#### Abstract

On a curved surface, epithelial cells can adapt to geometric constraints by tilting and by exchanging their neighbors from apical to basal sides, known as an apicobasal T1 (AB-T1) transition. The relationship between cell tilt, AB-T1 transitions, and tissue curvature still lacks a unified understanding. Here, we propose a general framework for cell packing in curved environments and explain the formation of AB-T1 transitions under different conditions. We find that steep curvature gradients can lead to cell tilting and induce AB-T1 transitions. Conversely, large curvature anisotropy can drive AB-T1 transitions by hydrostatic pressure. The two mechanisms compete to determine the impact of tissue geometry and mechanics on optimized cell rearrangements in 3D.

As the external surfaces and barriers of many organs, 51 epithelial tissues have to mechanically adapt to their en- 52 vironment [1, 2]. Extensive research into cell shape in ${ }_{53}$ 2D $3-10$ and 3D $11-14$ has revealed insights into how 54 cells pack and undergo rearrangement during epithelial ${ }_{55}$ tissue formation [7-10, 15]. Cellular dynamic processes, 56 like division and apoptosis, can rearrange cell neighbors. 57 T1-transitions - the exchange of neighbors without alter- ${ }_{58}$ ing the cell number - is another ubiquitous mechanism of 59 cell rearrangements [16, 17]. T1 transitions are important 60 in mediating planar tissue dynamics. For example, ori- 61 ented T1 transitions can lead to tissue elongation or flow 62 [15, 18-20], and the energetic barriers for T1 transitions ${ }_{63}$ to occur can dictate tissue fluidity/solidity [9, 21-23]. ${ }_{64}$

For a cell monolayer under 3D geometric constraint, ${ }_{65}$ cells can undergo apical-basal T1 (AB-T1) transitions 66 (Fig. 1A, top). Different from the planar and dynamic 67 T1-transitions described above, AB-T1 transitions are a 68 static exchange of neighbors from the apical to basal lay- ${ }_{9}$ ers of the cell. Such a 3D cellular arrangement, termed 70 as a scutoid in the context of epithelial tissues [24-26] 71 (Fig. 11A), has been observed in foams [27, 28] and bio- 72 logical systems with curved surfaces [29] 33 .

Tissue curvature is proposed to be pivotal in in- 74 ducing AB-T1 transitions. In the ellipsoidal early 75 Drosophila embryo, AB-T1 transitions appear most fre- 76 quently around $20-50 \mu \mathrm{~m}$ from the embryo head, a region 77 with low curvature anisotropy but large tilt of cell lateral 78 membranes [29] (Fig. 11A). During salivary gland forma- 79 tion in the Drosophila embryo, AB-T1 transitions occur ${ }_{80}$ at maximal curvature anisotropy [24]. Models have been ${ }_{81}$ proposed for cell packing in these specific cases [24, 29], 82 but there is currently no consensus on how curvature in- 83 duces AB-T1 transitions.

Here, we provide a framework for describing curvature- 85 induced cell deformation, which can be generalized to an ${ }_{86}$

array of geometries, and discuss the interplay between cell mechanics and tissue geometry in inducing AB-T1 transitions. We demonstrate that in 3D environments with steep curvature gradient, cells can tilt in order to pack efficiently. These tilted lateral membranes can exert tensions that contribute to in-plane stresses of opposite sign on the apical and basal plane stresses, thereby leading to AB-T1 transitions. Conversely, when hydrostatic pressure dominates, we find that AB-T1 transitions occur in regions with high curvature anisotropy. Overall, we find that the combination of tissue curvature, pressure, and lateral tensions determines the location of AB-T1 transition events.

Framework: We treat the epithelia as a material composed of two connected thin shells, representing the apical and basal surfaces of the tissue. Assuming the radius of curvature to be significantly larger than the cell size, we can use a continuum mechanics model based on membrane theory for elastic thin shells, neglecting bending stresses. Lateral membranes are included as part of the external load on the shell. Motivated by the Drosophila embryo, salivary gland and oocyte geometries, we focus on axisymmetric geometries, which have rotational symmetry about a polar axis (Fig. $1 B$ ). For any infinitesimal surface element $d A$ on the 3 D curved shell, it has a normal direction $d A$, and two tangential directions along the meridian $d \varphi$ and latitudinal radii $d \theta$ (Fig. 1 B ).

The in-plane stresses in the apical or basal layer are described as a stress tensor $\hat{\sigma}$ bearing two principal stresses $\sigma_{\varphi \varphi}, \sigma_{\theta \theta}$ and a shear stress component $\sigma_{\theta \varphi}$, with the basis $\hat{n}=(d \varphi, d \theta)^{T}$. This stress tensor $\hat{\sigma}$ can be decomposed into a hydrostatic part $\hat{\sigma}_{\text {stat }}=\frac{1}{2} \operatorname{Tr}(\hat{\sigma}) I$, corresponding to isotropic forces that induce local expansion or shrinkage of cell areas, and a deviatoric part $\hat{\sigma}_{\text {dev }}=\hat{\sigma}-\hat{\sigma}_{\text {stat }}$ corresponding to the anisotropic forces that induce shearing or anisotropic bulk compression/stretching (Fig. 1C).

The above stresses are balanced by the external loads from the lateral and apical/basal membrane generated by cell deformation or cellular active forces [34, 35]. For simplicity, we only consider axisymmetric external load, which can be decomposed into a normal part $\sigma_{N}$ (positive pointing outward) and a tangential part along the

FIG. 1. The effect of curvature on cell packing and cellular forces. (A) Top: Scutoid geometry in epithelial tissues; point $Q$ is the additional point shared by two columnar cells. The AB-T1 transition occurs at the edges highlighted in thick brown, leading to the exchange of neighbor pair from 1-4 (apical) to 2-3 (basal). Bottom: Tilt angle of lateral membrane (yellow) and percentage of scutoids (pink) peak near the head of a wild type Drosophila embryo, adapted from [29] under a Creative Commons License. (B) Two-layered model for curved epithelia on an axisymmetric object and the coordinates for a any local surface $d A$; (C) Graphical representation of the stress tensor decomposition, Eq. (1). (D) Force balance of a curved layer under axisymmetric loads: (left) at the meridional cut (red dashed ring) and (right) along the normal direction of the element surface $d A(\varphi, \theta)$. (E) A meridional cross section view of a two-layered prolate ellipse. The black tilted line is the tilted lateral membrane, with the basal end at $s$ and the apical end at $s^{\prime}$, with the tilt angle $\phi$ and apical-basal distance $e$ at $s$. The orange curves are the accumulated cell number from the head to $s$ at the basal side; the skyblue curve is the accumulated cell number from the head to $s$ at the apical side.
meridian $\sigma_{T}$ (positive pointing to the head) and hence ${ }_{118}$ the in-plane shear $\sigma_{\theta \varphi} \approx 0$. The meridional stress $\sigma_{\varphi \varphi}$ at any local cut (red ring in Fig. 1 D ) is balanced in the polar direction by the accumulated force over the revolved ${ }^{119}$ surface as:

$$
\sigma_{\varphi \varphi} 2 \pi r \delta \sin \varphi=\int_{0}^{s(\varphi)}\left[\sigma_{N} \cos \varphi+\sigma_{T} \sin \varphi\right] 2 \pi r d s
$$

where $\delta$ is the thickness of cell membrane, $r$ is the dis- ${ }_{124}$ tance to the polar axis from the local surface $d A$ (Fig. 1 D$)_{125}$ and $d s$ is the meridional arc length (for derivation, $\mathrm{see}_{126}$ Supp. Mat. A). The circumferential stress $\sigma_{\theta \theta}$ is derived ${ }_{127}$ from force balance along the normal direction of the sur- ${ }^{128}$ face:

$$
\begin{equation*}
C_{\varphi \varphi} \sigma_{\varphi \varphi}+C_{\theta \theta} \sigma_{\theta \theta}=\frac{\sigma_{N}}{\delta} \tag{2}
\end{equation*}
$$

where $C_{\varphi \varphi}$ and $C_{\theta \theta}$ are the principal curvatures along the ${ }_{133}$ meridional and circumferential direction, respectively. ${ }^{134}$

AB-T1 transitions: The stresses in apical or basal ${ }^{135}$ layers can induce cell shape changes and cell intercala-136 tions. Here, we assume that prior to any applied exter-137 nal load, cells are relaxed to isotropic shapes without any138 deviatoric strain. AB-T1 transitions will take place most ${ }_{139}$ frequently when the apical and basal sides of a cell have ${ }_{140}$ oppositely directed deviatoric stresses [36] under exter-141 nal loading. In the absence of shear components $\sigma_{\varphi \theta}$, we ${ }_{142}$ can define a measure for AB-T1 transitions, $\gamma$, as propor-143 tional to the difference of the deviatoric strain between ${ }_{144}$
the apical and basal sides:

$$
\begin{equation*}
\gamma=\frac{\sigma_{\varphi \varphi}^{a}-\sigma_{\theta \theta}^{a}}{\mu_{a}}-\frac{\sigma_{\varphi \varphi}^{b}-\sigma_{\theta \theta}^{b}}{\mu_{b}} \tag{3}
\end{equation*}
$$

where $\mu_{a, b}$ represent the effective elastic moduli at the apical and basal surfaces; $\gamma>0$ corresponds to cells that are stretched along the meridional direction at the apical side while compressed along the circumferential direction at the basal side. The parameter-dependence of $\mu_{a, b}$ depends on the underlying material properties. As demonstrated in Supp. Mat. B taking different forms for $\mu_{a, b}$ does not alter our key conclusions. Here, we consider $\mu=|\operatorname{Tr}(\hat{\sigma})|$, which avoids introducing an intrinsic elastic modulus for the cells. Under typical physiological regimes for epithelial cells, we expect $\left|\operatorname{Tr}\left(\hat{\sigma}^{a, b}\right)\right|$ to be non-zero, so $\gamma$ behaves well.

We first consider the case when external loads are hydrostatic $\left(\sigma_{T}=0\right.$ and $\left.\sigma_{N}=P\right)$. With large curvature anisotropy, $\left|C_{\theta \theta}-C_{\varphi \varphi}\right|$, the magniture of $\gamma$ is large, leading to AB-T1 transitions. In contrast, isotropic curvatures $\left(C_{\theta \theta}=C_{\varphi \varphi}\right)$ lead to $\gamma=0$ (derivations in Supp. Mat. C). This conclusion is consistent with the experimental observations in tubular epithelia [24].

Cell tilting: The results for hydrostatic systems above are not consistent with the AB-T1 transitions observed in the head of the early Drosophila embryo [29], where the curvature is nearly isotropic. However, in this system, the cells are observed to tilt (Fig. 1A). The profile of external load $\sigma_{T}, \sigma_{N}$ is affected by tilt of lateral

FIG. 2. The lateral tilt angle in the zero-lateral-tension limit, ${ }_{189}$ Eq. 6. as a function of the distance to the head along the polar ${ }_{190}$ direction $d=z / a$ (Fig. 1E) (A) under varying inverse aspect ${ }_{191}$ ratio $b / a$ at $\varepsilon / a=0.05, \beta=0$; (B) under varying thickness ${ }^{191}$ modulation $\beta$ at $\varepsilon / a=0.01, b / a=0.4$. Experimental data is ${ }^{192}$ shown for the cell tilt angle in the early Drosophila embryo ${ }^{193}$ ( $b / a \sim 0.4, \beta \sim 0.5$ ), with s.d., by grey dots (data from [29). ${ }^{194}$
membranes. We next investigated cell tilting within our model and explain its role in inducing AB-T1 transitions. ${ }^{197}$

The tilted lateral membrane leans to the head by a small angle $\phi$ away from the normal direction (illustrated ${ }_{198}$ in Fig. 1E) as

$$
\tan \phi(s) \sim \frac{\Delta s}{e(s)} \sim \frac{N^{a}(s)-N^{b}(s)}{2 \pi r^{a}(s) e(s) \rho^{a}(s)}
$$

where $\Delta s$ is the distance between the apical projection ${ }^{203}$ of $s$ and the apical end of the tilted lateral membrane $s^{\prime} ;{ }^{204}$ $e(s)$ is the distance between the apical and basal layer; ${ }^{205}$ $\rho^{a, b}(s)$ is the cell density; $r^{a, b}(s)$ is the distance from ${ }^{206}$ $s$ to the polar axis; $N^{a, b}(s)=\int_{0}^{s} \rho^{a, b} d A^{a, b}$ are the ac- ${ }^{207}$ cumulated number of cells from the head apex to the ${ }^{208}$ coordinate $s$ on the apical and basal sides, respectively. ${ }^{209}$ Although Fig. 1E is illustrated for an prolate ellipsoid, ${ }^{210}$ Eq. 4 works for any arbitrary axisymmetric shape.

The distribution of $\rho^{a, b}(s)$ and $e(s)$ are interdepen- ${ }^{212}$ dent, as a consequence of minimizing the system free ${ }^{213}$ energy including the contributions from cell lateral mem- ${ }^{214}$ branes (Supp. Mat. E). If the lateral membrane tensions ${ }^{215}$ are weak compared with the apical and basal cell layers, ${ }^{216}$ the apico-to-basal density ratio $\rho^{a}(s) / \rho^{b}(s)$ converges to ${ }^{217}$ a space-independent constant (Supp. Mat. D). In this ${ }^{218}$ limit, the tilt angle

$$
\begin{equation*}
\phi(s)=\phi^{*}(s)(1-\tilde{k}), \tag{5}
\end{equation*}
$$

where $\tilde{k} \ll 1$ is the ratio of tension strength between the lateral and apical/basal layers; $\phi^{*}$ is the tilt in the limit of zero lateral tension, depending on the curvature as:

$$
\begin{equation*}
\tan \phi^{*}(s) \sim \frac{N^{b}(s)\left(N_{\text {total }}-N^{b}(s)\left[\overline{H\left(s_{1}\right)}-\overline{H\left(s_{2}\right)}\right]\right.}{\pi r^{a}(s) \rho^{b}(s) N_{\text {total }}}, \tag{6}
\end{equation*}
$$

where $\overline{H\left(s_{1}\right)}$ and $\overline{H\left(s_{2}\right)}$ are the mean curvature weighted ${ }_{222}$ by cell numbers in a range of $0<s_{1}<s$ and $s<s_{2}<s_{0,223}$ respectively ( $s_{0}$ is the half meridian). For a convex ob-224 ject, a large gradient of $H(s)$ corresponds to a large mag-225 nitude of $\phi^{*}$ at $s$, with the corresponding tilt direction ${ }_{226}$ towards the region of higher positive curvature (Supp. 227 Mat. E].

Conversely, if lateral membranes are extremely rigid, the lateral membrane tends to stand perpendicular to the surfaces, and $\rho^{a}(s) / \rho^{b}(s)$ equals inverse apico-to-basal area ratio $d A^{b}(s) / d A^{a}(s)$, hence the tilt vanishes (Supp. Mat. G). To further simply the model, we show that the effect of any cell density inhomogeneity on cell tilt is negligible if cell density changes along the surface more slowly than the curvature does (Supp. Mat. E). We henceforth set a homogeneous density $\rho^{a, b}(s)=\rho_{0}^{a, b}$.

Ellipsoid case: We now apply this formalism to a prolate ellipsoidal geometry as shown in Fig. 1E. It has a major half axis $a$ and minor half axis $b$ (see Supp. Mat.[Ffor parameterization and the calculation of the curvature). Tissue height is determined mainly by the intrinsic cell volume control [37. To leading order in the arc length $s$ to the head, the height profile reads

$$
\begin{equation*}
e(s) \approx \varepsilon\left[1+\beta\left(\frac{s}{s_{1 / 4}}-\frac{1}{2}\right)\right] \quad \text { for } \quad s \in\left[0, s_{1 / 4}\right] \tag{7}
\end{equation*}
$$

where $s_{1 / 4}$ is the $1 / 4$ perimeter of the meridian ellipse and $\varepsilon$ is the average cell height across the surface and $\beta$ is a coefficient modulating the surface height with $\beta=0$ representing homogeneous cell height. As we assume cell size is much smaller than the radius of curvature, the average height of the tissue $\varepsilon$ has negligible impact on the tilt profile (see discussions in Supp. Mat. E).

We calculate the cell tilt angle $\phi^{*}$ in the zero-lateraltension limit as a function of the relative distance to the head of a prolate ellipsoid, $d(s)=z(s) / a$, where $z(s)$ is the distance to the head along the polar direction; $d=0$ corresponds to the head and $d=1$ to the trunk. The tilt angle increases with elongation of the ellipsoid (smaller $b / a)$, Fig. 2A. For a typical value observed experimentally in Drosophila ( $b / a \sim 0.4$ [29]), the tilt angle peaks around $30^{\circ}$. The impact of height inhomogeneity on the tilt angle is shown by Fig. 2 B : a large, positive $\beta$ (tissue height larger at the trunk) makes the peak of the tilt angle profile more pronounced. The calculated tilt profile is consistent with the data observed in the early Drosophila embryo ( $\beta \sim 0.5$ ), with the predicted magnitude of $\phi^{*}$ (red curve) slightly larger than the experimental measurements (black dots, from [29]) as expected by Eq. 5 .

External loads along the tilted lateral membranes can qualitatively change the stress distribution. We show in Fig. 3A-B a comparison of the stress components $\sigma_{\varphi \varphi}$ and $\sigma_{\theta \theta}$ between a hydrostatic case: $\sigma_{T}^{a}=\sigma_{T}^{b}=0, \sigma_{N}^{a}=$ $-\sigma_{N}^{b}=T$ and a case with the external stresses $T$ along tilted lateral membranes:
$\sigma_{T}^{a}=T \sin \phi, \sigma_{N}^{a}=T \cos \phi, \sigma_{T}^{b}=-T \sin \phi, \sigma_{N}^{b}=-T \cos \phi$.
The magnitude of $\sigma_{\theta \theta}$ and $\sigma_{\varphi \varphi}$ grows from the head to the trunk in different manners, depending on whether $T$ is perpendicular to the shells (hydrostatic) or $T$ along the tilted lateral membranes. The resultant AB-T1 transition rate, calculated through Eq. 3, flips its sign with or without the tilt (Fig. 3C). However, this qualitative difference will vanish when the surface approaches a sphere

FIG. 3. AB-T1 transition rate $\gamma$ calculated for a prolate ${ }_{264}$ ellipsoid with $b / a=0.4$. (A) A schematic illustration of the ${ }_{265}$ system under tensile lateral stress $T$ with a constant tissue ${ }_{266}$ height $\varepsilon=0.05 a$ for panel $B$ and $C$; (B) In plane, apical and ${ }^{266}$ basal stress components normalized by $T a / \delta$ as a function of ${ }^{267}$ the distance to the head. Left: $T$ perpendicular to the layer ${ }^{268}$ (hydrostatic); right: $T$ along tilted lateral membranes. The ${ }^{269}$ cyan and magenta curves stand for a sphere $(a=b)$. The ten-270 sile stresses have a positive sign (apical,blue) and contractile ${ }^{271}$ stress has a negative sign (basal, yellow). (C) The correspon-272 dent AB -T1 rate $\gamma$ for the prolate ellipsoid. (D) A schematic ${ }_{273}$ tissue setting under the external loads with pressures and in- ${ }_{274}$ homogeneous tissue height (Eq. 7). (E) Profile of the AB- ${ }_{275}$ T1 measure, $\gamma$, with varying apical pressure difference $\Delta \Pi^{a}{ }^{276}$ and with basal pressure difference $\Delta \Pi^{b}=0$. Left: the tissue ${ }^{276}$ height modulation rate $\beta=0$; right: $\beta=0.4$. Black dots indi- ${ }^{277}$ cate the peak, where the absolute AB-T1 measure $|\gamma|$ reaches ${ }^{278}$ the maximum. (F) The phase diagram for the peakiness of $\gamma,{ }^{279}$ which is calculated as $\operatorname{sign}\left(\gamma_{\text {peak }}\right) \times \| \gamma_{\text {peak }}\left|-\left|\gamma_{\text {trunk }}\right|\right|$. Left: ${ }^{280}$ $\beta=0$; right: $\Delta \Pi^{b}=0$. The size of the scattered square is ${ }^{281}$ $\propto\left(1-d_{\text {peak }}\right)^{2}$, so positions closer to the head $(d=0)$ are rep-282 resented by larger squares. The grey contours separate the ${ }_{283}$ trunk $\left(d_{\text {peak }}>0.5\right)$ and the head $\left(d_{\text {peak }}<0.5\right)$ regions.
$(a / b=1)$ (Fig. 3B; cyan and magenta lines), leading to ${ }_{287}$ no AB-T1 transition at all locations (Fig. 3C; black line). ${ }^{288}$

Next, we discuss results with pressure differences289 across the cell along the apical-basal axis (Fig. 3D). The ${ }_{290}$ tissue height follows Eq. 7. The apical and basal mem-291 branes are subject to pressure from: the outside $P_{\text {out }} ; 292$ from the internal cavity (e.g. yolk or luminal pres-293 sure) $P_{i n}$; and inside the tissue $P_{T}$. The pressure dif-294 ferences at the apical and basal surfaces are given by ${ }_{295}$ $\Delta \Pi^{a}=P_{T}-P_{\text {out }}$ and $\Delta \Pi^{b}=P_{\text {in }}-P_{T}$ respectively, 296 with positive $\Delta \Pi$ pointing towards the outside. Before ${ }_{297}$
applying external load, we assume cells have relaxed to their preferred cell shape with no internal strain. The external normal and tangential loads on the apical and basal side are $\sigma_{N}^{(a)}=\Delta \Pi+T \cos \phi, \sigma_{T}^{(a)}=\Delta \Pi+T \sin \phi$, $\sigma_{N}^{(b)}=\Delta \Pi+T \cos \phi$ and $\quad \sigma_{T}^{(b)}=\Delta \Pi-T \sin \phi$.

The system dominated by pressure $(\Delta \Pi / T \rightarrow \infty)$ corresponds to a hydrostatic limit, Fig. 3 B (left). In this limit, the profiles of stresses and the consequent spatial distribution of $\mathrm{AB}-\mathrm{T} 1$ transition frequency do not qualitatively depend on the pressure differences or the cell height profile (Supp. Mat. C). In contrast, strikingly, when the pressure difference is comparable with lateral stress $(\Delta \Pi \sim T), \gamma$ is sensitive to the two pressure differences and $\beta$, Fig. 3E. $\Delta \Pi$ can be negative (pointing inwards), thus the normal component of lateral tension $T$ can be partly balanced by this pressure and $\sigma_{T} / \sigma_{N}$ becomes much larger as if the cells tilt more significantly. When $\Delta \Pi^{a} / T$ shifts sign from negative to positive, at the trunk $(d=1) \gamma$ becomes negative, altering the orientation of AB-T1 transitions.

To capture the key features of the distribution of $\gamma$, we define the peak of $\gamma$ as where $\gamma_{\text {peak }}$ is the maximal value of $|\gamma|$ (Fig. 3 E ) and its value at peak (referred here as the peakiness $)$ as $\operatorname{sign}\left(\gamma_{\text {peak }}\right) \times \| \gamma_{\text {peak }}\left|-\left|\gamma_{\text {trunk }}\right|\right|$. Accordingly, we can construct a phase diagram of AB-T1 transitions, using the position of the peak and peakiness as the order parameters, Fig. 3F. We show the diagram in the $\Delta \Pi^{a}-\Delta \Pi^{b}$ space for $\beta=0$ (left) and in the space of $\beta-\Delta \Pi^{a} / T$ with $\Delta \Pi^{b}=0$ (right). The peak in the tendency of AB-T1 transition switches from trunk to head beyond a critical line $\beta(\Delta \Pi)$ (Fig. 3 F ). From these phase diagrams, we can estimate mechanical properties (e.g. pressure, lateral tension, or possible external loads) from the geometric cell profiles (e.g. cell tilt, cell height and AB-T1 locations/orientations).

Conclusions: We have proposed a model for the onset of cellular tilt within a curved monolayer. We find that the interplay between the lateral cell-cell tension and the cellular tilt leads to a shift in the location at which we expect the number of neighbor rearrangements to be maximal. Our formalism provides predictions for the location of AB-T1 transitions in several geometries that are echoed by experimental observations in various geometries [24, 29].

The lateral membranes play an essential role in balancing stress across the cell, thereby regulating cell shape. In particular, lateral membranes with low contractility lead to cell tilting, which cooperates with pressure and tissue thickness to result in a rich phase diagram for the tendency of AB-T1 transitions to occur. If the lateral membranes are sufficiently stiff, then the tilt of lateral membranes is suppressed and AB-T1 transitions occur at regions with large curvature anisotropy, following the model prediction in the hydrostatic limit.

Though we have focused on a prolate geometry with simple external loads, our formalism can be generalized to a diverse range of tissue geometries observed in vivo. We expect tilt to occur at the steepest curvature gra-
dient, even for non-axisymmetric and non-closed surface ${ }_{307}$ geometries; e.g. the brain and gut. We can also explore ${ }_{308}$ the role of in-plane shear and bending within this theo-309 retical framework. Internal cell strain, which is likely sig-310 nificant during cellular process such as cell division 38, 311 can also be considered as a source of external loading. 312 Finally, transient and reversible AB-T1 transitions have $3_{313}$ been observed [39, 40; the dynamic aspect of $\mathrm{AB}-\mathrm{T} 1_{314}$ transitions may be relevant to the mechanism of T1 tran-315
sitions [23, 36] and their contributions to processes like tissue folding or buckling $41-46$ remains to be investigated.

## SUPPLEMENTARY MATERIAL

## A. Force balance in axisymmetric systems

555

For a general elastic material, the force balance in556 terms of the stress tensor $\hat{\sigma}$ is

$$
\begin{equation*}
\nabla \cdot \hat{\sigma}+\hat{F}=0 \tag{8}
\end{equation*}
$$

where $\hat{F}=\left(F_{\varphi}, F_{\theta}, F_{N}\right)^{T}$ is the external body force ex-561 erted on a element of a small volume. For a thin elastic562 shell revolved around a polar axis with distance $r(s, \theta), 563$ this body element $=d A \cdot \delta$, where $d A=r d s d \theta$ and $\delta_{564}$ represents the thickness. $d s$ is an infinitesimal length565 along the meridional direction and $r d \theta$ is an infinitesimal566 length along the circumferential direction. The radius of $\mathrm{f}_{67}$ curvature along $d s$ and $r d \theta$ are denoted as $R_{\varphi \varphi}$ and $R_{\theta \theta, 568}$ respectively. Hence $d s=R_{\varphi \varphi} d \varphi$ and $R_{\theta \theta}=r / \sin \varphi$.

For a thin shell (i.e. $\delta$ is much smaller than the typical curvature radius of the system), these quantities can ${ }^{569}$ be taken as uniform along the thickness direction, so the transverse shear can be neglected. Therefore, only the in-570 plane stresses $\sigma_{\varphi \varphi}, \sigma_{\theta \theta}$ and $\sigma_{\varphi \theta}$ are considered in the force ${ }_{571}$ balance and their derivatives along the normal directions $5_{572}$ are neglected. Furthermore, we do not consider possi-573 ble bending stresses at the discontinuity of displacement $5_{54}$ (usually at the apex of the object) due to the in-plane ${ }_{575}$ stresses $[47-49$. With these assumptions, Eq. 8 leads to576 a set of force balance equations along the meridional $\overrightarrow{d \varphi}, 577$ circumferential $\overrightarrow{d \theta}$ and normal directions to the surface
$\overrightarrow{d A}:$

578

$$
\begin{align*}
\frac{\partial\left(r \sigma_{\varphi \varphi}\right)}{\partial s}+\frac{\partial \sigma_{\theta \varphi}}{\partial \theta}-\sigma_{\theta \theta} \cos \varphi & =-F_{\varphi} r \\
\frac{\partial\left(r \sigma_{\theta \varphi}\right)}{\partial s}+\frac{\partial \sigma_{\varphi \varphi}}{\partial \theta}+\sigma_{\theta \varphi} \cos \varphi & =-F_{\theta} r  \tag{9}\\
\frac{\sigma_{\varphi \varphi}}{R_{\varphi \varphi}}+\frac{\sigma_{\theta \theta}}{R_{\theta \theta}} & =F_{N}
\end{align*}
$$

For an axisymmetric system $r(\varphi, \theta)=r(\varphi)$, we drop $_{586}$ all the terms with derivatives with $\partial \theta$ and obtain the ${ }_{587}$ axisymmetric resultant for the top and bottom equations ${ }_{588}$ in Eq. 9 as

$$
\begin{align*}
\frac{d\left(r \sigma_{\varphi \varphi}\right)}{d s}-\sigma_{\theta \theta} \cos \varphi & =-F_{\varphi} r \\
\frac{\sigma_{\varphi \varphi}}{R_{\varphi \varphi}}+\frac{\sigma_{\theta \theta}}{R_{\theta \theta}} & =F_{N} \tag{10}
\end{align*}
$$

which are independent of shear. The torsion around the ${ }_{596}$ polar axis from shear force is exclusively determined by ${ }_{597}$ the second equation in Eq. 9. For our case, $F_{\theta}=0$ so the ${ }_{598}$ shear component must also be zero throughout the space considering the boundary condition $\sigma_{\theta \varphi}(\varphi=0, \pi)=0$. ${ }^{599}$ From Eq. 10, we obtain a differential equation for $\sigma_{\varphi \varphi}$

$$
\begin{equation*}
\frac{d}{d s}\left(r \sigma_{\varphi \varphi} \sin \varphi\right)=R_{\theta \theta}\left(F_{N} \cos \varphi-F_{\varphi} \sin \varphi\right) \sin \varphi \tag{11}
\end{equation*}
$$

Integrating and multiplying Eq. 11 by a factor $2 \pi \delta$ :

$$
\begin{equation*}
2 \pi \delta r \sigma_{\varphi \varphi} \sin \varphi=2 \pi \delta \int\left(F_{N} \cos \varphi-F_{\varphi} \sin \varphi\right) r d s+F_{c} \tag{12}
\end{equation*}
$$

where the left hand-side is the total force parallel to the polar axis found at a latitudinal cross-section of the shell positioned with arc length $s$. This force is balanced by the distributed load across the surface along with a concentrated force $F_{c}$ at the apex $s=0$. The indefinite integral could be alternatively expressed by a definite integral from $s=0$ to $s=s(\varphi)$.

Here, there is no reason to consider a concentrated force at the head apex, so we set $F_{c}=0$. We define the loading from the two external stresses $\sigma_{T, N}$ per unit area such that $\delta F_{\varphi}=-\sigma_{T}$ (with a minus sign so that $\sigma_{T}>0$ points towards the head) and $\delta F_{N}=\sigma_{N}$. With these notations, Eq. 12 is equivalent to Eq. 1 in the main text.

## B. Measure for AB-T1 transition likelihood

We define a measure $\gamma$ for the tendency of finding a $\mathrm{AB}-\mathrm{T} 1$ transition as the difference in the deviatoric strain between apical and basal layers (Eq. 3). The magnitude of $\gamma$ relates to the probability of finding an AB-T1 transition, and the sign of $\gamma$ indicates the orientation of the corresponding AB-T1 transition, as described in the text.

The deviatoric strain is the deviatoric stress [36, 50], divided by an effective tissue shear modulus $\mu$ as:

$$
\begin{equation*}
\epsilon_{\mathrm{dev}}=\frac{\sigma_{\mathrm{dev}}}{\mu} . \tag{13}
\end{equation*}
$$

Here, we ignore shear and torsion so $\sigma_{\mathrm{dev}}=\sigma_{\varphi \varphi}-\sigma_{\theta \theta}$. A positive sign indicates a tensile strain along the meridian direction with a compressive strain along the circumferential direction.

The effective shear modulus $\mu$ is related to the strength of the tissue in resisting deformation in exchanging neighbors along the AB direction. This modulus depends on how the cell cortex biopolymers connect, bend, and interact in the material. Some empirical and theoretical literature has shown that the shear modulus of tissues is stiffened by pre-compression or pre-expansion of the tissue 5153 . Tension stiffening originates from a bending-to-stretching mode transition, while the mechanism of compression stiffening originates from jamming [53, 54]. In some particular cases, a tissue can even display tension strain-softening due to connections breaking between adherent regions 54.

Supposing that the pre-stress in plane is small, we have a phenomenological linear relationship for the effective shear modulus

$$
\begin{equation*}
\mu=\mu_{0}+\Xi(\hat{\sigma}) \operatorname{Tr}(\hat{\sigma}) \tag{14}
\end{equation*}
$$

where $\mu_{0}$ is the intrinsic shear modulus of the material and the trace of in plane stress tensor indicates the isotropic tensile or compressive stresses in the layer. The

FIG. S1. Comparison among different models for effective shear modulus for a prolate ellipsoid $b / a=0.4$. (A-C) Distribution of $\gamma$ for varying apical pressure differences $\Delta \Pi^{a} / T$ from top to bottom: - 0.3 (skyblue), 0 (orange), 0.3 (green), 0.6 (red), 0.9 (purple), 1.2 (brown), 1.5 (pink), 1.8 (grey), 2.1 (golden), with different values of the basal pressure difference $\Delta \Pi^{b}$ and tissue height inhomogeneity $\beta$. Horizontal axis $d$ is the relative distance; $d=0$ indicates the head of a prolate ellipsoid and $d=1$ the trunk. Black dots indicate the peak of $|\gamma|$. (D) Diagrams of peakiness, which is defined as sign $\left(\gamma_{\text {peak }}\right) \times \| \gamma_{\text {peak }}\left|-\left|\gamma_{\text {trunk }}\right|\right|$. From top to bottom: Model 1, Model 2, Model 3, Model 4. White regions indicate peak of $|\gamma|$ at trunk, whereas coloured squares indicate peak of $|\gamma|$ at near the head. The corresponding diagrams for Model 0 are presented in the main text Fig 3 F .
dimensionless coefficient $\Xi$ can have various dependen-623 cies on the stresses $\hat{\sigma}$ for a broad range of hyperelastic 62 materials. Here, we discuss several simple forms for $\Xi$.

First of all, we consider a linear prestress-stiffening, ${ }^{625}$ modeled by a positive constant $\xi$ for tensile stresses (trace of stress tensor $>0$ ) and a negative constant $-\xi$ for com- ${ }^{626}$ pressive stresses (trace of stress tensor $<0$ ); hence Eq. 14 becomes

$$
\begin{equation*}
\mu=\mu_{0}+\xi|\operatorname{Tr}(\hat{\sigma})| . \tag{15}
\end{equation*}
$$

By tuning the value of $\xi$, one can explore varying effects of prestress-stiffening in the model.

If $\xi|\operatorname{Tr}(\hat{\sigma})| \gg \mu_{0}$ (a strong prestress-stiffening), the ${ }^{629}$ intrinsic shear modulus can be ignored such that

$$
\begin{equation*}
\mu \sim \xi|\operatorname{Tr}(\hat{\sigma})| \quad(\text { Model } 0), \tag{16}
\end{equation*}
$$

which, normalized by $\xi$, is used for the results shown $\mathrm{in}_{633}^{632}$ the main text.

Oppositely, if $\xi|\operatorname{Tr}(\hat{\sigma})| \ll \mu_{0}$ (negligible prestress- ${ }^{634}$ stiffening), the effective shear modulus is dominated by ${ }^{635}$ the intrinsic shear modulus such that

$$
\begin{equation*}
\mu \sim \mu_{0} \quad \text { (Model 1). } \tag{17}
\end{equation*}
$$

There are other simple forms for $\mu$ : (i) tensionstiffening while compression-softening:

$$
\begin{equation*}
\mu \sim \exp (\xi \operatorname{Tr}(\hat{\sigma})) \quad(\text { Model } 2) ; \tag{18}
\end{equation*}
$$

(ii) only tension-stiffening;

$$
\mu \sim\left\{\begin{array}{rl}
\mu_{0} & \text { for } \operatorname{Tr}(\hat{\sigma})<0  \tag{19}\\
\mu_{0}+\xi \operatorname{Tr}(\hat{\sigma}) & \text { for } \operatorname{Tr}(\hat{\sigma})>0
\end{array} \quad(\text { Model } 3) ;\right.
$$

or (iii) only compression-stiffening:

$$
\mu \sim\left\{\begin{align*}
\mu_{0}-\xi \operatorname{Tr}(\hat{\sigma}) & \text { for } \operatorname{Tr}(\hat{\sigma})<0  \tag{20}\\
\mu_{0} & \text { for } \operatorname{Tr}(\hat{\sigma})>0
\end{align*} \quad\right. \text { (Model 4). }
$$

The comparison of $\gamma$ under these five types of effective shear modulus are shown in Fig|S1. External load acts through pressures differences $\Delta \Pi^{a}$ and $\Delta \Pi^{b}$ at apical and basal sides, along with the lateral tension $T$, as demonstrated in the main text (Fig. 3D). In Models 2, 3, 4, we set $\mu_{0}=\xi$ and all the $\gamma$ shown here are normalized by $a / \delta \xi$. In Fig $\sqrt{\text { S1D }}$, we show the diagrams of peakiness as defined in the main text in the parameter space of $\Delta \Pi^{b} / T-\Delta \Pi^{a} / T$ and $\beta-\Delta \Pi^{a} / T$ for Models 2-4.

We can see for different models of the effective modulus $\mu$, the phase diagrams of peakiness have different boundaries between the trunk region (white) and the head region (colored) in the parameter space. Both the material properties and the tissue geometry play important roles in the occurrence and positioning of the AB-T1 transitions. To distinguish the models, we refer back to the experimental observations. In the early Drosophila embryo, AB-T1 transitions are very infrequent at the anterior head of the embryo and also in the trunk region. Comparing the $\gamma$ distribution between the different models, we see that a distribution with peak in $\gamma$ near (but not at) the head with near zero value in the trunk $\left(\gamma(d=1) / \gamma_{\text {peak }} \sim 0\right)$ has a very narrow parameter space in all the models. This is because $\gamma \sim 0$ at the trunk requires pressure and stresses along the lateral membrane to be closely balanced.

## C. Deviatoric strain under hydrostatic load

In this section, we show the analysis of the deviatoric strain profile and the correspondent AB-T1 likelihood under the hydrostatic external loads. Substituting $\sigma_{T}=0, \sigma_{N}=P$ into the force balance equations Eqs. 1.2 we arrive at:

$$
\sigma_{\varphi \varphi} C_{\theta \theta}=\frac{P}{2 \delta}
$$

$$
\begin{equation*}
\sigma_{\theta \theta} C_{\theta \theta}+\sigma_{\varphi \varphi} C_{\varphi \varphi}=\frac{P}{\delta} \tag{21}
\end{equation*}
$$

Solving Eq. 21 yields the following relations:

$$
\begin{equation*}
\sigma_{\theta \theta}+\sigma_{\varphi \varphi}=\frac{P}{2 \delta C_{\theta \theta}}\left(3-\frac{C_{\varphi \varphi}}{C_{\theta \theta}}\right), \tag{22}
\end{equation*}
$$

$$
\sigma_{\varphi \varphi}-\sigma_{\theta \theta}=\frac{P}{2 \delta C_{\theta \theta}}\left(1-\frac{C_{\varphi \varphi}}{C_{\theta \theta}}\right)
$$

Substituting Eq. 22 into a general expression of the de-690 viatoric strain, with the $\mu$ defined as in Eq. 15 in Supp. 691 Mat. B, we obtain the following analytical expression of ${ }_{692}$ the deviatoric strain for a layer:

$$
\begin{equation*}
\epsilon_{\mathrm{dev}}^{p}=\frac{\operatorname{sign}(P)}{\xi} \frac{1-C_{\varphi \varphi} / C_{\theta \theta}}{2 \xi_{c} / \xi+\left|3-C_{\varphi \varphi} / C_{\theta \theta}\right|}, \tag{23}
\end{equation*}
$$

where $\xi_{c}=\delta C_{\theta \theta} \mu_{0} /|P|$.
Note that for an axisymmetric system, $C_{\theta \theta}$ is always699 positive, i.e. the small arc along the circumference is $\mathrm{s}_{700}$ always convex to the polar axis, while $C_{\varphi \varphi}$ can either $\mathrm{r}_{701}$ be positive for a convex meridian or negative for a con-702 cave one, with respect to the polar axis. Figure S2,03 is a graphical representation of a normalized deviatoric704 strain $\tilde{\epsilon}_{\mathrm{dev}}=\epsilon_{\mathrm{dev}}^{p} \xi / \operatorname{sign}(P)$ against $C_{\varphi \varphi} / C_{\theta \theta}$. When705 $C_{\varphi \varphi} / C_{\theta \theta}=1$, the two prime curvatures of a local sur-706 face are the same and under hydrostatic external loading,707 $\epsilon_{\mathrm{dev}}^{p}=0$, independent of $\xi$.

FIG. S2. The normalized deviatoric strain $\tilde{\epsilon}_{\text {dev }}$ in relation to the ratio of prime curvatures $C_{\varphi \varphi} / C_{\theta \theta}$. All $\tilde{\epsilon}_{\text {dev }}$ with various $\xi$ at isotropic curvature condition $C_{\varphi \varphi}=C_{\theta \theta}$ (magenta line). There are three typical examples of different curvature ratio below: brown (left) for $C_{\varphi \varphi} / C_{\theta \theta}<0$; yellow (middle) for $0<C_{\varphi \varphi} / C_{\theta \theta}<1$; pink (right) for $C_{\varphi \varphi} / C_{\theta \theta}>1$. The arrow indicates the polar axis. The radius of curvature $R_{\theta \theta}=1 / C_{\theta \theta}$ and $R_{\varphi \varphi}=1 / C_{\varphi \varphi}$ are highlighted by the red and blue lines respectively.

When $\xi \gg \xi_{c}$ (strong stress-stiffening, blue curves in Fig. S2, the largest magnitude of $\epsilon_{\text {stat }}^{p}$ occurs at $C_{\varphi \varphi} / C_{\theta \theta}=3$ with its value

$$
\begin{equation*}
\epsilon_{\mathrm{dev}, \text { peak }}^{p}=-\frac{1}{\xi_{c}}=-\frac{P}{\delta \mu_{0} C_{\theta \theta}} \tag{24}
\end{equation*}
$$

For a shape elongated along the polar axis without bumps, $\left|C_{\varphi \varphi}-C_{\theta \theta}\right|=3$ is not feasible. In this case, the magnitude of $\epsilon$ increases with $C_{\varphi \varphi} / C_{\theta \theta} \rightarrow-\infty$, where the curvature anisotropy $\left|C_{\varphi \varphi}-C_{\theta \theta}\right|$ becomes large.

When $\xi \ll \xi_{c}$ (weak stress-stiffening, green curves in Fig. S2 , the magnitude of $\epsilon_{\text {stat }}^{p}$ always increases with the growth anisotropy of curvature. The largest magnitude of deviatoric strain occurs with value $\epsilon_{\text {stat }}^{p}= \pm 1 / \xi$ when $C_{\varphi \varphi} / C_{\theta \theta} \rightarrow \mp \infty$.

When $\xi \sim \xi_{c}=\delta \mu_{0} C_{\theta \theta} /|P|$ (orange curve in Fig. S2), the largest magnitude of $\epsilon_{\text {stat }}^{p}$ occurs where $C_{\varphi \varphi} / C_{\theta \theta}>3$. Large $C_{\varphi \varphi} / C_{\theta \theta}$ corresponds to geometries such as bumps, see the right bottom panel in Fig. S2.

Although the strength of prestress-stiffening (value of $\xi)$ affects the magnitude of deviatoric strain in different ways for $C_{\varphi \varphi} / C_{\theta \theta}>1$, the behaviors of deviatoric strain are robust against $\xi$ for the region $C_{\varphi \varphi} / C_{\theta \theta}<1$, which is typically the curvature ratio for a regular elongated axisymmetric shape, such as an ellipsoid and cylindrical tube. In these systems, the largest magnitude of deviatoric strain occurs at the smallest value of $C_{\varphi \varphi} / C_{\theta \theta}$. If we narrow the cases to only convex surfaces, i.e. $C_{\varphi \varphi}>0$ (see the middle bottom panel in Fig. (S2), then the largest
magnitude of deviatoric strain occurs at $C_{\varphi \varphi}=0$. This corresponds to the trunk region of a prolate ellipsoid. This conclusion also holds when considering the other forms of the effective shear modulus $\mu^{a, b}$ (e.g. those discussed in Supp. Mat. B).

Let $c$ denote the ratio between two principal curvatures $C_{\varphi \varphi} / C_{\theta \theta}$. Under hydrostatic situation, the AB-T1 tendency profile $\gamma$, which is the difference of deviatoric strain between apical and basal side, becomes

$$
\begin{equation*}
\gamma^{p}(s) \sim \frac{1}{\xi}\left[\operatorname{sign}\left(P^{a}\right) \frac{1-c^{a}(s)}{\left|3-c^{a}(s)\right|}-\operatorname{sign}\left(P^{b}\right) \frac{1-c^{b}(s)}{\left|3-c^{b}(s)\right|}\right] \tag{25}
\end{equation*}
$$

for $\xi / \xi_{c} \gg 1$ and

$$
\begin{equation*}
\gamma^{p}(s) \sim \frac{1}{2 \delta \mu_{0}}\left[\frac{P^{a}}{C_{\theta \theta}^{a}(s)} \frac{1-c^{a}(s)}{\left|3-c^{a}(s)\right|}-\frac{P^{b}}{C_{\theta \theta}^{b}(s)} \frac{1-c^{b}(s)}{\left|3-c^{b}(s)\right|}\right] \tag{26}
\end{equation*}
$$

for $\xi / \xi_{c} \ll 1$.
Since the cell height $e$ is much smaller than the radius of curvature (our model assumption), $c^{a} \sim c^{b}+$ $e\left[C_{\theta \theta}^{b}-C_{\varphi \varphi}^{b}\right], C_{\theta \theta}^{a} \sim C_{\theta \theta}^{b} /\left(1+e C_{\theta \theta}^{b}\right)$, then the profile of $\gamma^{p}(s)$ is approximately proportional to the normalized hydrodtatic deviatoric strain at the basal side $\tilde{\epsilon}^{b}{ }_{\operatorname{dev}}(s)=\left[1-c^{b}(s)\right] /\left|3-c^{b}(s)\right|$ as

$$
\begin{equation*}
\gamma^{p}(s) \propto \tilde{\epsilon}_{\mathrm{dev}}(s)+\mathcal{O}\left(e(s)\left(C_{\varphi \varphi}(s)+C_{\theta \theta}(s)\right)\right. \tag{27}
\end{equation*}
$$

with a linear coefficients determined by the hydrostatic loading $P^{a, b}$ and a negligibly small correction from the ${ }_{756}$ cell height. Hence, the AB-T1 tendency under hy-757 drostatic conditions, $\gamma^{p}$, is near zero at locations with ${ }_{758}$ isotropic curvature and increases with the curvature anisotropy.

759

## D. Calculation of tilt angle of the lateral membrane on an arbitrary axisymmetric object

Fig. S3illustrates a meridional cross section for an $\mathrm{ar}^{-763}$ bitrary axisymmetic shell. A surface element $d A(\varphi, \theta)_{764}$ located at $s$ on the basal side (golden in Fig. $\overline{\mathrm{S} 3}$ ), can be $\mathrm{e}_{765}$ mapped to another surface element $d A^{a}\left(\varphi^{\prime}, \theta^{\prime}\right)$ located $_{766}$ at $s^{\prime}$ in such a way that the accumulated number of cells ${ }_{767}$ from the head of the object to $s$ on the basal side is the $\mathrm{e}_{768}$ same as the cell number accumulated from the head to $s^{\prime}{ }_{769}$ at the apical side. Hence, the angle $\phi$ between the nor-770 mal direction of the surface and $\overrightarrow{s s^{\prime}}$ is the tilt angle of the cells at $d A$. The surface element $d A=r(s) d \theta d s$, where $r(s)$ is the distance to the polar axis, and $r d \theta$ and $d s$ are $_{77}$ the two orthogonal vectors along the circumferential and meridional directions, respectively.

Given our assumption of an axisymmetric surface, the 2D integral of surface element $d A$ over the whole shell ${ }_{772}$ surface can be reduced to a 1D integral with only the ${ }_{773}$ meridional variable from 0 to $s$. The accumulated num-774 ber of cells $N$ from the head to $s$ on the basal side is is75

FIG. S3. A meridional cross section of an arbitrary axisymmetric shell with apical (navy) and basal (golden) layers. The apical layer is an outward projection of the basal layer along the normal direction at each local surface element with a distance $e$. The position $s^{\prime}$ on the apical side corresponds to position $s$ on the basal side in such a way that the cell number accumulated on the apical surface from the head to $s^{\prime}$ equals the basal one accumulated from head to $s$; therefore, the angle between the vector from $s$ to $s^{\prime}$ (black bold line) and the the surface normal direction (red dashed arrow) is the cell tilt angle $\phi$ describing the degree of cell tilt at the local surface.
given by

$$
\begin{equation*}
N^{b}(s)=\int_{0}^{s} \int_{0}^{2 \pi} \rho^{b}(s) r^{b}(s) d \theta d s=\int_{0}^{s} \rho^{b}(s) 2 \pi r^{b}(s) d s \tag{28}
\end{equation*}
$$

and it is equal to the accumulated number of cells $N^{a}$ on the apical side:

$$
\begin{equation*}
N^{b}(s)=N^{a}\left(s^{\prime}\right)=\int_{0}^{s^{\prime}} \rho^{a}\left(s^{a}\right) 2 \pi r^{a}\left(s^{a}\right) d s^{a} \tag{29}
\end{equation*}
$$

where $\rho^{b}(s)$ or $\rho^{a}(s)$ is the cell density on the basal or apical surface, $r^{b}(s)$ or $r^{a}(s)$ is the circumferential radius at $s$. The density $\rho^{a, b}(s)$ is determined by minimizing the membrane tensions on apical, basal and lateral sides. Here, we do not consider any other cues guiding cell location within the tissue environment.

The cell density at the apical side is related to that at the basal side at $s$ as $\rho^{a}(s)=\alpha(s) \rho^{b}(s)$. Since the total number of cells are the same at the two sides, the distribution of apico-to-basal ratio of density $\alpha(s)$ must follow:

$$
\begin{align*}
N_{\text {total }} & =2 \pi \int_{0}^{s_{0}} \rho^{b}(s) r^{b}(s) d s \quad(\text { basal }) \\
& =2 \pi \int_{0}^{s_{0}^{a}} \rho^{a}\left(s^{a}\right) r^{a}\left(s^{a}\right) d s^{a} \quad(\text { apical }), \tag{30}
\end{align*}
$$

where the integration of $d s^{a}$ (apical) or $d s$ (basal) is over the whole meridional range $\varphi \in[0, \pi]$ and $s_{0}^{a}$ or $s_{0}$ represents the half meridian and $N_{\text {total }}$ is the total cell number covering the shell. When the apical element $d A^{a}$ is only
a normal projection of the basal element $d A$ with a dis-805 tance $e(s)$, then one can obtain:

$$
\begin{align*}
\frac{r^{a}(s)}{r^{b}(s)} & =1+e(s) C_{\theta \theta}(s)  \tag{31}\\
\frac{d s^{a}}{d s} & =1+e(s) C_{\varphi \varphi}(s)
\end{align*}
$$

Inserting Eq. 31 into Eq. 29 leads to

$$
\begin{equation*}
\int_{0}^{s} \rho^{b}(s) r^{b}(s) d s=\int_{0}^{s^{\prime}} \alpha(s) \kappa(s) \rho^{b}(s) r^{b}(s) d s \tag{32}
\end{equation*}
$$

814
where $\kappa(s)=1+2 e(s) H(s)+e^{2}(s) G(s)$, with

$$
\begin{equation*}
H(s)=\left(C_{\theta \theta}(s)+C_{\varphi \varphi}(s)\right) / 2 \tag{33}
\end{equation*}
$$

the mean curvature and

$$
\begin{equation*}
G(s)=C_{\theta \theta}(s) C_{\varphi \varphi}(s) \tag{34}
\end{equation*}
$$

the Gaussian curvature.
Equation 32 now only depends on quantities with $\mathrm{Su}_{816}$ perscript $b$, so for neatness we omit this superscript from ${ }_{817}$ here and write $\rho^{b}(s)=\rho(s), N^{b}(s)=N(s)$. Reorganizing ${ }_{818}$ the integration on the right hand side, we can transform 819 Eq. 32 into

$$
\begin{align*}
& =\int_{0}^{s}(\alpha(s) \kappa(s)-1) \rho(s) r(s) d s  \tag{35}\\
& =\frac{1}{2 \pi}\left(N^{a}(s)-N(s)\right)
\end{align*}
$$

For $s^{\prime}-s \rightarrow 0$, the left hand side of Eq. 35 is approximated as

$$
\begin{equation*}
\int_{s^{\prime}}^{s} \alpha(s) \kappa(s) \rho(s) r(s) d s \sim \alpha(s) \rho(s) r^{a}(s) \Delta s(s) \tag{36}
\end{equation*}
$$

where $\Delta s$ is the arc length difference from $s$ to $s^{\prime}$ at the apical side. Accordingly, Eq. 35 becomes

$$
\begin{equation*}
\alpha(s) r^{a}(s) \rho(s) \Delta s(s)=\int_{0}^{s}(\alpha(s) \kappa(s)-1) \rho(s) r(s) d s \tag{37}
\end{equation*}
$$

We then derive the tilt angle $\phi$ as:

$$
\begin{equation*}
\tan \phi(s) \approx \frac{\Delta s}{e(s)}=\frac{\int_{0}^{s}(\alpha(s) \kappa(s)-1) \rho(s) r(s) d s}{r^{a}(s) e(s) \alpha(s) \rho(s)} \tag{38}
\end{equation*}
$$

or in a more compact form

$$
\begin{equation*}
\tan \phi(s) \sim \frac{N^{a}(s)-N^{b}(s)}{2 \pi r^{a}(s) e(s) \alpha(s) \rho(s)} \tag{39}
\end{equation*}
$$

as shown in Eq. 4 in the main text.
Now we consider two extreme cases. If the the lat-841 eral membrane tension overwhelms the apical/basal layer ${ }_{842}$
tension, the lateral membranes tend to stand perpendicularly to the basal side. In this case, we have $\alpha(s)=$ $1 / \kappa(s)$, so that $\phi(s)$ is zero across the space. By contrast, if the lateral membranes have low contractility compared with the apical/basal membranes, the cells tend to adjust the area sizes in both layers into homogeneous distributions, so that $\alpha$ becomes independent of the local curvature. We can derive a form for $\alpha$ as:

$$
\begin{equation*}
\alpha^{*}=\frac{\int_{0}^{s_{0}} \rho(s) r(s) d s}{\int_{0}^{s_{0}} \kappa(s) \rho(s) r(s) d s} \tag{40}
\end{equation*}
$$

Inserting Eq. 40 into Eq. 38 gives

$$
\begin{align*}
& \tan \phi^{*}(s) \approx \\
& \frac{\int_{0}^{s} d s_{1} \int_{0}^{s_{0}} d s_{2}\left[\left(\kappa\left(s_{1}\right)-\kappa\left(s_{2}\right)\right) \rho\left(s_{1}\right) r\left(s_{1}\right) \rho\left(s_{2}\right) r\left(s_{2}\right)\right]}{r^{a}(s) e(s) \rho(s)\left(N_{\text {total }} / 2 \pi\right)} \\
& =\frac{\int_{0}^{s} d s_{1} \int_{s}^{s_{0}} d s_{2}\left[\left(\kappa\left(s_{1}\right)-\kappa\left(s_{2}\right)\right) \rho\left(s_{1}\right) r\left(s_{1}\right) \rho\left(s_{2}\right) r\left(s_{2}\right)\right]}{r^{a}(s) e(s) \rho(s)\left(N_{\text {total }} / 2 \pi\right)} . \tag{41}
\end{align*}
$$

As the cell size is much smaller than the radius of curvature, $\kappa\left(s_{1}\right)-\kappa\left(s_{2}\right) \sim 2\left[e\left(s_{1}\right) H\left(s_{1}\right)-e\left(s_{2}\right) H\left(s_{2}\right)\right]$ with the second order term neglected. To clearly see the dependency of $\phi^{*}$ on curvature, we transform the integration of $d s$ in Eq. 41 into integration by local cell number $d N(s)=2 \pi \rho(s) r(s) d s$ as

$$
\begin{equation*}
\tan \phi^{*}(s) \approx \frac{\int_{0}^{s} d N\left(s_{1}\right) \int_{s}^{s_{0}} d N\left(s_{2}\right)\left[\kappa\left(s_{1}\right)-\kappa\left(s_{2}\right)\right]}{2 \pi r^{a}(s) e(s) \rho(s) N_{\text {total }}} \tag{42}
\end{equation*}
$$

The integral $\int_{x}^{y} \kappa(s) d N(s)$ could be alternatively expressed as $\overline{\kappa(s)} \times[N(y)-N(x)]$, where

$$
\begin{equation*}
\overline{\kappa(s)}=\frac{\int_{x}^{y} \kappa(s) d N(s)}{N(y)-N(y)} \tag{43}
\end{equation*}
$$

is the weighted average of $\kappa(s)$ in the range of $x<s<y$. Hence, Eq. 42 be expressed as

$$
\begin{equation*}
\tan \phi^{*}(s) \approx \frac{N(s)\left(N_{\text {total }}-N(s)\right)\left[\overline{\kappa\left(s_{1}\right)}-\overline{\kappa\left(s_{2}\right)}\right]}{2 \pi r^{a}(s) e(s) \rho(s) N_{\text {total }}} \tag{44}
\end{equation*}
$$

As long as the change of cell height $e(s)$ with $s$ is less radical than the change of curvature, we can approximate the difference of $\kappa$ mainly by the change of mean curvature as $\overline{\kappa\left(s_{1}\right)}-\overline{\kappa\left(s_{2}\right)} \sim e(s)\left[\overline{H\left(s_{1}\right)}-\overline{H\left(s_{2}\right)}\right]$, and finally we arrives at Eq. 6 in the main text.

We can relate the difference between the weighted average of the mean curvature to the mean curvature gradient. For $\bar{H}$ averaged from $x<s<y$, according to the integral mean value theorem, we can always find an $\bar{s} \in(x, y)$ such that $H(\bar{s})=\overline{H(s)}$. Hence, the difference of $\bar{H}$ could be re-expressed as

$$
\begin{equation*}
\overline{H\left(s_{1}\right)}-\overline{H\left(s_{2}\right)}=H(\bar{s})-H(\overline{\tilde{s}}) \tag{45}
\end{equation*}
$$

where $0<\bar{s}<s$ and $s<\overline{\tilde{s}}<s_{0}$. Since $\bar{H}$ is the average weighted by the cell number at $s, \bar{s}$ and $\overline{\tilde{s}}$ should be close
to where the local cell number $d N(s)$ is large, i.e., where ${ }_{889}$ $\rho(s) r(s)$ is large. If the cell density does not radically ${ }_{890}$ change with $s, r(s)$ will dominate where $\bar{s}$ and $\overline{\tilde{s}}$ locates.

When $s \rightarrow 0$ or $s \rightarrow s_{0}, \phi^{*}$ is close to zero because $N(s)\left(N_{\text {total }}-N(s)\right) \rightarrow 0$ and the contribution from the ${ }^{891}$ curvature becomes trivial. When $s$ is neither close to the head $(s=0)$ nor the tail $\left(s=s_{0}\right)$, if the surface is convex, $r(s)$ is large and $\bar{s}$ and $\tilde{\tilde{s}}$ will be in a vicinity of $s$, where the distance $r(\bar{s})$ and $r(\overline{\tilde{s}})$ is relatively large. According to the mean value theorem, we could find another $s^{*} \in$ $(\bar{s}, \overline{\tilde{s}})$ such that

$$
\begin{equation*}
H^{\prime}\left(s^{*}\right)(\bar{s}-\overline{\tilde{s}})=H(\bar{s})-H(\overline{\tilde{s}}), \tag{46}
\end{equation*}
$$

where $H^{\prime}$ is the gradient of curvature and $s^{*}$ is even more close to $s$ than $\bar{s}$ and $\overline{\tilde{s}}$. If the gradient of curvature is also continuous and differentiable (as seen in the ellipsoidal or tubular structures in biological systems), $H^{\prime}\left(s^{*}\right) \approx H^{\prime}(s)+\left(s^{*}-s\right) H^{\prime \prime}(s) ;$ therefore, given a steep ${ }^{892}$ mean curvature gradient at $s$, we predict a large tilt an- ${ }^{893}$ gle $\phi^{*}$ at $s$ in the zero-lateral-tension limit, as long as $s^{894}$ is not at the head or the tail. Meanwhile, since $\bar{s}-\tilde{\bar{s}}<0,{ }^{895}$ a negative gradient of curvature along $s$ corresponds to ${ }^{896}$ the positive tilt angle towards the head. In other words, ${ }^{897}$ the tilt will lean to the vicinity of $s$ with a higher positive ${ }^{898}$ curvature.

For more general cases, where the cells are subject to ${ }^{900}$ both the lateral and apical/basal layers, the distribution ${ }^{901}$ of $\alpha(s)$ is between $1 / \kappa(s)$ and $\alpha^{*}$. Without other active sources, density projection rate $\alpha(s)$ together with the cell basal density $\rho(s)$, and cell thickness $e(s)$ are the mechanical consequence of cells minimizing their free9oz energy as discussed further in Supp. Mat. G.

## E. Further simplifying the model for tilt

Using the mean value theorem to eliminate the integral905 Eq. 41, we obtain:

$$
\tan \phi(s) \approx \frac{s\left(s_{0}-s\right)[(\kappa(\bar{s})-\kappa(\overline{\tilde{s}})) \rho(\bar{s}) r(\bar{s}) \rho(\overline{\tilde{s}}) r(\overline{\tilde{s}})]}{r^{a}(s) e(s) \rho(s)\left(N_{\text {total }} / 2 \pi\right)}
$$

$(47)^{910}$
We can further simplify the model by setting a homo- ${ }^{911}$ geneous density $\rho(s) \sim \rho_{0}$ and $e(s) \sim \varepsilon$ to arrive at a tilt ${ }^{912}$ profile purely depending on the geometry of the surface: ${ }^{913}$

$$
\begin{equation*}
\tan \phi^{\mathrm{H}}(s) \approx \frac{s\left(s_{0}-s\right)[(H(\bar{s})-H(\overline{\tilde{s}})) r(\bar{s}) r(\overline{\tilde{s}})]}{\left(1+\varepsilon C_{\theta \theta}\right) r(s)\left(A_{\text {total }} / 2 \pi\right)} \tag{48}
\end{equation*}
$$

917
We can now evaluate the contributions from height ${ }^{918}$ modulation and basal density modulation separately. We ${ }^{919}$ define $\hat{s}$ such that the total cell number at the apical side ${ }^{920}$ $N_{\text {total }}=\rho(\hat{s}) A_{\text {total }}$, where $\rho(\hat{s})$ is a weighted average of ${ }^{921}$ density from $s=0$ to $s=s_{0}$. According to Eq. 48, the tilt ${ }^{922}$ profile with modulated inhomogeneous density becomes ${ }^{923}$

$$
\begin{equation*}
\tan \phi(s) \approx \tan \phi^{\mathrm{H}}(s) \frac{\rho(\overline{\tilde{s}}) \rho(\bar{s})}{\rho(s) \rho(\hat{s})} \tag{49}
\end{equation*}
$$

If $\rho(s)$ is nearly homogeneous as $|d \rho / d s| \ll 1$, we assume $\rho(s) \sim \rho_{0}\left[1+\eta(s)(s-\hat{s}) / s_{0}\right]$ with $|\eta(s)| \ll 1$. Then,

$$
\begin{equation*}
\frac{\rho(\overline{\tilde{s}}) \rho(\bar{s})}{\rho(s) \rho(\hat{s})} \sim 1+\eta[\bar{s}+\overline{\tilde{s}}-s-\hat{s}] / s_{0}+\mathcal{O}\left(\eta^{2}\right) \tag{50}
\end{equation*}
$$

Recall that $\hat{s}$ is the averaged position weighted by $\rho(s) r(s)$ while $\bar{s}$ and $\overline{\tilde{s}}$ is the averaged position weighted by $\kappa(s) \rho(s) r(s)$. With a radius of surface curvature much larger than the typical cell size $-\kappa$ is only slightly larger than 1 (an assumption of our model) - we approximately have $\bar{s}<\hat{s}<\overline{\tilde{s}}$. In this case, the first order term in $\eta$ is negligible. In particular,

$$
\frac{\rho(\overline{\tilde{s}}) \rho(\bar{s})}{\rho(s) \rho(\hat{s})}<1
$$

is valid when $\rho(s)$ is a monotonic function. Therefore, the tilt angle under mild inhomogeneity of density is always slightly smaller the scenario with homogeneous density.

The tilt profile with modulated inhomogeneous cell height $e(s)$ can be evaluated similarly, supposing $e(s)=$ $\varepsilon\left(1+\eta^{\prime}(s)(s-\hat{s}) / s_{0}\right)$ with $\left|\eta^{\prime}(s)\right| \ll 1$. Clearly, the value of $\varepsilon$ has negligible effect on the result as long as $\varepsilon H(s) \ll 1$ (our basic model assumption) is valid.

Then, the tilt profile corrected by inhomogeneous cell height is

$$
\begin{align*}
& \tan \phi(s) \approx \tan \phi^{\mathrm{H}}(s)(1 \\
& \quad+\eta^{\prime}[(\bar{s}-s) H(\bar{s})-(\overline{\tilde{s}}-s) H(\overline{\tilde{s}})] / s_{0}  \tag{51}\\
& \left.\quad+\mathcal{O}\left(\eta^{\prime 2}\right)\right)
\end{align*}
$$

which has a more significant first order correction term in $H(\bar{s})$ than Eq. 49 . Therefore, inhomogeneity in cell height causes greater deviation of the tilt angle from the homogeneous limit $\phi^{\mathrm{H}}$ than inhomogeneity in cell density.

In Fig. S4, we show the tilt profile and corresponding phase diagram for the AB-T1 transition measure for a prolate ellipsoidal system with $b / a=0.4$ and $\varepsilon / a=0.05$. The horizontal axis is the relative distance to the head and $d=1$ represents the trunk. Tissue height and basal density are modulated linearly with $s$, with coefficients $\beta$ and $\lambda$ respectively. Modulation of density slightly suppresses the final tilt angle (the straight curves slightly lower than the dashed curves). Meanwhile, modulation of height affects the tilt more significantly, not only affecting the magnitude but also the shape of the distribution profile (as compared with the yellow lines, which corresponds to a homogeneous or zero modulation limit).

In conclusion, assuming the change of cell shape is relatively small to the change of curvature along the surface, we can simplify the model by ignoring the interdependency between the cell height and density. We just consider the inhomogeneity of cell height modulation, while keeping the density in either apical or basal side in a homogeneous setting.

FIG. S4. Results with an inhomogeneous basal density distribution modulated as $\rho(s)=\rho_{0}\left[1+\lambda\left(s / s_{1 / 4}-1 / 2\right)\right]$ and inhomogeneous cell height distribution $e(s)=\varepsilon\left[1+\beta\left(s / s_{1 / 4}-1 / 2\right)\right]$, where $s$ is the arc length along the prime meridian surface and $s_{1 / 4}$ is the $1 / 4$ arc length. The system is a prolate with $b / a=0.4$ and tissue height $\varepsilon / a=0.05$. (A) A comparison of tilt angle profile between $\lambda=\beta$ (straight) and $\lambda=0$ (dashed) for varying $\beta$ from -0.4 to 0.4 . (B) A comparison of phase diagrams for the peak of the AB-T1 transition measure $\gamma$ (main text Eq. 3). The color indicates the peak prominence, calculated as $\operatorname{sign}\left(\gamma_{\text {peak }}\right) \times \| \gamma_{\text {peak }}\left|-\left|\gamma_{\text {trunk }}\right|\right|$, and the size of the data square scales as $\propto\left(1-d_{\text {peak }}\right)^{2}$ for a demonstration of the peak position. The closer the peak to the trunk, the smaller the data squares. If $d_{p e a k}=1$ (peak at the trunk), the square is not visible.

## F. Tissue geometry on the surface of a prolate ${ }_{952} d A^{a}(t)$ at the basal side are ellipsoid

Prolate spheroids were generated from revolving an ellipse around its the long axis as shown in Fig. S5A. An arbitrary point $(x, y, z)$ on the surface of a prolate ellipsoid in 3D obeys

$$
\begin{equation*}
\frac{x^{2}+y^{2}}{b^{2}}+\frac{z^{2}}{a^{2}}=1 \tag{52}
\end{equation*}
$$

where $z$ axis is the polar axis and $\sqrt{x^{2}+y^{2}}=r$ is the ${ }^{956}$ radial distance from the point to the polar axis $z$. Conventionally, $r$ and $z$ can be parameterized as

$$
\begin{equation*}
r=b \sin t, \quad z=a \cos t \tag{53}
\end{equation*}
$$

where $\pi / 2-t$ is the reduced latitude of a spheroid. ${ }^{961}$ Considering elliptical symmetry, we discuss just the first quadrant $(0<t<\pi / 2)$ in the following equations. The962 angle $\varphi$ between the normal direction of a surface element and the polar axis is a function of $t$ as

$$
\begin{equation*}
\varphi=\arctan \left(\frac{a}{b} \tan t\right) . \tag{54}
\end{equation*}
$$

We assume the basal side of tissue is a surface of the ${ }^{967}$ prolate, while the apical side of the tissue is a projection ${ }_{969}^{968}$ on the normal direction with a distance

$$
\begin{equation*}
e(t)=\varepsilon\left[1+\beta\left(s(t) / s_{1 / 4}-\frac{1}{2}\right)\right] \tag{55}
\end{equation*}
$$

where $s(t)$ is the arc length at $t, s_{1 / 4}$ is $1 / 4$ the ellipse ${ }_{975}$ perimeter and $\beta$ is the rate of modulation of the tissue ${ }_{976}$ height. Note that $d s(t)=R_{\varphi \varphi}(t) d \varphi(t)$.

The two principal curvatures of the surface element978

$$
\begin{align*}
C_{\theta \theta}^{b}(t) & =\frac{1}{R_{\theta \theta}^{b}(t)}=\frac{\sin \varphi(t)}{r(t)}=\frac{a}{b\left(a^{2} \sin ^{2} t+b^{2} \cos ^{2} t\right)^{1 / 2}} \\
C_{\varphi \varphi}^{b}(t) & =\frac{1}{R_{\varphi \varphi}^{b}(t)}=\frac{a b}{\left(a^{2} \sin ^{2} t+b^{2} \cos ^{2} t\right)^{3 / 2}} \tag{56}
\end{align*}
$$

The curvature at the apical side depends on the tissue height $e(t)$ as

$$
\begin{equation*}
C_{\theta \theta}^{a}=\frac{1}{1 / C_{\theta \theta}^{b}(t)+e(t)}, C_{\varphi \varphi}^{a}=\frac{1}{1 / C_{\varphi \varphi}^{b}(t)+e(t)} \tag{57}
\end{equation*}
$$

The projected area element at the apical side $d A^{a}(t)$ is larger than the area at the basal side $d A^{b}(t)$ by a ratio that decreases from the head of the prolate to the trunk due to the varying local principal curvatures. This area ratio can be expressed as:

$$
\begin{equation*}
\frac{d A^{a}(t)}{d A^{b}(t)}=\frac{r^{a}(t) d s^{a}(t) d \theta}{\left.r^{b}(t) d s^{b}(t)\right) d \theta}=\frac{C_{\varphi \varphi}^{b}(t) C_{\theta \theta}^{b}(t)}{C_{\varphi \varphi}^{a}(t) C_{\theta \theta}^{a}(t)} \tag{58}
\end{equation*}
$$

The horizontal axis $d=1-\cos (t) \in[0,1]$ quantifies how close the point is to the head of the spheroid along the polar axis. For a smaller inverse aspect ratio $b / a$, the apico-to-basal area ratio is much larger at the head so that it decreases more sharply (straight curves for $b / a=0.3$ and dashed curves for $b / a=0.4$, Fig. S5]. For $b=a$, the prolate ellipsoid is reduced to a sphere and the two principal curvatures become identical at any $t$, so that the apico-to-basal area ratio remains constant everywhere (inset in Fig. $\mathrm{S5B}$ ). Meanwhile, a larger thickness of tissue causes a larger difference between the head and the trunk (different colors in Fig. S5B). The two stars in Fig. S5B indicate the area ratio measured from cells in the experiments $(\sim 1.35$ near the head and $\sim 1.23$ near the trunk) for a relative thickness of tissue about 0.05 and an inverse aspect ratio $b / a \sim 0.4$. Comparing these two

FIG. S5. Apical to basal surface area on a prolate ellipsoid!1018 (A) Illustration of the prolate ellipsoid. (B-D) Ratio of apicalo19 to basal area with different distance between the apical and ${ }_{020}$ the basal sides $(\epsilon)$ as a function of the arc length as $e(s) \overline{1}_{1021}$ $\varepsilon\left[1+\left(\beta s / s_{1 / 4}-1 / 2\right)\right]$, where $s_{0}$ is the $1 / 4$ of the perimeter of ${ }_{1022}$ the meridian ellipse. (B) $\beta=0$; (C) $\beta<0$; (D) $\beta>0$. Different colors indicate different tissue heights $\varepsilon$. All the insets in (BD) are for a spherical system $(a=b)$. As a comparison, the ${ }^{1023}$ two stars are the measured area ratios in the experimental data from [29] for wild type embryos; the ratio at the head iso24 about 1.35 for the anterior side $(d<0.15)$ and the ratio atoro the trunk is about 1.23 for the trunk side $(d>0.7)$.
 that the cells at the apical surface, as measured in [29], are not perfectly normal projections of the basal layer. See Fig. S5CC-D for the area ratios under inhomogeneous tissue height.

The cell packing - which determines the cell areas ono32 apical, basal and lateral sides - reaches a stable config ${ }^{\text {to3 }}$ uration when the system finds its minimal free energy. Here, we derive several analytical expressions for the tilto34 angle based on a mechanical model of cell geometry regulation. Following the established literature of vertexo35 models [35, 43, 44, we describe the forces regulating theors cell shape tissue as a derivative of the following free ento37 ergy function:

$$
\begin{equation*}
E=\Sigma_{i}\left[k^{a}\left(A_{i}^{a}-A_{i, 0}^{a}\right)^{2}+k^{b}\left(A_{i}^{b}-A_{i, 0}^{b}\right)^{2}+k^{l} A_{i}^{l}\right], \tag{59}
\end{equation*}
$$ where $\left.A_{i, 0}^{a(o r}{ }^{b}\right)$ is the preferred cell area at the apical (o ${ }^{104042}$ basal) layer for each cell $i . k^{a(o r ~ b)}$ is the apical (or basal) $)_{03}$ elasticity coefficient and $k^{l}$ is the lateral tension strength,1044 $A_{i}^{a}, A_{i}^{b}$ and $A_{i}^{l}$ are the areas of cell $i$ at apical, basal ando45

lateral surfaces respectively.

$$
\begin{equation*}
\Sigma_{i} A_{i}^{a}=\Sigma_{i} A_{i, 0}^{a}=A_{\text {total }}^{a}, \Sigma_{i} A_{i}^{b}=\Sigma_{i} A_{i, 0}^{b}=A_{\text {total }}^{b} . \tag{60}
\end{equation*}
$$

The packing equilibrium corresponds to the minimum of the free energy (Eq. 59) under the surface constraints given by Eq. 60

If the lateral membrane is far less contractile than the apical and basal membranes, i.e., $k^{l} \ll k^{a, b} A_{i, 0}^{a, b}$, the minimization of this free energy will cause the cell to optimize its area towards $A_{i, 0}^{a, b}$ in the apical and basal sides and the lateral membrane will tilt when the local curvatures of the shell change along the surface. By contrast, if $k^{l} \gg k^{a, b} A_{i, 0}^{a, b}$, the minimization of the free energy leads to the lateral membrane orientating perpendicular to the apical and basal sides, with the cell apical area becoming a normal projection of the basal area, depending on the local curvatures. This can be seen from calculating the functional derivatives of Eq. 59
For a demonstrative purpose, we show a derivation in a 2D equivalent and assume the preferred area of cells is homogeneous along the surface such that $A_{i, 0}^{a, b}=A_{0}^{a, b}$. We first discuss a case without the single-cell volume constraint and then extend to a case with the volume constraint. The free energy in a 2D system is

$$
\begin{equation*}
E_{2 D}=\Sigma_{i}\left[k^{a}\left(s_{i}^{a}-s_{0}^{a}\right)^{2}+k^{b}\left(s_{i}^{b}-s_{0}^{b}\right)^{2}+k^{l} s_{i}^{l}\right], \tag{61}
\end{equation*}
$$

where $s_{i}^{a, b}$ are the arc lengths of the cell at the apical or basal sides and $s_{i}^{l}$ is the length of the cell lateral membrane. Note that cell height $e_{i}=s_{i}^{l} \cos \varphi_{i}$, where $\varphi_{i}$ is the tilt of lateral membrane of cell $i$. Minimizing this free energy constrains the cell side lengths so that the functional derivatives of the free energy become zero:

$$
\left\{\begin{array}{l}
\frac{\delta E_{2 D}}{\delta s_{i}^{a}}=2 k^{a}\left(s_{i}^{a}-s_{0}^{a}\right)+k^{l} \frac{\delta s_{i}^{l}}{\delta s_{i}^{a}}=0  \tag{62}\\
\frac{\delta E_{2 D}}{\delta s_{i}^{b}}=2 k^{b}\left(s_{i}^{b}-s_{0}^{b}\right)+k^{l} \frac{\delta s_{i}^{l}}{\delta s_{i}^{b}}=0
\end{array}\right.
$$

where $s_{i}^{l}=\sqrt{\Delta^{2} s_{i}+e_{i}^{2}}$ as depicted by the line $s s^{\prime}$ in Fig. S3 The surface constraint (Eq. 60) accordingly turns into a 1D form as

$$
\begin{equation*}
\Sigma_{i} s_{i}^{a}=\Sigma_{i} s_{0}^{a}=s_{\text {total }}^{a}, \Sigma_{i} s_{i}^{b}=\Sigma_{i} s_{0}^{b}=s_{\text {total }}^{b} . \tag{63}
\end{equation*}
$$

For simplicity, we assume $k^{b} \rightarrow \infty$ (due to the symmetry of the energy function, this assumption is equivalent to the case with a finite $k^{b}$ but $k^{a} \rightarrow \infty$ ), meaning that the basal layer is solid and thus the second equation in Eq. 62 can be ignored with $s_{i}^{b}=s_{0}^{b}$.

Note that $\Delta s_{i}$ is also the difference between the $\Sigma_{0}^{i} s^{\prime}{ }_{j}$, which is the accumulated normal projection length from the basal arc, and $\Sigma_{0}^{i} s_{j}^{a}$, which is the accumulated apical arc length at cell $i$. Let $\kappa_{i}\left(C_{i}, e_{i}\right)$ be the normal projection rate merely depending on the curvature $C_{i}$ and cell height $e_{i}$ of cell $i$, and $\alpha_{i}=s_{i}^{b} / s_{i}^{a}$ be the ratio of basal
length over apical length of cell $i$ (in the large cell num+o68 ber limit, this quantity is equivalently defined before as the apico-to-basal ratio of cell density), then

$$
\begin{equation*}
\Delta s_{i}=\Sigma_{0}^{i}\left(\kappa_{j} \alpha_{j}-1\right) s_{j}^{b} / \alpha_{j}=\Delta s_{i-1}+\kappa_{i} s_{i}^{b}-s_{i}^{a} \tag{64}
\end{equation*}
$$

Eq. 62 then becomes

$$
\begin{equation*}
2 k^{a}\left(s_{i}^{a}-s_{0}^{a}\right)+k^{l}\left(\frac{\delta \Delta^{2} s_{i}}{s_{i}^{l} \delta s_{i}^{a}}+\frac{\delta e_{i}^{2}}{s_{i}^{l} \delta s_{i}^{a}}\right)=0 . \tag{65}
\end{equation*}
$$

Without the volume constraint, the cell height distri ${ }^{1073}$ bution $e_{i}$ is a consequence of multiple regulators, hence ${ }^{1074}$ we take $\delta e_{i}^{2} / \delta s_{i}^{a}=0$. Eq. 65 reduces to:

$$
\begin{equation*}
2 k^{a}\left(s_{i}^{a}-s_{0}^{a}\right)+k^{l} \frac{2 \Delta s_{i} \delta \Delta s_{i}}{s_{i}^{l} \delta s_{i}^{a}}=0 . \tag{66}
\end{equation*}
$$

Inserting Eq. 64 into Eq. 66 we get

$$
\begin{equation*}
k^{a}\left(s_{i}^{a}-s_{0}^{a}\right) \sqrt{\Delta^{2} s_{i}+e_{i}^{2}}=k^{l} \Delta s_{i} . \tag{67}
\end{equation*}
$$

Let $\tilde{k}$ be $k^{l} / k^{a} e_{i}$. For an extreme limit $\tilde{k} \gg 1$ (rigid ${ }^{88}$ lateral membrane) we get

$$
\begin{equation*}
s_{i}^{a} \sim \kappa_{i} s_{0}^{b}\left[1+\left(\frac{1}{\kappa_{i} \alpha}-1\right) \frac{1}{\tilde{k}}\right]+\mathcal{O}\left(\frac{1}{\tilde{k}^{2}}\right), \tag{68}
\end{equation*}
$$

and for another extreme limit $\tilde{k} \ll 1$ (less contractile ${ }^{1084}$ lateral membrane) we get

$$
\begin{equation*}
s_{i}^{a} \sim s_{0}^{a}\left[1+\left(\Sigma_{0}^{i}\left(\kappa_{j} \alpha-1\right)-\frac{\Delta \bar{s}}{s_{0}^{a}}\right) \tilde{k}\right]+\mathcal{O}\left(\tilde{k}^{2}\right) \tag{69}
\end{equation*}
$$

where $\alpha=s_{0}^{b} / s_{0}^{a}$, depending purely on the geometri $G_{088}$ information of the surfaces, and $\Delta \bar{s}=\Sigma_{i}^{N-1} \Delta s_{i}^{*} / N$ is theor9 average tilted angle in a zero limit of lateral membraneo90 contractility.

For a rigid membrane ( $\tilde{k} \gg 1$, Eq. 68 , the tilt angle is

$$
\begin{equation*}
\phi_{i} \sim \frac{\Delta s_{i}^{*}}{\tilde{k} e_{i}} \sim 0 . \tag{70}
\end{equation*}
$$

For a membrane with small contractility, $(\tilde{k} \ll 1$, Eq. 69 , substituting Eq. 69 into Eq. 64 leads to

$$
\begin{equation*}
\phi_{i} \sim \phi_{i}^{*}\left[1-K_{i} \tilde{k}\right] \tag{71}
\end{equation*}
$$

where $0<K_{i} \sim 1$.
We next consider the effects of cell volume constraints. Now, the cell height, in relation to the basal and apical lengths, becomes

$$
\begin{equation*}
e_{i}\left(s_{i}^{a}+s_{i}^{b}\right)=A \tag{72}
\end{equation*}
$$

Inserting Eq. 72 into Eq. 65 and also assuming $s_{i}^{b}=s_{0}^{b}$, we obtain:

$$
\begin{equation*}
k^{a}\left(s_{i}^{a}-s_{0}^{a}\right)=k^{l}\left(\frac{\Delta s_{i}}{s_{i}^{l}}+\frac{A e_{i}}{s_{i}^{l}\left(s_{i}^{a}+s_{0}^{b}\right)^{2}}\right) . \tag{73}
\end{equation*}
$$

For a low contractility membrane, let $\tilde{k}$ be $k^{l} / k^{a} e_{i} \gg 1$, then

$$
\begin{equation*}
s_{i}^{a} \sim s_{0}^{a}+\tilde{k}\left[\Sigma_{0}^{i}\left(\kappa_{j} \alpha-1\right) s_{0}^{a}+\frac{A^{2}}{\left[s_{0}^{a}(1+\alpha)\right]^{3}}\right]+\mathcal{O}\left(\tilde{k}^{2}\right) \tag{74}
\end{equation*}
$$

which has a correction term from the volume constraint $A$ in the first order term of $\tilde{k}$ as compared with Eq. 69 . The tilt angle becomes

$$
\begin{equation*}
\phi_{i} \sim \phi_{i}^{*}\left(1-\tilde{K}_{i} \tilde{k}\right) \tag{75}
\end{equation*}
$$

where $\tilde{K}$ also has a correction $\sim 1$ term from the volume constraint. Similarly, one can get the results under volume constraint for a rigid lateral membrane limit (not shown here).
