks on the density curve

Figure S6: Distribution of absolute divergence d_{xy} values for different pairwise populations tested. Distribution of absolute divergence (d_{xy}) values for each pairwise population comparison from the genomic scan analysis. Density is given as an overlapping window number for a specific value of d_{xy} , each window being 7.5 kb wide with a step of 5 kb (optimal values based on variants densities). A black vertical line indicates the threshold of 1% highest values kept for the enrichment test. 9 DioRxiv preprint doi: https://doi.org/10.1101/2022.05.17.492043; this version posted August 12, 2022. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted bioRxiv a license to display the preprint in perpetuity. It is made available under aCC-BY-NC-ND 4.0 International license.

1647 Figure S7: Genomic scan of within-population genetic diversity and between-1648 population differentiation in *Geotrichum candidum*.

1649 Genomic of the nucleotide diversity π , watterson's theta θ_{w} , absolute divergence d_{xy} 1650 and fixation index F_{ST} (Hudson et al., 1992) along the scaffold 1 of the CLIB 918 1651 reference genome. At the bottom a guide indicates genic regions in black and non 1652 genic regions in white. 7.5 kb overlapping windows with a step of 5 kb (optimal 1653 values based on variant densities). On the bottom of the figure, genic regions are 1654 shown in black (not positively selected) or red (positively selected in the MK test 1655 analysis) rectangle. On the first panel (nucleotide diversity π), 5% lowest π values in 1656 the three cheese populations were highlighted by black dots. On the third panel 1657 (absolute divergence d_{xy}), 1% highest values of d_{xy} of each pairwise comparison 1658 were highlighted by back dots. These outliers were checked for gene presence and 1659 functions that could be involved in cheese adaptation and subsequently tested for 1660 enrichment within this subset of outliers compared to the whole genome

1661 Figure S8: Differences in growth among the five populations of *Geotrichum*1662 *candidum* populations for different media and temperature

1663 Mean radial growth of the three cheese populations, mixed-origin and wild 1664 populations on cheese (1% salt), yeast peptone dextrose (YPD) and minimal media 1665 at 10, 15 and 25°C for 7, 11 and 14 days.

Each point represents a strain, horizontal dotted lines and vertical lines represent the mean and the standard deviation of the population respectively. The number *n* at the bottom of plots indicates the number of strains per population used for measuring these phenotypes. To assess difference in means between populations, significant pairwise Tukey tests are indicated with brackets and p-values.

1671 Figure S9: Differences in lipolytic and proteolytic activity among the five populations1672 of *Geotrichum candidum* populations for different growing time and temperature

1673 A: Lipolytic activity of *Geotrichum candidum* at 15 and 25°C and grown for 7, 14 and 1674 21 days.

1675 B: Proteolytic activity of *G. candidum* at 15 and 25°C and grown for 7, 14 and 21 1676 days.

1677 Each point represents a strain, horizontal dotted lines and vertical lines represent the 1678 mean and the standard deviation of the population respectively. The number n at the 1679 bottom of plots indicates the number of strains per population used for measuring 1680 these phenotypes. To assess difference in means between populations, significant 9 BoRxiv preprint doi: https://doi.org/10.1101/2022.05.17.492043; this version posted August 12, 2022. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted bioRxiv a license to display the preprint in perpetuity. It is made available under a CC-BY-NC-ND 4.0 International license.

pairwise Tukey tests are indicated with brackets and p-values. Length of lysis was measured as a radius between the center of the colony and the limit of the lysis area when lysis happened under the colony or measured as the thickness of the lysis area when there was no lysis under the colony.

Figure S10: Differences in salt tolerance, growth on different milk and volatilecompounds in detail among the five populations of *Geotrichum candidum*.

Each point represents a strain, horizontal dotted lines and vertical lines represent the mean and the standard deviation of the phenotype in the population, respectively. The number *n* at the bottom of plots indicates the number of strains used per population for measuring the corresponding phenotypes. The pairwise Tukey tests performed to assess whether there were mean differences between populations are indicated with brackets and their p-values are given.

- 1693 (A) Mean radial growth at 10°C of the three cheese, mixed-origin and wild 1694 populations of *Geotrichum candidum* on cheese agar medium with different salt 1695 concentrations: unsalted, 1% salt for mimicking St Nectaire and cream cheeses, 2% 1696 salt for mimicking Camembert and goat cheeses and 4% salt for mimicking blue 1697 cheeses.
- 1698 (B) Mean radial growth at 10° C of the three cheese populations, the mixed-origin and 1699 the wild populations on yogurt agar media made with raw cow, goat and sheep milks. 1700 (C) Relative proportions of major volatile compounds in Cheese_1, Cheese_3, 1701 mixed-origin or wild populations of *G*; *candidum*. The volatile compounds shown 1702 were those contributing the most to the two first PCA axes or that are important for 1703 cheese ripening. For each compound, the related corresponding descriptor from 1704 thegoodscentscompany.com was added.

1713

1707 Supplementary Table:

1708 Table S1: Description of the origin, phylogenetic assignation, sequencing statistics, and phenotype tested of *Geotrichum candidum* strains used in this study. 1709 1710 Strains: Name of the strains; ESE collection number: collection number of strains 1711 kept at the author laboratory; Population: population attributed to the strains in this

1712 study; Clonal group: strains with the same number are clonal (less than 1,200 SNP

between them); Species name: species identified either based on public collection or 1714 from ITS identification for collected strains in this study; Environment of sampling

1715 simplified: broader categories for source of sampling; Milk type: if extracted from

1716 dairy, indicates species from which was made the dairy; Location: Region or country

1717 of origin; Mating type: mating type identified in *Geotrichum candidum* either MATA or

1718 MATB (Morel et al., 2015).

1719 Table S2: Population genetics statistics estimating genetic differentiation (F_{st}, d_{xy}) in 1720 the five Geotrichum candidum populations and among the identified population 1721 within each of two other fungal species (Penicillium camemberti and Penicillium 1722 roqueforti) (Dumas et al., 2020; Ropars et al., 2020b)

1723 Table of F_{st} (fixation index) and d_{xy} (absolute divergence) (Hudson et al., 1992; Nei 1724 and Li, 1979). Values for Geotrichum candidum, Penicillium roqueforti (Dumas et al., 1725 2020), Penicillium camemberti (Ropars et al., 2020b) are indicated for each 1726 population. Cells are colored from the lowest (white) and the highest (red) value of 1727 each indices.

1728 Table S3: Proportions of fixed, shared and private SNPs for each pair of populations of Geotrichum candidum population and for each pair of populations within each of 1729 1730 two other fungal species (Penicillium camemberti and Penicillium rogueforti) (Dumas et al., 2020; Ropars et al., 2020b). 1731

1732 Percent and number of fixed, shared or private single nucleotide polymorphisms

1733 (SNPs) for Geotrichum candidum, Penicillium roqueforti (Dumas et al., 2020),

1734 Penicillium camemberti (Ropars et al., 2020b) are indicated for each populations.

- 1735 The method of attributions of SNPs to different categories are available on
- 1736 https://github.com/BastienBennetot/fixed shared private count.

97 BioRxiv preprint doi: https://doi.org/10.1101/2022.05.17.492043; this version posted August 12, 2022. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted bioRxiv a license to display the preprint in perpetuity. It is made available under aCC-BY-NC-ND 4.0 International license.

1737 Table S4: F3 test performed on each trio of populations of *Geotrichum candidum*1738 populations.

1739 The F3 test is a test between three populations. It tests whether a target population

1740 (C) is admixed between two source populations (A and B) and gives a measure of

1741 shared drift between two test populations (A and B) from an outgroup (C). In case of

1742 introgression, we expect negative F3 values. A Z-score is computed based on F3

- 1743 value and the standard error to assess the deviation from zero of the F3 value. If the
- 1744 Z-score is inferior to minus three then we can conclude a significant rejection of the
- 1745 Null hypothesis (F3 value is not negative).
- 1746
- 1747

1748 Table S5: Population genetics statistics estimating genetic diversity (π , watterson's 1749 θ) in the five *Geotrichum candidum* populations and among the identified population 1750 of three other fungal species (*Penicillium roqueforti, Penicillium camemberti* and 1751 *Saccharomyces cerevisiae*) (Dumas et al., 2020; Peter et al., 2018; Ropars et al., 1752 2020b).

1753 Nucleotide diversity statistics (π and watterson's θ) are indicated for *Geotrichum*

1754 candidum, Penicillium roqueforti (Dumas et al., 2020), Penicillium camemberti

1755 (Ropars et al., 2020b) and Saccharomyces cerevisiae (Peter et al., 2018). Cells are

1756 colored from the lowest (white) and the highest (red) value of each indices.

- 1757 Table S6: Distribution of the two mating types in each population and proportion test1758 of the deviation from 1:1 ratio.
- 1759 Table S7: Phi test of each population of *Geotrichum candidum* using the first scaffold1760 of CLIB 918 assembly.
- 1761 Pairwise homoplasy index (PHI) test helps to discriminate between the presence or
- 1762 absence of recombination between a population (Bruen et al., 2006). It tests with

1763 permutations the null hypothesis of no recombination by looking at the genealogical

- 1764 association among adjacent sites. The PHI test was performed using PhiPack v1.1
- 1765 and the first scaffold of the CLIB 918 assembly as reference.

1766 Table S8: Number and percentage of SNPs classified by impact, functional class,1767 effect and genomic regions for each *Geotrichum candidum* populations.

1768 Based on the 7,150 CDS of the CLIB 918 assembly, the effect of all variants was

1769 assessed. Each variant is categorized in different functional effects on the protein

- 1770 sequence. Results are meaned by population and shown either as the mean number
- 1771 of SNP or percentage. Results were computed using snpeff (Cingolani et al., 2012).
- 1772 (A) Total number of single nucleotide polymorphism (SNP) within each *G. candidum*1773 populations.
- 1774 (B) Putative variant impact prediction. Different impacts categories are defined in 1775 Snpeff manual in 'Input & output files' section
- 1776 (C) Protein sequence effect of SNPs. Variants can either not change amino acid
 1777 sequence (silent), change the amino acid (missense) or induce stop codons
 1778 (nonsense)
- 1779 (D) Functional effect of SNPs defined in Snpeff manual in 'Input & output files'1780 section
- 1781 (E) Position of the SNPs compared to genes

Table S9: Number of copy number variants windows that differentiated Geotrichum *candidum* populations and test for enrichment of gene ontologies contained within
these windows.

1785 Copy number windows (non-overlapping windows of 500 bp) were subsetted and 1786 classified in three comparison when the median copy number between the two 1787 clades compared was different: wild against all other populations (mixed origin and 1788 cheese populations), mixed-origin against cheese clade, and any pairwise difference 1789 within the different cheese populations (subtable A and B). For each comparison, 1790 when subsetted windows contained genes, gene ontologies (GO) of these genes 1791 were used to perform an enrichment test compared to the rest of the genome 1792 (subtable C and D). The same methodology was used for LMA 244 (Wild) or CLIB 1793 918 (Cheese 3) as reference assembly ensuring we see regions unique to the 1794 Cheese 3 and the Wild populations.

1795 (A) Number of windows subsetted in each clade comparison using LMA 2441796 assembly as reference

- 1797 (B) Number of windows subsetted in each clade comparison using CLIB 9181798 assembly as reference
- 1799 (C) Enrichment test on gene ontologies (GO) present within the subsets of windows
- 1800 in each clade comparison using CLIB 918 assembly as reference
- 1801 (D) Enrichment test on gene ontologies (GO) present within the subsets of windows
- 1802 in each clade comparison using LMA 244 assembly as reference

1803 Table S10: Repeat copy number for the different strains of *Geotrichum candidum*.

1804 In order to de novo detect repeats within *Geotrichum candidum*, RepeatModeler 1805 v2.0.2 (Flynn et al., 2020) was run on the pacbio genome assembly of LMA 244 1806 generating a library of 176 repeats. The repeat redundancy was reduced using cd-1807 hit-est, as described in Goubert et al., giving a final library of 108 repeats (presented in column "Clustering of repeat family") (Goubert et al., 2022). Sometimes the type 1808 1809 and family of these repeats was inferred (column type of repeat and repeat family). 1810 To estimate the per strain copy number of each repeat, illumina reads were aligned 1811 using bwa mem (v0.7.17; Li, 2013) to the repeat library and the median coverage for 1812 each repeat was then normalized by the LMA 244 genome wide median coverage. 1813 Strain: name of the strains studied; relative median coverage: Coverage of all 1814 genomic reads mapped to the repeated sequence normalized by genome wide 1815 coverage before taking the median of all nucleotides of the repeated sequence 1816 (gives an idea of the copy number of the repeated element genome-wide); Copy 1817 number relative to LMA-244 strains: relative median coverage of the strain divided by 1818 the one of LMA-244 (Wild) strain to better emphasize repeat expansion within the 1819 cheese clade.

1820

1821 Table S11: Test for enrichment of gene functions that showed footprints of divergent1822 selection and recent selective sweeps.

1823 We tested gene function enrichment that were detected either by keeping 1%

1824 highest of absolute divergence (d_{xy}) between cheese and wild strains (A) or 5%

1825 lowest nucleotide diversity (π) in the cheese populations but not in the wild 1826 population (B). Only functions related to lactose, lipid, protease were kept. Windows

- 1827 were 7.5 kb wide and overlapping windows with a step of 5 kb.
- 1828 (A) Test for enrichment of gene functions within the 1% highest Dxy windows when
- 1829 comparing a cheese population to the Wild population
- 1830 The subsetted windows for each test are based on the 1% highest Dxy windows for
- 1831 a specific comparison between a cheese and the wild population
- 1832 (B) Test for enrichment of gene functions within the 5% lowest Pi windows in cheese
- populations. Windows are excluded when they are also in the 5% lowest Pi of thewild population.
- 1835 The subsetted windows for each test are based on the 5% lowest Pi windows for a1836 specific cheese population.
- 1837
- 1838

1839 Table S12: Results of the McDonald and Kreitman (MK) test for positive selection.

1840 Genes evolving under positive selection were assessed using McDonald and 1841 Kreitman (MK) tests. Using contrasting levels of polymorphism and divergence at 1842 neutral and functional sites, MK test estimates the fraction of substitutions at the 1843 functional sites that were driven by positive selection. When fisher. P. value was lower 1844 than 0.05, we considered that the gene was under positive selection. Only genes under positive selection were shown in the table. The mixed-origin population was 1845 1846 compared to the cheese clade (A), Cheese 1 (B), Cheese 2 (C) and Cheese 3 (D). 1847 Ortho id: identifier of the orthologous gene; P1 nonsyn: the number of non-1848 synonymous polymorphisms in the first population; P2 nonsyn: the number of non-1849 synonymous polymorphisms in the second population; P1 syn: the number of 1850 synonymous polymorphisms in the first population; P2 syn: the number of 1851 synonymous polymorphisms in the second population; D nonsyn: the number of 1852 non-synonymous substitutions: D syn: the number of synonymous substitutions; 1853 neutrality.index: guantifies the degree of departure from neutrality; alpha: the 1854 proportion of substitutions driven by positive selection; fisher.P.value: P-value of the 1855 MK test; GeneID: gene identifier in the CLIB 918 assembly annotation; Contig Start: 1856 Start of the gene sequence; Stop: Stop of the gene sequence; Name: Name of the 1857 closest orthologous annotated genes; Product: Function of the protein; PFAM: pfam 1858 database annotation; InterPro: InterPro database annotation

1862 Table S13: Anova table of all phenotypic linear models and post-hoc test table.

1863 All outputs of analysis of variance (ANOVA) (A) and post-hoc test (B) based on different linear models that were used for phenotypic analyses. Linear models tested: 1864 1865 Effect of media, temperature on radial growth (1); effect of media and population on 1866 radial growth of Geotrichum candidum at 25°C (2); effect of salt content and population on radial growth (3); effect of milk origin and population on radial growth 1867 1868 (4); effect of media and population on opacity (5); effect of population of *Geotrichum* 1869 candidum on competitor growth (6); competition abilities by volatiles on splitted Petri 1870 dishes (7); effect of population on relative proportions of volatile compounds (8).

1871 In ANOVA table, columns correspond to degree of freedom (Df), sum of squares 1872 (Sum Sq), mean square (Mean Sq), the F statistic (value) and the p-value of this 1873 test.

1874 Columns in post-hoc tables before the "term column" gives the condition kept for 1875 each single test. term: variable used for pairwise comparison; group1: the group that 1876 we compare against group2; group2: a second group that we compare to group1; 1877 null.value: value of group1 - group2 under the null.hypothesis; estimate: value of 1878 group1 - group2 using the data; conf.low: Lower value of the confidence interval; 1879 conf.high: higher value of the confidence interval; p.adj: adjusted p-value; p.ad.signif: 1880 significance of the adjusted p-value (p-value >0.05:n.s.; <0.05:*; <0.01:**; <0.001:***, <1E-04:****). Post hoc test for testing the effect of salt content and population on 1881 1882 radial growth of G. candidum.

1883

1884 Table S14: Anova table and post-hoc test of lipolysis and proteolysis analyses.

All outputs of analysis of variance (ANOVA) (A) and post-hoc test (B) based on different linear models that were used for lipolysis (1) and proteolysis (2) analyses. Radius of lysis for lipolytic and proteolytic activities experiments was often discrete, strains either showing lytic activity or not at all. Thus, data were transformed into qualitative discrete data and a generalized linear model with a binomial function as logit was fitted. No post-hoc tests were computed for the lipolysis analysis because there was no population effect.

1892 In ANOVA table we find columns σ 2: mean random effect variance of the model; τ 00: 1893 The random intercept variance of a given variable, or between-subject variance; ICC: 1894 the intraclass correlation coefficient; N variable: the number of categories of the 1895 given variable; Observations: sample size of the model; marginal R² : represents the 1896 variance explained by the fixed effects; conditional R²: interpreted as the variance 1897 explained by the entire model (i.e. the fixed and random effects).

1898 In post hoc table we find columns Linear Hypotheses: null hypothesis considered for
1899 each post-hoc test; Estimate: Measured value; Std. Error: standard error of this
1900 measure; z value: Z statistic of this test.
