Abstract

Genome instability is a hallmark of cancer. The most common form of genome instability is chromosomal instability (CIN), a condition in which cells mis-segregate their chromosomes during cell division. CIN leads to aneuploidy, a state of karyotype imbalance, often found in tumors. Although the causal relationship between CIN and aneuploidy is well established, evidence is limited for a direct involvement of aneuploidy in promoting CIN. Here, we show that aneuploid cells experience DNA replication stress in their first S-phase and precipitate in a state of continuous CIN, eventually accumulating complex karyotypes. Mechanistically, we find that aneuploid cells fire dormant replication origins through a Dbf4-dependent kinase (DDK)-driven mechanism and complete replication of genomic loci through mitotic DNA synthesis (MiDAS). By following the fate of aneuploid cells, we also show that, when they divide, DNA damage can be distributed asymmetrically between daughter cells, and this may partially explain why some aneuploid cells are able to continue proliferating and others stop dividing. We further found that cycling aneuploid cells display lower karyotype complexity compared to arrested ones and increased expression of gene signatures associated to DNA repair. Interestingly, by stratifying aneuploid human cancer cells by their doubling times, we found the same DNA repair signatures to be upregulated in highly-proliferative cancer cells, which might enable them to keep proliferating despite the disadvantage conferred by aneuploidy-induced genome instability. In summary, our study reveals the origins of genome instability following induction of aneuploidy and indicates the aneuploid state of cancer cells as a point mutation-independent source of genome instability, providing an explanation for the high occurrence of aneuploidy in tumors.

Introduction

Chromosomal instability (CIN), a condition of continuous chromosome mis-segregation, is a pervasive feature of tumors [1–4]. CIN confers enhanced evolutionary capabilities on cancer cells by increasing intratumor heterogeneity and by enabling chemoresistance [5–8]. CIN leads invariably to aneuploidy, a state of karyotype imbalances, found in more than 90% of solid tumors and about 65% of blood cancers [9]. The presence of aneuploid karyotypes leads to several detrimental defects, including proteotoxic stress [10–12], metabolic alterations [13] and induction of DNA damage [10,14–18]. Importantly, the presence of aneuploid karyotypes strongly correlates with poor patient prognosis [3]. This might be due to the fact that specific aneuploid karyotypes could confer a proliferative advantage, thus fueling tumorigenesis [7,8] and promoting survival under sub-optimal conditions [5,6]. Such an advantage could be explained by the possibility that aneuploidy induces CIN (and, more broadly, genome instability), which might enable a continuous sculpting of the genome, eventually

63 leading to cumulative haploinsufficiency and triplosensitivity [19,20] of genes crucial for sustained
64 proliferation. In agreement with this idea, studies in yeast have demonstrated that gain of a single
65 chromosome leads to defective DNA damage repair [15]. Further, aneuploid strains often divide in
66 presence of unrepaired DNA, which triggers chromosomal translocations [21]. Similar observations
67 were made in higher eukaryotes [22]. For example, a comparison between trisomic and diploid human
68 cells has revealed that aneuploid cells are characterized by increased frequency of lagging
69 chromosomes in anaphase [23,24]. Thus, this evidence points at aneuploidy as an instigator of genome
70 instability [20]. It is plausible that this instability is due to the strong impact of karyotype abnormalities
71 on gene expression and protein homeostasis. In fact, aneuploid cells were found to display imbalances
72 in factors critical for DNA replication (such as MCM2-7), DNA repair and mitosis [17], processes that
73 are all fundamental for the maintenance of genome integrity. In line with this possibility, our previous
74 studies have revealed that aneuploid cells exhibit an increased S-phase duration, display reduced
75 DNA replication fork rate and increased fork stalling [17,18]. Due to the intrinsic genomic instability
76 and other stresses typically associated with aneuploidy, cells with abnormal karyotypes often exhibit
77 delayed cell cycle progression. In some cases, they even lose their proliferative capacity and stop
78 dividing [1,18,25], resulting in their reduced sensitivity to chemotherapies [26–28].

79 Given the high prevalence of unbalanced karyotypes in tumors and its impact on the proliferation of
80 cancer cells [5–8], elucidating the contribution of aneuploidy to genome instability, deciphering the
81 molecular mechanisms by which it occurs and deconvolving its cellular consequences remain of
82 paramount importance in cancer biology.

83 Here, by inducing controlled chromosome mis-segregation in otherwise pseudo-diploid human cells,
84 we set out to identify the origins of genome instability in aneuploid cells and to understand whether
85 protective mechanisms operate to preserve genome integrity. Our data indicate that in the first S phase
86 following chromosome mis-segregation, aneuploid cells fire dormant replication origins through a
87 DDK-dependent mechanism and complete replication of genomic loci through mitotic DNA
88 synthesis (MiDAS). Importantly, those pathways, acting both in interphase and mitosis, are crucial
89 for aneuploid cells to protect them against further genome instability. We also show that the DNA
90 damage associated with aneuploidy can be distributed asymmetrically between daughter cells during
91 cell division and this, at least partially, can explain why some cells (*i.e.* those who have inherited
92 most of the damage) stop dividing. By establishing a novel method for the separation of arrested and
93 cycling aneuploid cells, we found that cycling aneuploid cells exhibit increased expression of DNA
94 repair genes. Interestingly, the same transcriptional signature was upregulated in cancer cells
95 characterized by high proliferative capacity. We speculate that elevated expression of DNA damage
96 repair genes in highly proliferative cancers is able to help them counteracting the burden associated

97   with genome instability, allowing them to benefit from a continuous reshuffling of the karyotype,

98   which is crucial to sustain enhanced proliferation [5,6]. Finally, we speculate that interfering with those

99   pathways, including DDK-mediated origin firing and MiDAS, is crucial for limiting DNA damage

100 and might provide novel therapeutic interventions in cancer therapy. An example of this is given by

101 ongoing clinical trials involving agents inhibiting DDK-mediated origin firing (*e.g.*,

102 ClinicalTrials.gov Identifier: NCT03096054 and NCT05028218), and our work might help in the

103 stratification of patients who could benefit from those treatments based on their proliferative capacity.

104

Results

Identification of mechanisms responsible for tolerance to aneuploidy-induced replication stress

107 Aneuploidy is associated with increasing genome instability [20], affecting the fidelity of both genome

108 replication and segregation. To dissect the mechanisms through which aneuploid cells seek to limit

109 this instability and thus keep proliferating, we quantified the direct effects of aneuploidy on genome

110 integrity. For this, we analyzed chromosome aberrations immediately after the induction of mitotic

111 errors (1st mitosis) and after one cell cycle later (2nd mitosis). To this aim, we synchronized

112 untransformed and genomically-stable, pseudo-diploid hTERT RPE-1 cells at the G1/S border and,

113 after release into the cell cycle, pulsed them with DMSO (vehicle control) or reversine, an Mps1

114 inhibitor widely-used to generate aneuploid cells as a consequence of chromosome segregation errors

115 [29]. Cells were then either harvested for karyotype analysis of the 1st mitosis or, after reversine wash-

116 out, allowed to continue in the cell cycle, and then harvested for the same purpose in the 2nd mitosis

117 (Fig. 1a). By doing so, analysis of 1st mitosis provided a measurement of the degree of chromosome

118 aberrations directly caused by aneuploidy induction, whereas quantification of 2nd mitosis allowed

119 for the estimation of genome alteration as a consequence of harboring aneuploid karyotypes. By using

120 multi-color FISH (mFISH), we found abnormal events – including gains, losses and translocations –

121 in both the 1st and 2nd mitoses (Fig. 1b,c and Extended Data Fig. 1a,b). Importantly, the percentage

122 of cells harboring more than 10 abnormal events more than doubled from the 1st to the 2nd mitosis

123 (Fig. 1b,c), indicating that the aneuploid state *per se* negatively impacts genome stability. To decipher

124 how aneuploidy affects genome integrity, we examined at high resolution the 1st S phase of newly-

125 generated aneuploid cells. For this, we used three complementary approaches: 1) ultra-structural

126 visualization of replication forks through electron microscopy (EM), 2) single-cell analysis of

127 replication stress and DNA damage markers by immunofluorescence and 3) assessment of replication

128 dynamics by DNA combing (Fig. 1d). These efforts led to three key observations. First, EM analysis

129 of replication intermediates revealed an increase in reversed replication forks in aneuploid cells,

130 compared to pseudo-diploid counterparts (Fig. 1e,f). Accumulation of these intermediates is

131   associated with an increased frequency of replication fork stalling [30] and is consistent with previous

132   observations of ongoing replication stress in aneuploid cells [18]. Further, aneuploid cells displayed

133   increased levels of DNA replication stress and DNA damage markers such as FANCD2 (mean foci

134   in control: 15,2 ± 1,9; aneuploid: 47,7 ± 4,6), RPA (mean foci in control: 10,6 ± 1,8; aneuploid 16,3

135   ± 2) and pChk1 (mean foci in control: 23 ± 1,8; aneuploid 33,3 ± 3,1) (Fig. 1g-l). Among them, the

136   number of FANCD2 foci per S phase cell was found to be even higher in aneuploid cells than in cells

137   treated with the DNA replication inhibitor aphidicolin, used as a positive control (FANCD2 mean

138   foci in aphidicolin-treated cells: 40,7 ± 3; RPA mean foci 49 ± 3,9; pChk1 mean foci 44,1 ± 2,6) (Fig.

139   1h). Finally, we found that fork density and origin firing rate in aneuploid cells were higher than

140   euploid counterparts (Fig. 1m-o), suggesting that dormant replication origins were fired in the 1st S

141   phase following chromosome mis-segregation events. In our previous study we reported that

142   aneuploid cells have reduced fork rate and a higher number of stalled forks as compared to euploid

143   cells (Santaguida et al., 2017). Cells activate dormant origins in response to reduced fork rate and

144   stalled forks to ensure that the genome gets fully replicated in time. Hence, we estimated origin firing

145   rate and fork density, calculated as the total number of forks per Mb of DNA [31]. The total origin firing

146   rate was 2-fold higher in aneuploid cells compared to euploid cells (p=1,5x10^{-34}). Consistent with the

147   origin firing data, fork density was also 1,7-fold higher in aneuploid cells (p=7,46x10^{-13}). Analog-

148   specific estimations for both the parameters also showed similar trends. Our data is also consistent

149   with increased origin firing observed in aneuploid human pluripotent stem cells [32]. Overall our data

150   shows that aneuploid cells struggle to complete replication and therefore activate backup mechanisms

151   such as dormant origin firing to ensure genome duplication and tolerance of replication stress.

152   Altogether, these data provide crucial insights into the effects of aneuploidy on genome integrity. We

153   find that 1) cells harboring aneuploid karyotypes tend to accumulate increasing levels of chromosome

154   abnormalities. Importantly, 2) those defects might be the consequence of DNA replication stress, and

155   3) are correlated with a higher incidence of replication fork reversal and increased DNA damage

156   markers. Finally, 4) at the same time, aneuploid cells also show an increased usage of dormant origins,

157   which we speculate it might act as a mechanism to tolerate aneuploidy-induced replication stress.

158

Aneuploid cells rely on DDK to cope with replication stress

160   Dormant origin firing is a well-known rescue mechanism that protects cells during replication stress

161   [33]. To test whether aneuploid cells would also rely on this salvage mechanism, we inhibited the

162   activity of DDK, a key player in origin firing [34–37]. For this, aneuploid cells or pseudo-diploid

163   counterparts (generated as in Fig. 1a) were arrested in late G1 (after the 1st mitosis) and then released

164   in the presence or absence of the DDK inhibitor XL413 [38] (Fig. 2a). After 6 hours, cells were pulsed

165 with the thymidine analogue ethynyl deoxy-uridine (EdU) for 30 minutes to label S phase cells and

166 then fixed and stained for FANCD2, RPA and pChk1. We find that inhibition of DDK led to

167 significantly increased levels of FANCD2 (mean foci in control: $40,9 \pm 2,9$; control + DDKi: $52,6 \pm$

168 $2,9$; aneuploid $72,2 \pm 3,5$; aneuploid + DDKi: $84,5 \pm 4,9$), RPA (mean foci in control: $56,3 \pm 3,7$;

169 control + DDKi: $36,2 \pm 2,9$; aneuploid $83,5 \pm 5,8$; aneuploid + DDKi: $103,9 \pm 6,4$) and pChk1 (mean

170 foci in control: $44,1 \pm 2,6$; control + DDKi: $44,9 \pm 2,8$; aneuploid $62,9 \pm 4,2$; aneuploid + DDKi: $74,7$

171 $\pm 4,2$) in aneuploid cells, indicating that replication stress is exacerbated when interfering with

172 dormant origin firing through DDK inhibition (Fig. 2b-g). These results prompted us to test whether

173 DDK activity, and its involvement in dormant origin firing, would also be critical for aneuploid cell

174 proliferation. Interestingly, we found that aneuploid cells were more sensitive to DDK inhibition

175 compared to pseudo-diploid counterparts (Fig. 2h,i), indicating that they rely more than euploid cells

176 on the function of DDK to survive. Altogether, our data show that DDK-mediated origin firing

177 represents a protective mechanism that acts in S phase of aneuploid cells to limit replication stress.

178 Importantly, inhibition of this mechanism exacerbates replication stress in aneuploid cells and

179 reduces their viability.

180

181 **Aneuploid cells undergo mitotic DNA synthesis to limit the consequences of replication stress**

182 **on genome stability**

183 DNA replication stress - defined as any slowing or stalling of replication fork progression and/or

184 DNA synthesis [39] - impacts mitotic fidelity [40–42]. Thus, we thought to study how the events occurring

185 in the 1st S phase of aneuploid cells affect the following cell division. To this aim, we performed live-

186 cell imaging experiments with hTERT RPE-1 cells stably expressing PCNA-GFP and H2b-RFP. This

187 allowed to monitor S phase length through the measurement of time elapsed between appearance and

188 disappearance of PCNA foci (a well-known feature of this DNA clamping factor, [43]) and mitotic

189 timing and quality by tracking chromosomes through H2b. Cells were synchronized with thymidine,

190 then pulsed with reversine while they were transiting through the 1st mitosis. Cells were then washed-

191 out and imaged every 10 minutes for 72 hours in order to evaluate the duration of the first S phase

192 after chromosome mis-segregation and the quality of the 2nd mitosis (Fig. 3a,b). First, we found that

193 aneuploid cells displayed a longer S phase compared to euploid controls (mean S phase length in

194 control: $540,1 \pm 17,82$; aneuploid: $662,5 \pm 29,89$. Extended Data Fig. 1c), in agreement with the fact

195 that they experience ongoing DNA replication stress and in line with previous reports [17,18]. Next, we

196 decided to correlate S phase length to the quality of the 2nd mitosis. Thus, we classified mitotic figures

197 in "normal mitoses", for those not displaying defects, and "abnormal mitoses", for those showing

198 mitotic errors, including chromatin bridges, lagging chromosomes or micronuclei in the following

6

199 G1. Interestingly, we found a positive correlation between S phase length and frequency of abnormal

200 mitoses (mean S phase length in control: $603,3 \pm 55,4$; aneuploid: $728,7 \pm 46,2$) (Fig. 3c). Further,

201 aneuploid cells that displayed mitotic errors spent more time in mitosis (Fig. 3d), which we could

202 fully attribute to spindle-assembly checkpoint activation, since SAC inhibition rescued this delay

203 (Extended Data Fig. 1d).

204 Based on the evidence that aneuploid cells suffer from replication stress in the 1st S phase following

205 chromosome mis-segregation events, we wanted to investigate whether they would attempt to finish

206 DNA replication in the subsequent mitosis, as previously discovered in cancer cells as a consequence

207 of S phase stress [44]. In order to evaluate mitotic DNA synthesis (MiDAS) pathway activation,

208 aneuploid cells generated as in Fig. 1a were arrested at the G2/M boundary with the CDK1 inhibitor

209 RO3306 and released in the presence of EdU and Colcemid to monitor sites of active DNA synthesis

210 in prometaphase cells. We observed that the number of EdU foci per spread was significantly higher

211 in aneuploid cells in comparison to the control (mean EdU foci in control: $0,1 \pm 0,04$; aneuploid: $0,9$

212 $\pm 0,1$; Fig. 3e,f). The DNA replication inhibitor aphidicolin was added in S phase as replication stress

213 inducer (mean EdU foci: $2,6 \pm 0,3$) [45]. Next, to test the efficacy of MiDAS in fixing unfinished DNA

214 replication, we inhibited the pathway and evaluated the consequences on genome stability in the

215 following G1 (Fig. 3g). To this aim, we first tested if MiDAS could be inhibited by adding a high

216 dose of aphidicolin in mitosis similarly as observed in cancer cells [44,46,47]. Our results showed that

217 indeed this was the case, since the number of EdU foci per prometaphase cell was significantly

218 reduced upon addition of aphidicolin in mitosis (mean EdU foci in control: $0,2 \pm 0,1$; control +

219 MiDASi: $0,1 \pm 0,03$; aneuploid: $1,3 \pm 0,2$; aneuploid + MiDASi: $0,5 \pm 0,1$; Fig. 3H and I). As readouts

220 of genome instability, we analyzed 53BP1 bodies and micronuclei in the G1 phase after the 2nd mitosis

221 in which MiDAS had occurred. We found that both 53BP1 bodies per cell and the frequency of G1

222 cells with micronuclei were significantly increased in aneuploid cells in which MiDAS was inhibited

223 in comparison with those in which MiDAS occurred properly (Fig. 3j-l). This correlation was also

224 observed in aphidicolin-treated cells (mean EdU foci: $4,5 \pm 0,6$; + MiDASi: $0,7 \pm 0,3$), in agreement

225 with previous studies [44]. Altogether, our data demonstrate that MiDAS acts as a safeguard mechanism

226 in the 2nd mitosis to prevent genome instability from further increasing.

227

228 **Dormant origin firing and MiDAS protect aneuploid cells from further increase in genome**

229 **instability**

230 The results obtained from the characterization of the first S phase after chromosome mis-segregation

231 and the subsequent mitosis revealed two protective mechanisms operating in aneuploid cells with the

232 role of limiting genome instability. To test if the combined action of these two pathways indeed serves

233   to protect aneuploid cells, we simultaneously inhibited DDK in S phase and MiDAS in the subsequent

234   M phase and evaluated DNA damage and chromosomal aberrations in the following G1 phase (Fig.

235   4a). As DNA damage markers, we used FANCD2, a reliable replication stress/DNA damage marker

236   in aneuploid cells (Fig. 1h), and γH2AX, an early marker of DNA double-stranded breaks [48]. To

237   specifically look at G1 cells, we used cytochalasin B to block cytokinesis and analyze daughter cells

238   (Fenech and Morley 1985). We observed that the number of both FANCD2 and γH2AX foci was

239   significantly higher in aneuploid cells in which DDK and MiDAS were inhibited compared to

240   aneuploid cells in which only either DDK or MiDAS was hindered (Fig. 4b-d). Interestingly,

241   inhibition of those pathways led to an increase in FANCD2 and γH2AX foci also in euploid cells,

242   highlighting that their proper functioning is crucial for maintaining genome integrity. Then, to assess

243   the frequency of chromosomal aberrations upon DDK and MiDAS inhibition, G1 cells were treated

244   with the PP1/PP2A phosphatase inhibitor calyculin A to induce premature DNA condensation [50] and

245   obtain metaphase-like spreads. By mFISH analysis, we were able to observe an almost 2-fold increase

246   in the percentage of cells with translocations between aneuploid cells in which DDK and MiDAS

247   were or were not inhibited (mean percentage of cells with at least 1 translocation in aneuploid cells:

248   33,4; in aneuploid cells + DDKi + MiDASi: 63,2) (Fig. 4e-g). Taken together, these data indicate that

249   the presence of both pathways protects aneuploid cells from further increasing their genome

250   instability.

251   Interestingly, while scoring DNA damage in G1 cells we noticed that distribution of FANCD2 or

252   γH2AX foci in aneuploid cells was not always symmetric between daughter cells. Thus, we decided

253   to specifically look at the pattern of DNA damage inheritance in the aneuploid sample and the euploid

254   control, along with aphidicolin-treated cells where it has been recently shown that DNA damage can

255   be distributed asymmetrically between daughters [51]. Our data indicated that FANCD2 and γH2AX

256   foci were asymmetrically distributed in about 20% and 10% of aneuploid daughter cells, respectively

257   (Fig. 4h-j). These data suggested that non-random distribution of DNA damage between aneuploid

258   daughter cells could underlie the difference in proliferation observed among aneuploid cells [18,25].

259

A novel method to separate arrested and cycling aneuploid cells

261   The asymmetric inheritance of DNA damage and cell fate determinants have been hypothesized to

262   underlie stem cell self-renewal [52,53]. Thus, based on asymmetric portioning of DNA damage markers

263   in aneuploid cells (Fig. 4h-j), we reasoned that, like stem cells, they might segregate DNA damage

264   asymmetrically, partially explaining why some aneuploid cells can keep cycling while others get

265   arrested and enter senescence [18,25]. To test this hypothesis, we first needed to confirm that a proportion

266   of aneuploid cells indeed gets arrested in the cell cycle and becomes senescent over time. Hence, we

267   let aneuploid cells progress for about 3 cell cycles before harvesting them for β-galactosidase staining,

268   a widely used marker of senescence [54]. As a positive control, we used cells treated with doxorubicin

269   for 7 days, as DNA damage is an established senescence-inducer [55]. Our results indicated that, as

270   expected [18], there was a sub-population of senescent cells in the aneuploid sample (Fig. 5a). In order

271   to characterize, in detail, the aneuploid cells that were still able to cycle and those that underwent

272   senescence, we decided to establish a novel method for their isolation and separation. For this, we

273   reasoned that the main (and, at the same time, potentially exploitable) difference between aneuploid

274   cycling and arrested cells is that the latter are senescent. Thus, we developed a FACS-sorting based

275   assay employing the fluorescent substrate of the β-galactosidase enzyme (which is highly active in

276   senescent cells) 9H-(1,3-dichloro-9,9-dimethylacridin-2-one-7-yl) β-d-galactopyranoside (DDAOG)

277   [56]. We then exposed aneuploid cells to DDAOG and separated cells that were able to metabolize it

278   (*i.e.*, senescent cells) from those that could not metabolize it (*i.e.*, cycling cells) (Fig. 5b,c; Extended

279   Data Fig. 2a). First, we confirmed that sorted cells were indeed either arrested or cycling by β-

280   galactosidase staining and found the former to be highly reactive to senescence-associated β-

281   galactosidase staining (Fig. 5d). Further, we used hTERT FUCCI RPE-1 cells [57] to obtain the cell

282   cycle profile of the two sorted aneuploid cell populations, together with the aneuploid sample before

283   sorting and the euploid control (Extended Data Fig. 2b). Our data confirmed that aneuploid cells

284   positive for DDAOG were indeed arrested, since the vast majority of them (86 ± 14,1%) were stuck

285   in G1, as expected for senescent cells. On the other hand, negative ones were able to proliferate

286   (Extended Data Fig. 2c and Fig. 5e,f) and the percentage of G1 cells were 24% (± 8,5%) (Extended

287   Data Fig. 2c and Fig. 5e,f). Collectively, these data indicate that our method allows for the successful

288   separation and recovery of arrested and cycling aneuploid cells that could be used for further analysis

289   and characterization of the two populations.

290

291   **Cell cycle arrest in aneuploid cells is due to both DNA damage and karyotype complexity**

292   To validate our hypothesis that asymmetric inheritance of DNA damage would contribute to cell

293   cycle arrest in aneuploid cells, we evaluated DNA damage in cycling and arrested aneuploid cells,

294   together with aneuploid cells before sorting and the euploid control. Our data indicate that aneuploid

295   arrested cells display increased levels of FANCD2 and γH2AX foci compared to aneuploid cycling

296   cells (mean FANCD2 foci in aneuploid arrested: 71,8 ± 3,9; in aneuploid cycling: 46,9 ± 2,2; mean

297   γH2AX foci in aneuploid arrested: 6,4 ± 1,1; in aneuploid cycling 2,4 ± 0,5) (Fig. 5g-i). Further, we

298   also analyzed the karyotype of cycling and arrested aneuploid cells by single-cell whole genome

299   sequencing (scWGS) and observed an increased frequency of cells with at least 3 aneuploid

300   chromosomes in arrested aneuploid cells (Fig. 5j,k). Altogether, these data show that both DNA

301   damage and severe karyotype imbalances contribute to cell cycle arrest in aneuploid cells.

302

303   **Cycling aneuploid cells display increased expression of DNA repair genes**

304   In line with reduced DNA damage and karyotype abnormalities in the aneuploid cells that retained

305   their proliferation capacity, we found that the frequency of mitotic errors (such as anaphase bridges

306   and micronuclei) in aneuploid cycling cells was comparable to that of the controls for at least 3

307   generations by live-cell imaging (Fig. 6a-c). This result suggests that the karyotype of these cells is

308   likely to remain stable over time, which is indicative of low levels of genome instability in aneuploid

309   cycling cells. This also indicates that aneuploidy does not invariably leads to CIN and it suggests that

310   specific chromosome assortments are more prone than others to be genomically unstable, reflecting

311   imbalances of specific genes crucial for genome replication and segregation. Having established a

312   tool to separate the two sub-populations of aneuploid cells, we turned our attention to the

313   identification of features distinguishing aneuploid cycling cells from those that arrested. To address

314   this question, we decided to analyze their transcriptional signatures via RNAseq. This analysis

315   revealed that the two samples are indeed quite different (Fig. 6d). In particular, aneuploid arrested

316   cells displayed overexpression of p53 and inflammation-related genes, in agreement with previous

317   findings [18]. Conversely, aneuploid cycling cells, as expected based on their retained ability to divide,

318   exhibited increased expression of cell cycle genes compared to aneuploid arrested cells. Interestingly,

319   we also noticed that DNA damage and repair genes were overexpressed in aneuploid cycling cells

320   (Fig. 6d and Extended Data Table 1). To further highlight differences in gene expression between the

321   two subpopulations of aneuploid cells, we generated a heatmap showing that the main DNA repair

322   related gene categories are more expressed in cycling *vs* arrested aneuploid cells (Fig. 6e). In line

323   with this, when exposed to ionizing radiation (IR), cycling aneuploid cells were able to repair DNA

324   damage more efficiently than the arrested ones (Extended Fig. 3a and Fig. 6f,g). Indeed, we measured

325   a faster decay kinetics of γH2AX and 53BP1 levels in the cycling population compared to the arrested

326   one (Extended Fig. 3a and Fig. 6f,g). Non-sorted aneuploid cells were also included in the analysis,

327   and they turned out to have a lower efficiency compared to the euploid controls in fixing IR-induced

328   DNA damage (Extended Fig. 3). Importantly, the activation of DNA damage repair pathways in

329   aneuploid cells is consistent with our recent findings in cancer [27] and untransformed cells [58]. We

330   therefore hypothesized that higher expression of DNA damage repair genes would confer a growth

331   advantage to the cells. To confirm this, we turned to the CCLE (Cancer Cell Line Encyclopedia)

332   database [59,60] to analyze the association between doubling time and DNA damage repair gene

333   expression in more than 400 human cancer cell lines. We divided the cell lines into top and bottom

334 quartiles based on their doubling times, and then compared their gene expression profiles. Cells with

335 a low doubling time (<35 hours) exhibited increased expression of DNA repair related gene signatures

336 in comparison to cells with a high doubling time (>65 hours) (Fig. 6i-j), suggesting that elevated

337 expression of this gene category can confer a proliferative advantage to aneuploid cells and make

338 them able to cycle despite the disadvantage conferred by the aneuploid status. Altogether, our data

339 revealed the existence of protective mechanisms in aneuploid cells, namely DDK-mediated origin

340 firing in S phase and MiDAS in the subsequent mitosis, which operate in order to limit their genome

341 instability (Fig. 7). Also, cell cycle arrest in aneuploid cells is due to not only the degree of karyotype

342 aberrations but also to the levels of DNA damage harbored by the cells. Importantly, an increased

343 capacity to repair DNA damage confers a proliferative advantage not only to untransformed but also

344 to cancer aneuploid cells (Fig. 7).

345

Discussion

347 Genome instability is an established hallmark of cancer [61]. Its most common form is chromosomal

348 instability (CIN), which has been shown to promote tumorigenesis and confer proliferative

349 advantages to cancer cells [5–8]. Because CIN refers to a condition of continuous chromosome

350 missegregation, this indicates that genomic instability can directly cause aneuploidy. In this study,

351 we demonstrated that aneuploidy can also instigate genome instability. By combining biochemical

352 and live cell imaging experiments with single-molecule replication-mapping technologies and single-

353 cell multi-omics analysis, we found that the acquisition of unbalanced karyotypes can directly

354 contribute to genome instability, which in turn yields a diverse array of karyotypic landscapes. This

355 effect feeds a self-sustaining loop, in which aneuploidy leads to CIN, thus generating more aneuploid

356 daughter cells able to propagate genome diversity through continuous errors during genome

357 replication and segregation.

358 Previous reports have shown that aneuploid cells can experience replication stress [17,18]. Here, we

359 show that dormant origin firing operates during the first S phase following chromosome mis-

360 segregation and acts as a protective mechanism to cope with replication stress. The fact that DDK

361 inhibition impacts on aneuploid cell viability reveals the importance of this pathway in the context of

362 karyotype imbalances. Although we identified DDK-mediated dormant origin firing as a protective

363 mechanism operating in the 1st S phase of aneuploid cells, it is still unclear what exactly triggers it,

364 *i.e.* what are the actual sources of replication stress in cells with abnormal karyotypes. Many possible

365 sources of DNA replication stress have been described so far, which include difficulties in the

366 template DNA (*e.g.*, repetitive sequences and/or secondary structures), collisions between the

367 replication fork and the transcriptional machinery, nucleotide pool imbalances and scarcity of

11

368   replication factors to perform DNA synthesis [39]. Among them, insufficient amount of replication

369   factors seems to be the most likely cause of replication stress in aneuploid cells, based on the fact that

370   decreased levels of MCM2-7 proteins were reported in RPE-1 and HCT116 stable aneuploid clones

371   with defined trisomies [17]. Also, a recent work has revealed that tetraploid cells encounter replication

372   stress as a result of insufficiency of DNA replication factors [62], a mechanism that could also apply to

373   aneuploid cells. Because in our system we observe dormant origin firing, we speculate that the

374   limiting DNA replication factors are those downstream of origin firing, such as PCNA, RFC and

375   DNA polymerases [63]. Future studies will be aimed at exploring this possibility, with the goal of

376   elucidating the contributions of those factors in DNA replication of aneuploid cells. This line of study

377   might also open novel therapeutic interventions through selective targeting of aneuploid cancer cells

378   by targeting those limiting DNA replication factors.

379   Along this line, another important implication of our finding that DDK and MiDAS play a central

380   role in helping cells coping with aneuploidy is that these mechanisms could well be targetable

381   vulnerabilities of aneuploid cancers. Although it might be challenging to selectively target MiDAS -

382   its key players SLX4-MUS81, RAD52 and POLD3 [44,46] are also involved in other processes beyond

383   MiDAS, such as homologous recombination (HR) repair and canonical S phase DNA replication –

384   things could be different for DDK. In particular, the DDK inhibitor TAK-931 was recently tested in

385   a phase 2 clinical trial for the treatment of advanced solid tumors [64]. Based on our study, we speculate

386   that this drug (and similar ones) could be combined with inhibitors of DNA repair, such as the

387   products of genes playing a role in HR repair, since they were the most differentially regulated in our

388   analysis (Extended Table 1). Thus, the combined inhibition of DDK and HR repair factors could

389   potentially be very effective to treat aneuploid cancers. This approach would have the great advantage

390   of being highly selective against cancer aneuploid cells, lowering the side-effects of the DNA repair-

391   based cancer therapies and the frequent chemoresistance associated with them [65].

392   In summary, by providing a detailed characterization of the role of aneuploid karyotypes in the

393   acquisition of aggressive cancer-like features, we demonstrate that aneuploidy provides a point

394   mutation-independent source of genome instability. Although this might offer a source of karyotypic

395   variations capable of enabling proliferative capacity of cancer cells, it also leads to extensive DNA

396   damage. Thus, we speculate that aneuploidy-induced genome instability might be a double-edged

397   sword for cancer cells. On one hand, it is crucial for providing genome plasticity, on the other it might

398   be extremely deleterious because of continuous DNA damage and replication stress. We propose that

399   cancer cells solve this issue by limiting DNA damage - through upregulation of DNA repair genes -

400   to a level compatible with cell proliferation. At the same time, this allows them to keep some degree

401   of genomic instability and thus to continuously sample diverse karyotypic landscapes. Our

402 observation shed new light on the bidirectional association between aneuploidy and genomic
403 instability and propose new approaches for the selective eradication of aneuploid tumors.
404

Methods

405

Cell culture conditions

406

407 hTERT RPE-1 cells, including those expressing H2b-RFP and PCNA-GFP or H2b-GFP or LCK-
408 GFP (all generated in house) and the hTERT Fluorescent Ubiquitination-based Cell Cycle Indicator
409 (FUCCI) RPE-1 (kind gift of Professor Simona Polo, IFOM, Milan, Italy), were all tested free of
410 mycoplasma contamination using Myco Alert (Lonza) according to manufacturer's instructions. All
411 the cells were maintained in a humified environment at 37 degrees with 5% CO_2 and cultured in
412 Dulbecco's modified Eagle's medium (DMEM) supplemented with 10% fetal bovine serum and 1%
413 penicillin/streptamycin.

414

Cell synchronization and treatments

415

416 To harvest metaphase cells for mFISH analysis, hTERT RPE-1 cells were pulsed with the Mps1
417 inhibitor reversine (500nM, Cayman Chemical) or the vehicle control (dimethyl sulfoxide, DMSO)
418 for 24 hours and then harvested for karyotype analysis either immediately after the pulse ('1st
419 mitosis') or 24 hours later ('2nd mitosis'). In both cases, colcemid (100ng/ml, Merck Millipore) was
420 added 2 hours before harvesting the cells in order to block cells in prometaphase. To perform ultra-
421 structural analysis of replication intermediates and analyze replication dynamics, cells were treated
422 as above and analyzed immediately after the 24-hour reversine/DMSO pulse.

423 To analyze DNA replication stress markers in S phase, hTERT RPE-1 cells were plated onto
424 fibronectin (5μg/ml, Sigma-Aldrich) coated coverslips at approximately 30% confluence and
425 synchronized at the G1/S boundary with thymidine (5mM, Merck Millipore) for 24 hours. After 3
426 washes in 1X PBS, cells were pulsed for 18 hours with reversine or vehicle control (DMSO) and
427 released in the presence of mimosine (0,5mM, Merck Millipore) for 18 hours. After 3 washes in 1X
428 PBS, cells were incubated for 6 hours in the presence or absence of aphidicolin (400nM, Merck
429 Millipore) or the DDK inhibitor XL413 (10μM, Aurogene) prior to fixation for immunofluorescence.
430 The thymidine analog ethynyl deoxy-uridine (EdU) was added at a final concentration of 10μM
431 during the last 30 minutes to label S phase cells.

432 To assess S phase length and quality of the subsequent mitosis by time-lapse microscopy, after plating
433 onto a fibronectin-coated glass 12wellplate, hTERT RPE-1 cells were blocked in G1/S with
434 thymidine for 24 hours, then washed out, pulsed with reversine/DMSO for 18 hours and filmed for
435 72 hours.

436 For MiDAS detection, hTERT RPE-1 cells were treated as above and, after reversine/DMSO

437 washout, released in RO3306 (7,5μM, Merck Millipore) for 12 hours to arrest them in late G2 phase.

438 Then, after 3 washes in 1X PBS, cells were released in mitosis in the presence of EdU 20μM and

439 colcemid for 2 hours to harvest prometaphase cells for MiDAS detection. Aphidicolin 400nM was

440 added to a subpopulation of cells pulsed with DMSO just after DMSO washout in order to induce

441 DNA replication stress (positive control). To investigate the consequences of MiDAS inhibition in

442 G1 cells, cells were plated and treated as above. After RO3306 washout, cells were released in EdU

443 20μM in the presence or absence of aphidicolin (2μM, Merck Millipore) for 40 minutes (for

444 prometaphase cells) or 3 hours (for G1 cells) prior to fixation of immunofluorescence.

445 In order to harvest daughter pseudo-G1 cells, after thymidine and reversine pulses, hTERT RPE-1

446 LCK-GFP cells were released in the presence or absence of XL413 10μM and arrested in late G2

447 phase with RO3306 7,5μM. After drug washout, cells were incubated in the presence or absence of

448 aphidicolin 2μM for 3 hours together with cytochalasin B (3μg/ml, Merck Millipore) to block

449 cytokinesis prior to fixation for immunofluorescence.

450 To obtain metaphase-like spreads from G1 cells, calyculin A (50ng/ml, Sigma-Aldrich) was added

451 for 45 minutes to G1 cells treated as above to induce premature chromosome condensation, prior to

452 harvest for mFISH analysis.

453 To evaluate β-galactosidase positivity in aneuploid cells, after reversine washout, hTERT RPE-1 cells

454 were allowed to progress for about 60 hours before fixation. The same protocol was used to generate

455 aneuploid cells for sorting, including hTERT FUCCI RPE-1 and hTERT RPE-1 H2b-GFP cells. After

456 sorting, some cells were replated and fixed 16 hours later to perform β-galactosidase staining, while

457 some other were replated for live cell imaging experiments or directly harvested as frozen pellets for

458 RNA extraction. As a positive control for senescence, cells continuously treated with doxorubicin

459 (200nM, Merck Millipore) for 7 days were used.

460

Multicolor fluorescence in situ hybridization (mFISH)

462 After the treatments described above, hTERT RPE-1 cells blocked in prometaphase or G1 cells in

463 which premature condensation was induced were trypsinized and centrifuged to obtain cell pellets.

464 Cell pellets were resuspended in KCl 75mM and incubated for 10 min in a 37 degrees waterbath.

465 After centrifugation, cells were fixed in freshly-prepared Carnoy solution (methanol-acetic acid in a

466 3:1 ratio) while vortexing and then incubated for 30 minutes at room temperature (RT). After a wash

467 in freshly-prepared Carnoy solution, minimum volume of fixative was left to resuspend the pellet and

468 cells were dropped onto glass slides. mFISH staining was performed following manufacturer's

469 instructions (MetaSystems). The Metafer imaging platform (MetaSystems) and the Isis software

14

470 (MetaSystems, version 5.5) were used for automated acquisition of the chromosome spread and
471 mFISH image analysis.

472

Ultra-structural analysis of replication intermediates

474 For EM analysis, hTERT RPE-1 cells were pulsed for 24 hours with reversine or vehicle control
475 (DMSO) and then harvested. Immediately after, cells were psoralen-crosslinked *in vivo* to stabilize
476 replication intermediates as described in [66]. The cell suspension was first incubated with 30 µg/ml 4,
477 5′, 8-trimethylpsoralen (2mg/ml, Sigma) for 5 min in the dark and then exposed to 365 nm UV light
478 for 8 min in a UV Stratalinker 1800, (Stratagene), with 365 nm UV bulbs (model UVL-56, UVP) at
479 2–3 cm from the light source. The incubation and irradiation steps were repeated three more times (4
480 cycles total). Genomic DNA (gDNA) was extracted with phenol-chloroform as described in [66]. 50 µg
481 of gDNA were digested with KpnI and passed through a QIAGEN Genomic-tip 20/G column
482 (QIAGEN) to enrich for replication intermediates, as described by Zellweger and Lopes [67]. EM
483 spreads and imaging was performed as described in [68].

484

Immunofluorescence analysis and EdU detection

486 At the end of the treatments described above, hTERT RPE-1 or hTERT RPE-1 LCK-GFP cells were
487 washed once in 1X PBS and then fixed in 4% paraformaldehyde (PFA) for 15 minutes at RT. After
488 3 washes in 1X PBS, cells were blocked in 3% bovine serum albumin (BSA) + 0.5% Triton-X in 1X
489 PBS for 30 minutes and incubated with the following primary antibodies diluted in the same buffer
490 for 90 minutes at RT: anti-FANCD2 (Novus Biologicals) 1:400, anti-RPA (Abcam) 1:200, anti-
491 pChk1 (Cell Signaling Technology) 1:200, anti-53BP1 (Abcam) 1:1000, anti-γH2AX (Millipore)
492 1:400. After 3 washes in 1X PBS, cells were incubated with secondary antibodies (ThermoFisher
493 Scientific) diluted 1:400 in 3% BSA + 0.5% Triton-X in 1X PBS for 45 minutes at RT in the dark.
494 Coverslips were then mounted on glass slides using Vectashield Antifade Mounting Medium with
495 DAPI (Vectorlabs).
496 Where indicated, immunofluorescence was combined with EdU detection. Briefly, after the blocking,
497 EdU detection was performed using the Click-iT EdU Cell Proliferation kit for Imaging
498 (ThermoFisher Scientific) following the manufacturer's instructions. After the washes, incubation of
499 the cells in primary antibodies and the subsequent steps of immunofluorescence were performed as
500 indicated above.

501

DNA fiber analysis

503 Cells were labeled sequentially with IdU (green [G]) and CldU (red [R]) and were harvested and

504   processed as described in [18]. Data was collected from 2 independent experiments. A total of 47 and

505   54 Mb of DNA and 33 and 38 Mb of DNA was collected from the control and the aneuploid cells,

506   respectively. Data analysis was performed as described in detail in [31]. Please note that the order of

507   labeling is reversed (CldU → IdU) in the experiments described in [31], therefore, the interpretation of

508   patterns is also reversed as compared to this article. Briefly, origin firing rate is the total number of

509   origins that fired during the first and the second analog in each fiber divided by the total length of

510   the un-replicated DNA in that fiber and the total length of the analog labeling pulses (120 minutes).

511   Origins that fire during the first analog will appear as Red-Green-Red [RGR] and origins that fire

512   during the second analog will appear as Red [R] events. However, origins that fire during the first

513   analog will appear as RGR only if both the forks progress into the second analog. The origins will

514   appear as RG or GR if either of the fork stalls or as G if both the forks stall. Thus, the total number

515   of origins in each fiber was estimated by accounting for the probability of forks stalling.

516   Fork density is the total number of forks in each fiber divided by the total length of the un-replicated

517   DNA of that fiber. Origins and termination events account for 2 forks each and unidirectional fork

518   events account for 1 fork each. However, some of the unidirectional forks could be an origin whose

519   left or rightward fork is stalled. Thus, the total number of forks on each fiber was estimated by

520   accounting for the probability of forks stalling. Please see [31] for calculation of fork stall rate and how

521   the probability of fork stalling was used to estimate the final origin firing rate and fork density for

522   each fiber.

523

524   **Cell proliferation assay**

525   After thymidine synchronization and reversine/DMSO pulse as above, hTERT RPE-1 cells were

526   trypsinized, counted and plated into a 96wellplate in the presence of XL413 10μM or the vehicle

527   control (DMSO). Drugs were re-added fresh every 48-72 hours during the 120 hour -treatment. Then,

528   cell viability was assessed by using the CellTiter-Glo Luminescent cell viability assay (Promega)

529   following manufacturer's instructions.

530

531   **Live cell imaging**

532   To monitor S phase length and M phase duration and quality, cells were treated as above. After

533   reversine/DMSO washout, fresh medium without phenol red was added to the cells. Cells were

534   imaged every 10 minutes for 72 hours under a 20x objective with an inverted Nikon Eclipse Ti

535   microscope equipped with incubator for live cell imaging. The same microscope and acquisition

536   settings were used to film aneuploid cycling cells after sorting for 72 hours to assess their genome

537   stability.

538

MiDAS detection

540 To detect MiDAS on metaphase spreads, after incubation in EdU and colcemid as above, cells were

541 treated similarly to those for mFISH analysis. After cell dropping onto glass slides and complete

542 evaporation of the Carnoy solution, slides washed in 1X PBS in agitation. EdU detection was

543 performed with the Click-iT EdU Cell Proliferation kit for Imaging (ThermoFisher Scientific)

544 according to manufacturer's instructions with some minor modifications as described in [69]. Slides

545 were then mounted using Vectashield Antifade Mounting Medium with DAPI.

546 To detect MiDAS on prometaphase cells, at the end of the treatments described above, cells were

547 fixed in 4% PFA for 15 minutes at RT, then washed 3 times in 1X PBS. EdU detection was performed

548 as above [69] and coverslips were then mounted on glass slides using the same mounting medium as

549 above.

550

Distribution of DNA damage in pseudo-G1 cells

552 First, the number of FANCD2 and γH2AX foci per daughter cell was counted. Based on the average

553 number of foci per cell, cells with less than 6 or 4 foci (for FANCD2 or γH2AX, respectively) were

554 excluded from the analysis. Then, the total number of foci between the two daughters (*e.g.* 13+10)

555 was calculated and divided by 2 to obtain the number of foci predicted to be inherited by each

556 daughter cell in case of symmetric distribution of DNA damage (*e.g.* 23 divided by 2 is equal to 11,5).

557 Subtraction or addition of this number to the total number of foci in the daughters was used to set a

558 threshold for asymmetric distribution of DNA damage, *e.g.* 23-11,5= 11,5, which is the lowest

559 threshold; 23+11,5= 34,5, which is the highest threshold; if a daughter cell has less than 11,5 or more

560 than 34,5 foci the distribution of DNA damage is considered as non-random (non-random

561 distribution, NDD).

562

β-galactosidase staining

564 DMSO- and reversine-pulsed cells allowed to progress for about 72 hours after DMSO/reversine

565 washout, together with sorted cycling and arrested aneuploid cells, were plated into a 6 well plate at

566 $1x10^6$ cells/well and allowed to attach overnight. Then, cells were stained using the Senescence β-

567 Galactosidase Staining Kit (Cell Signaling Technology) following manufacturer's instructions.

568

Sorting of aneuploid cells

570 Cells were plated into 150 mm plates (900.000 cells/plate) and treated as above. After

571 reversine/DMSO washout, cells were allowed to divide for about 60 hours. Then, they were incubated

17

572 with the fluorescent substrate of the β-galactosidase enzyme DDAO-Galactoside (DDAOG) 10mM

573 for 90 minutes. At the end of the incubation, cells were harvested for FACS sorting and acquired

574 using a FACSAria Fusion flow cytometer (BD). Cells were gated for singlets and alive cells and then

575 FSC-A, SSC-A and Alexa-647 intensity were used to distinguish cycling from arrested cells, *i.e.*

576 cycling cells were gated using the same Alexa-647 Mean Fluorescence Intensity of the control sample

577 without DDAOG, while arrested cells were gated imposing 0,1% on Alexa-647 signal to the control

578 sample without DDAOG. FlowJo was used to perform data analysis and generate the plots in Figure

579 5 and Extended Data Fig. 2.

580

581 **Cell cycle profile analysis through the FUCCI system**

582 hTERT FUCCI RPE-1 cells were used to generate euploid, aneuploid, cycling aneuploid and arrested

583 aneuploid cells as described above. After the sorting, cells were plated in a 12wellplate, allowed to

584 attach overnight and then filmed using an inverted Nikon Eclipse Ti microscope with a 40x objective

585 equipped with incubator for live cell imaging. Brightfield, green (GFP) and red (mCherry) channels

586 were used to acquire the movie. Images were taken every 30 minutes for 24 hours. Cell cycle stage

587 was determined based on nuclear color: red nuclei were scored as G1 phase, while yellow and green

588 nuclei were scored as S/G2 phase; lastly, M phase was characterized by uncolored nuclei of two

589 dividing cells [57].

590

591 **Sample processing for RNAseq**

592 Aneuploid cycling and arrested cells post sorting were centrifuged and cell pellets were obtained.

593 RNA was extracted from them using a RNeasy kit (QIAGEN) and its quality was assessed with a

594 Bioanalyzer 2100 (Agilent). Then, for each sample, total RNA was depleted of ribosomal RNA and

595 the RNAseq libraries were prepared with the Illumina TruSeq Stranded Total RNA kit following the

596 manufacturer's protocol. Briefly, after the fragmentation of RNA using divalent cations at elevated

597 temperature, cDNA was synthesized, end-repaired and 3'-end-adenylated. Following adapter

598 ligation, libraries were amplified by PCR. Amplified libraries were checked on a Bioanalyzer 2100

599 (Agilent) and quantified with picogreen reagent. Libraries with distinct TruSeq adapter UDIndexes

600 were sequenced for 50 bases in the paired-end mode with 35 million reads in coverage on a Novaseq

601 6000 sequencer.

602

603 **Data analysis for RNAseq**

604 RNA reads were aligned to the GRCh38 primary assembly with Ensembl 104 [70] gene annotations

605 using. STAR 2.7.9a [71]. Gene counts were quantified with subread 2.0.2 [72]. Differentially expressed

606   genes were determined using DESeq2 1.30.0 [73] with a Wald test, regressing out for the batch factor.

607   Subsequently, genes were filtered based on significance (P-value ≤0.05 and PADJ ≤0.25; for the

608   aneuploid vs. control analysis results were filtered only based on p-value). Pre-ranked gene set

609   enrichment analysis (PreRanked GSEA) was performed to identify enriched pathways [74]. Single cell

610   gene set enrichment analysis (ssGSEA) was performed using GenePatterns [74,75], to compare the

611   expression of specific DNA damage-related signatures across samples. Z-scores were calculated for

612   each gene signature across and plotted as a heatmap. Plots were generated using the Python's

613   'seaborn' library (Van Rossum and Drake, 2009).

614

615   Kinetics of DNA repair upon exposure to IR

616   After cell sorting (as described above), aneuploid cycling and arrested cells, together with non-sorted

617   aneuploid cells and euploid controls, were plated on coverslips and incubated overnight. The day

618   after, cells were γ-irradiated (1.25Gy) and fixed for immunofluorescence as indicated above at

619   different timepoints. In order to exclude S phase cells, cells were pulsed with EdU 10μM for 30

620   minutes before fixation. Non-irradiated cells were fixed together with the first timepoint. i.e. 0h post

621   irradiation.

622

623   Association of DDR gene expression with doubling time

624   CCLE (Cancer cell line encyclopedia) gene expression data were obtained from DepMap

625   (https://depmap.org/portal/) 22Q1 release [60] and cell line doubling times were obtained from

626   Tsherniak et al. 2017. Cell lines were divided to quartiles according to their doubling time, while

627   ssGSEA scores were generated using the GenePattern platform (https://www.genepattern.org/) [74,75]

628   and compared between the top and bottom quartiles. Statistical analysis (two-tailed Student' t-test)

629   and plotting were performed using GraphPad PRISM v9.3.1.

630

631   Sample processing for single-cell whole genome sequencing (scWGS)

632   Cell pellets were resuspended in cell lysis buffer (100mM Tris-HCl pH 7.4, 154mM NaCl, 1mM

633    $CaCl_2$, 500μM $MgCl_2$, 0,2% BSA, 0,1% NP-40, 10μg/ml Hoechst 33358, 2μg/ml propidium iodide

634   in ultra-pure water) and incubated on ice in the dark for 15 minutes to ensure complete lysis. Resulting

635   single nuclei of G1 phase (as determined by Hoechst and PI staining) were sorted into single wells of

636   96 wellplates on a MoFlo Astrios cell sorter (Beckman Coulter) and sorted at -80C until firther

637   processing. Automated library preparation was performed (Bravo Automated Liquid Handling

638   Platform, Agilent Technologies) as previously described [76]. Resulting single-cell libraries were

639   pooled for subsequent sequencing.

640

Data analysis for scWGS

642 Sequencing was performed using a NextSeq 500 machine (Illumina; up to 77 cycles – single end or

643 up to 68 and 9 cycles – paired end; excluding sample-specific barcodes). Reads were afterwards

644 aligned to the human reference genome (GRCh38/hg38) using Bowtie2 (version 2.2.4 or 2.3.4.1;

645 Langmead and Salzberg 2012). Duplicate reads were marked with BamUtil (version 1.0.3; [77]) or

646 Samtools markdup (version 1.9; [78]. The aligned read data (bam files) were analyzed with a copy

647 number calling algorithm called AneuFinder (https://github.com/ataudt/aneufinder; [79]). Following

648 GC correction and blacklisting of artefact-prone regions (extreme low or high coverage in control

649 samples), libraries were analyzed using the dnacopy and edivisive copy number calling algorithms

650 with variable width bins (average bin size = 1 Mb; step size = 500 kb). Results were afterwards

651 curated by requiring a minimum concordance of 95% between the results of the two algorithms.

652 Libraries with on average less than 10 reads per bin (~ 30,000 reads for a diploid genome) were

653 discarded. A chromosome was classified as aneuploid when at least 95 % of the bins showed a

654 deviation from euploid (deviation from 2-somy). Chromosomes 10 and 12 were excluded for the

655 calculation of whole-genome scores.

656

Quantification and statistical analysis

658 Statistical analyses were performed using GraphPad Prism software. Statistical significance in each

659 case was calculated using Student's t-test, Chi-squared test or Fisher's exact test. Error bars represent

660 SEMs or SDs. All experiments were performed in at least three biological replicates, with some

661 exceptions (see Figure legends).

Figure legends

887   **Fig. 1: Aneuploid cells accumulate increasing genome instability and display higher levels of**

888   **DNA replication stress markers in S phase. a,** Experimental setup for the analysis of genome

889   instability of cells obtained from the 1st and the 2nd mitosis. Karyotype aberrations were assessed by

890   mFISH analysis. **b,c,** Representative mFISH images of karyotypes obtained from the 1st and the 2nd

891   mitosis in aneuploid cells and relative quantification. T(10,X) and +12 were excluded from the

892   analysis as they are clonal in hTERT RPE-1 cells. **d,** Schematic representation of the experimental

893   approaches used for the study of the 1st S phase after induction of chromosome missegregation. A

894   short EdU pulse was performed before cell harvest in order to label S phase cells to be analyzed by

895   immunofluorescence. **e,f,** Representative images of normal and reversed replication forks analyzed

896   by electron microscopy and quantification of the reversed ones in control and aneuploid cells. 108

897   and 95 forks were analyzed in the control and in the aneuploid sample, respectively. **g,h,**

898   Representative images and quantification of FANCD2 foci per S phase cell in control and aneuploid

899   cells. **i,j,** Representative images and quantification of RPA foci per S phase cell in control and

900   aneuploid cells. **k,l,** Representative images and quantification of pChk1 foci per S phase cell in

901   control and aneuploid cells. Cells treated with aphidicolin (RS, replication stress) were used as a

902   positive control. **m,** Representative images of DNA fiber analysis in control and aneuploid cells. **n,o,**

903   Quantification of (**n**) fork density per Mb and (**o**) origin firing rate per Mb in control and aneuploid

904   cells. Ctrl, control (DMSO pulsed). Aneu, aneuploid cells (Mps1 inhibitor pulsed). RS, replication

905   stress (aphidicolin treated cells). Scale bars, 5μm. LUT was inverted for FANCD2, RPA and pChk1

906   images. Data are means of at least three biological replicates, except for the EM (one replicate) and

907   the DNA combing (two replicates) analyses. Error bars represent SEMs. ** denotes p<0,01; ****

908   denotes p <0,001.

909

910   **Fig. 2: DDK protects aneuploid cells from DNA damage accumulation and consequent cell**

911   **death. a,** Experimental workflow for the analysis of DNA replication stress markers in S phase cells

27

912   upon treatment with the DDK inhibitor XL-413. A short EdU pulse was performed before cell harvest

913   in order to label S phase cells. **b,c,** Representative images and quantification of FANCD2 foci per S

914   phase cell in control or aneuploid cells ± DDK inhibitor. **d,e,** Representative images and

915   quantification of RPA foci per S phase cell in control or aneuploid cells ± DDK inhibitor. **f,g,**

916   Representative images and quantification of pChk1 foci per S phase cell in control or aneuploid cells

917   ± DDK inhibitor. **h,** Experimental workflow for the assessment of cell viability upon exposure to the

918   DDK inhibitor. **i,** Quantification of live cells upon DDK inhibitor treatment in control and aneuploid

919   cells. Ctrl, control (DMSO pulsed). Aneu, aneuploid cells (Mps1 inhibitor pulsed). DDKi, DDK

920   inhibitor. Scale bars, 5μm. LUT was inverted for FANCD2, RPA and pChk1 images. Data are means

921   of at least three biological replicates. Error bars represent SEMs. * denotes $p<0,05$; ** denotes

922    $p<0,01$; *** denotes $p< 0,005$; **** denotes $p<0,001$.

923

924   **Fig. 3: MiDAS protects aneuploid cells from a further increase in their genome instability. a,**

925   Experimental workflow for the analysis of the 1st S phase duration, 2nd M phase duration and quality

926   by live-cell imaging in hTERT RPE-1 cells expressing H2b-RFP and PCNA-GFP. **b,** Representative

927   images from the movies of mitosis duration and quality in control and aneuploid cells. **c,d,** Correlation

928   between (**c**) S phase duration and quality of the subsequent mitosis and (**d**) mitotic timing and mitotic

929   quality in control and aneuploid cells. **e,f**, Representative images and quantification of EdU

930   incorporation on metaphase spreads in control and aneuploid cells. Cells treated with aphidicolin (RS,

931   replication stress) were used as a positive control. **g,** Experimental workflow for the assessment of

932   genome instability in the following G1 phase upon MiDAS inhibition. **h,i,** Representative images and

933   quantification of EdU incorporation in prometaphase cells upon MiDAS inhibition. Cells treated with

934   aphidicolin (RS, replication stress) were used as a positive control. **j,k,l,** Representative images (**j**)

935   and quantification of 53BP1 body (**k**) and micronucleus (**l**) accumulation in G1 cells following

936   inhibition of MiDAS. Ctrl, control (DMSO pulsed). Aneu, aneuploid cells (Mps1 inhibitor pulsed).

937   RS, replication stress (aphidicolin treated cells). MiDASi, MiDAS inhibitor. Normal M, normal

938   mitosis. Abnormal M, abnormal mitosis. Scale bars, 5 or 10 μm. Data are means of at least three

939   biological replicates. Error bars represent SEMs. * denotes $p<0,05$; **denotes $p<0,01$; *** denotes

940    $p< 0,005$; **** denotes $p<0,001$.

941

942   **Fig. 4: DDK and MiDAS act as surveillance mechanisms to limit genome instability**

943   **accumulation in aneuploid cells. a**, Experimental workflow for the analysis of DNA damage and

944   chromosome aberrations in G1 cells following DDK and MiDAS inhibition in the cell cycle after

945   chromosome missegregation induction. **b,c,d,** Representative images (**b**) and quantification of

946 FANCD2 (**c**) and γH2AX (**d**) accumulation in cytokinesis-blocked pseudo-G1 cells expressing LCK-

947 GFP. **e**, Representative mFISH images of G1 cell-derived metaphase-like chromosomes from

948 aneuploid cells upon DDK and MiDAS inhibition. **f**, Zoomed image of the chromosome highlighted

949 in the dotted-line box in panel E (image on the right) from the aneuploid sample in which DDK and

950 MiDAS were inhibited showing a translocation between chromosome 19 and chromosome 18. **g**,

951 Quantification of the percentage of cells with more than 1 translocation in the two samples. **h,i,j**,

952 Representative images (**h**) and quantification of FANCD2 (**i**) and γH2AX (**j**) non-random distribution

953 between the daughter pseudo-G1 cells. Cells treated with aphidicolin (RS, replication stress) were

954 used as a positive control. Ctrl, control (DMSO pulsed). Aneu, aneuploid cells (Mps1 inhibitor

955 pulsed). RS, replication stress (aphidicolin treated cells). MiDASi, MiDAS inhibitor. NDD, non-

956 random distribution. Scale bars, 5 or 10 μm. Data are means of at least three biological replicates,

957 except for data in panels e-g that were obtained from two biological replicates. Error bars represent

958 SEMs. * denotes p<0,05; ** denotes p<0,01; *** denotes p< 0,005; **** denotes p<0,001.

959

960 **Fig. 5: Aneuploid cells that retained their proliferative capacity exhibit reduced levels of DNA**

961 **damage and genome instability. a**, Senescence-associated β-galactosidase staining in control and

962 aneuploid cells. Doxorubicin-treated cells were used as a positive control. **b**, Experimental workflow

963 for a new method to separate and recover both cycling and arrested aneuploid cells based on FACS-

964 sorting and the usage of a fluorescent substrate of the b-galactosidase enzyme. **c**, FACS profiles

965 showing the percentage of DDAOG-positive cells in aneuploid cells incubated or not with the

966 DDAOG substrate. **d**, Senescence-associated β-galactosidase staining in cycling and arrested

967 aneuploid cells obtained after sorting. **e**, Cell cycle profiles of control, aneuploid, aneuploid cycling

968 and aneuploid arrested FUCCI-cells analyzed by live-cell imaging. **f**, Quantification of percentage of

969 G1 cells in the four samples analyzed by live-cell imaging. **g,h,i,** Representative images (**g**) and

970 quantification of FANCD2 (**h**) and γH2AX (**i**) foci per cell in the different samples. Only EdU

971 negative cells were analyzed in order to exclude the contribution of S phase cells present in the non-

972 arrested cell samples. **j**, scWGS of cycling and arrested aneuploid cells. Single cells are represented

973 in rows and chromosomes plotted as columns. Copy-number states are indicated in colors (see legend

974 on the right). hTERT RPE-1 cells have clonal gains of 10q and chromosome 12 [80]. **k,** Quantification

975 of cells with at least 3 aneuploid chromosomes in the two samples. Gains of 10q and chromosome 12

976 were excluded from the analysis. Ctrl or Ct, control (DMSO pulsed). Aneu or An, aneuploid cells

977 (Mps1 inhibitor pulsed). Aneu cycling or An cy, aneuploid cycling cells. Aneu arrested or An ar,

978 aneuploid arrested cells. Scale bars, 5μm. Data are means of at least three biological replicates, except

979 for panel f (one replicate). Error bars represent SEMs, except for panel E (SDs). * denotes p<0,05;

980 **** denotes p<0,001.

981

982 **Fig. 6: Cycling aneuploid cells display decreased karyotype aberrations and upregulate DNA**

983 **repair genes in comparison with arrested aneuploid cells. a**, Experimental workflow for the

984 assessment of genome instability levels by live-cell imaging in aneuploid cycling cells expressing

985 H2b-GFP. **b**, Representative images of cell divisions in the different samples. **c**, Quantification of

986 mitotic errors in 3 cell division rounds in control and aneuploid cycling cells. Cells treated with the

987 Mps1 inhibitor just before starting the time-lapse were used as a positive control for mitotic errors.

988 **d**, Volcano plot illustrating the differentially expressed pathways between cycling and arrested

989 aneuploid cells. Specific gene sets are highlighted in color. **e,** Heat-map showing the z-scores of

990 single-sample GSEA (ssGSEA) scores for DNA damage-related gene sets. **f,g,** Quantification of

991 γH2AX foci (f) and 53BP1 bodies (g) in cycling and arrested aneuploid cells upon IR exposure. Only

992 EdU negative cells were analyzed in order to exclude the contribution of S phase cells present in the

993 non-arrested cell samples. **h,i,j,** Association between ssGSEA score for GOBP DNA repair (**h**) or

994 GOBP DNA synthesis involved in DNA repair (**i**) or GOBP regulation of DNA repair (**j**) and

995 proliferation capacity in top vs. bottom quartiles of cancer cell lines from [59]. Aneu cycling or An cy,

996 aneuploid cycling cells. Aneu arrested or An ar, aneuploid arrested cells. M, mother division. D,

997 daughter division. GD, grand-daughter division. Mps1i, Mps1 inhibitor. #1 and #2 refer to biological

998 replicates. Not irrad., not irradiated. Data are means of at least two biological replicates. Error bars

999 represent SEMs. Shaded error bands in panels f,g are shown above and below for arrested and cycling

1000 cells, respectively. **** denotes p<0,001; ns, not significant.

1001

1002 **Fig. 7: Final model.** A model for how aneuploidy induces genome instability and its consequences.

1003 See text for more details.

1004

1005 **Extended Data Fig. 1: Impact of chromosome mis-segregation induction on karyotype changes,**

1006 **S and M phase. a**, Representative images of the karyotype obtained from the 1st and the 2nd mitosis

1007 in control cells. **b**, Quantification of percentage of cells with chromosome gains, losses or

1008 translocations in the 1st or 2nd mitosis in control cells. **c**, Quantification of S phase duration by live-

1009 cell imaging in control and aneuploid cells. The graph refers to the experiment in Figure 3, panels A-

1010 D. **d**, Quantification of mitotic division timing upon SAC inhibition in control and aneuploid cells

1011 that underwent normal or abnormal mitosis. Ctrl, control (DMSO pulsed). Aneu, aneuploid cells

1012 (Mps1 inhibitor pulsed). Mps1i, Mps1 inhibitor. Data are means of at least three biological replicates.

1013 Error bars represent SEMs. *** denotes p<0,005; **** denotes p<0,001.

1014

1015 **Extended Data Fig. 2: Separation and characterization of aneuploid cycling and arrested cells.**

1016 **a**, FACS profiles showing the percentage of DDAOG positive cells in DMSO and doxorubicin treated

1017 cells, used as a positive control. **b,** Illustration depicting the change in nuclear color in the FUCCI

1018 cells. **c**, Representative images showing the starting (0h) and end point (24h) of the time-lapse in the

1019 four different samples. Scale bar 20μm.

1020

1021 **Extended Data Fig. 3: Kinetics of DNA damage repair in aneuploid cells and respective controls**

1022 **upon IR exposure. a,b,** Representative images (**a**) and quantification (**b**) of γH2AX foci per cell.

1023 **c,d,** Representative images (**c**) and quantification (**d**) of 53BP1 bodies per cell. Only EdU negative

1024 cells were analyzed in order to exclude the contribution of S phase cells present in the non-arrested

1025 cell samples. Ctrl, control (DMSO pulsed). Aneu, aneuploid cells (Mps1 inhibitor pulsed). Aneu

1026 cycling, aneuploid cycling cells. Aneu arrested, aneuploid arrested cells. Not irrad., not irradiated.

1027 Data are means of two biological replicates. Shaded error bands in panels f,g are shown above and

1028 below for aneuploid cells and euploid controls, respectively.

1029

1030 **Extended Data Table 1: List of genes differentially expressed in arrested vs. cycling aneuploid**

1031 **cells.** Data were obtained by RNAseq (Fig. 6).
