Abstract

Long-term reconstituting haematopoietic stem cells (LT-HSCs) are used to treat blood disorders via allogeneic stem cell transplantation (alloSCT), to engraft and repopulate the blood system. The very low abundance of LT-HSCs and their rapid differentiation during *in vitro* culture hinders their clinical utility. Previous developments using stromal feeder layers, defined media cocktails, and bioengineering have enabled HSC expansion in culture, but of mostly short-term HSCs (ST-HSC) and progenitor populations at the expense of naïve LT-HSCs. Here, we report the creation of a bioengineered LT-HSC maintenance niche that recreates physiological extracellular matrix organisation, using soft collagen type-I hydrogels to drive nestin expression in perivascular stromal cells (PerSCs or pericytes). We demonstrate that nestin, which is expressed by HSC-supportive bone marrow stromal cells, is cytoprotective and, via regulation of metabolism, is important for HIF-1α expression in PerSCs. When CD34[+ve] HSCs were added to the bioengineered niches comprising nestin/HIF-1α expressing PerSCs, LT-HSC numbers were maintained with normal clonal and *in vivo* reconstitution potential, without media supplementation. We provide proof-of-concept that our bioengineered niches can support the survival of CRISPR edited HSCs. Successful editing of LT-HSCs ex vivo can have potential impact on the treatment of blood disorders.

Introduction

Haematopoietic diseases are a major healthcare burden, costing the UK economy £4B pa[1], with leukaemia therapy typically requiring multiple courses of intensive chemotherapy, often followed by allogeneic haematopoietic stem cell (HSC) transplant (alloSCT). AlloSCT transplantation replaces a patients hematopoietic cells through myeloablation of host bone marrow (BM), followed by reconstitution with transplanted donor cells to restore normal immune function[2]. Given that alloSCT has been demonstrated to be an increasingly efficacious therapy for not only leukaemias but also for primary immuno-deficiencies and autoimmune conditions, there is an increasing demand for HSC transplantation and for matched donors[3], particularly in the context of an aging and ethnically diverse population. However, we currently cannot meet the clinical demand as there is no defined and regulated expansion methodologies for BM HSCs meaning that we are reliant on donation. Furthermore, engraftment of HSCs can be limited following alloSCT, leading to prolonged haemopoietic recovery time post-transplantation which is a major cause of transplant failure and patient mortality[2].

Long-term (LT)-HSCs are critically important for therapy as they engraft to repopulate the blood system following alloSCT[4]. However, LT-HSCs rarely divide and represent just 0.01 - 0.04% of the mononuclear bone marrow population[5]. They rapidly differentiate towards short-term (ST)-HSCs and progenitor cells upon their culture *in vitro*, which provide only temporary engraftment and myeloid/lymphoid progenitors[4,5]. Therefore, maintaining and, ultimately, expanding LT-HSCs ex vivo has become a major focus of research. Several culture systems, such as Dexter cultures[6], and the use of cytokines[7] and small molecules[8], have successfully expanded heterogenous CD34+ HSCs *in vitro* but with the concomitant loss of naïve LT-HSCs, producing populations with clonal heterogeneity[9]. Subsequent transplantation studies and phase I/II clinical trials (e.g. with the small molecule Stem Reginin-1) have shown that most engrafted cells are ST-HSCs and their subsequent progenitors[10].

The inability to maintain LT-HSCs, or to support their self-renewal, in these systems is likely to be related to the lack of the many physical and functional signalling components of the highly complex BM microenvironment, where the expansion and differentiation of HSCs and other hematopoietic cells are regulated[11]. To maintain LT-HSCs ex vivo, there needs to be defined conditions which allow activation and proliferation without inducing differentiation to ST-HSC and subsequent committed progenitors[4]. This has proven to be impossible to achieve in a heterogenous BM cell population, especially when a single parameter, such as one signalling pathway, is targeted with small molecules[8]. Multiple cell types also interact in the BM and co-operate with each other through cell-cell adhesion and paracrine signals, such as mesenchymal stromal cells (MSCs) and perivascular stromal cells (PerSCs)[12–16]. Other critical cellular factors in the BM stem cell niche are C-X-C motif chemokine 12 (CXCL12, also known as stromal cell-derived factor 1 (SDF1)) abundant reticular (CAR) cells[17], and bone-forming osteoblasts[15,16] (Figure 1). All are implicated in LT-HSC maintenance, while nestin[+ve] PerSCs are specifically implicated in LT-HSC self-renewal in murine studies[12,13,18]. This observation of nestin[+ve] stromal cells being important to LT-HSC phenotype is interesting as soft materials, such as hydrogels, have been implicated in the expression of nestin in MSCs[19]. While originally this was ascribed to a neural phenotype[19], we hypothesise this seminal

observation can be important in engineering of a niche-stromal phenotype and that stromal nestin expression will provide key niche functionalities.

Indeed, the BM itself is a soft material, comprising extracellular matrix (ECM) with a Young's modulus of $1 - 10^4$ Pa[20], that interfaces with hard materials, such as the bone lining (endosteal) surfaces[21] and the arterioles and sinusoidal capillaries, to which PerSCs adhere, affecting their mechanotransductive signalling and phenotype[13,22]. Growth factors (GFs) and cytokines interact with ECM's structural proteins, such as fibronectin (FN), facilitating synergistic signalling between ECM-adhering integrin receptors and GF receptors, further influencing the stromal phenotype[23]. The BM niche also features hypoxic environments[24]. The endosteal niche was traditionally considered to be highly hypoxic, but it has been shown that the endosteal surface is perfused with a network of oxygenated arterioles[13,24]. By contrast, the central cavity is filled with more hypoxic sinusoids[13,24]. Hypoxic conditions can influence cell phenotypes, with hypoxic culture conditions reducing stromal cell proliferation and maintaining their stem cell phenotype[25]. Indeed, hypoxia inducible factor (HIF) expression by stromal cells is believed to be important for their HSC regulatory capacity[26].

We propose that multiple elements of the BM's complexity needs be recapitulated *in vitro* to maintain LT-HSCs. Numerous *in vitro* models of the BM niche are currently in development. Some integrate multiple types of support cells[18,27], 3D hydrogels[28,29] and scaffolds[30], while others employ perfusion cultures[31], and combine different approaches on organ-on-chip devices[32]. While these emerging models inform our understanding of the human BM during injury or neoplasia[32], and of CD34[+ve] HSC expansion[18,27], they have their limitations. Many use murine CD34[+ve] cells, despite the notable differences between human and murine HSC regulation[33], others measure expansion based on CD34[+ve] numbers rather than on the LT-HSC population, while some models are complex or hard to use or recover cells from[4]. To our knowledge, there is no reported system that focuses on enhancing human LT-HSC maintenance in a simple-to-use, practical, system. Such a system could inform on both maintenance of LT-HSCs for therapeutic use as well as providing a platform to test novel drugs or gene editing of HSCs *in vitro*, that can offer novel therapeutic cell-based therapies to treat malignant and non-malignant blood disorders.

In this study, we employ bioengineering approaches in order to direct the physiology of the stromal feeder layer and enhance its ability to support and maintain quiescent LT-HSCs in culture without unwanted drift towards non-engrafting ST-HSCs and progenitor cells. In this study, we define LT-HSCs *in vitro* by survival in a long-term culture initiating cell assay (LTC-IC) and *in vivo* by engraftment post 3-month. For the bioengineered niche, we employ a polymeric surface that controls FN, a major component of BM ECM[34], fibril formation allowing both an adhesive and direct GF signal to stromal cells[35,36], as well as a soft material to induce nestin expression to stimulate the stromal HSC-supportive phenotype[12,13,18]. Our findings show that nestin expression, linked to changes in respiration, are central to enhanced LT-HSC maintenance. We further demonstrate that our bioengineered niches have the potential to support improved survival of CRISPR edited HSCs in this clinically important population.

Figure 1 | Schematic of the bone marrow (BM) niche microenvironment. Long-term HSCs (LT-HSC) and Nestin^{high}/LEPR^{-ve} Perivascular stem cells (PerSCs) reside close to the endosteum and the oxygenated arterioles that perfuse the endosteal niche, whereas short-term HSCs (ST-HSCs) and LEPR^{+ve}/Nestin^{low} PerSCs are in close proximity to the sinusoidal vessels that carry deoxygenated blood away from the BM. The BM extracellular matrix (ECM) is a low-stiffness network comprised primarily of collagen and fibronectin (FN). Modified with permissions from [37].

Results

Recapitulating the endosteal surface *in vitro*

The BM niche has different putative regions with different roles in HSC regulation. The sinusoidal (central marrow cavity) niche is associated with sinusoidal capillaries and is more hypoxic relative to other BM regions[24], and self-renewing ST-HSCs are considered to reside there[14]. The endosteal surface, which is in close proximity to a large network of oxygenated arterioles, is believed to retain a more quiescent pool of LT-HSCs[12,13,24,38,39]. The BM also has a dense ECM network, the constituents of which are exchanged between the endosteal and sinusoidal niches (Figure 1). At the endosteal surface, the ECM is stiffer and FN rich. Towards the sinusoidal niches in the central BM cavity, the ECM becomes progressively less stiff and more collagen- and laminin-rich [40,41]. The conformation of ECM proteins, as well as their type and density, all strongly influence BM cell interactions[42].

Our previous work has shown that fibrillar FN can efficiently bind and present BMP-2 (bone morphogenetic protein 2, an osteogenic GF) to promote osteogenesis in MSCs *in vitro*[35] and fracture healing *in vivo*[36]. We have adapted these findings here to recreate the ECM properties of the more-quiescent endosteal niche. Poly(ethyl acrylate) (PEA) leads to the spontaneous unfolding of FN (Figure 2a), as visualised with atomic force microscopy (AFM) (Figure 2b, supplementary Figure 1a). This cell-driven unfolding process leads to the exposure of key binding domains in the FN molecule[43]. Chemically similar poly(methyl acrylate) (PMA) is used as a reference polymer here, on which FN is adsorbed and maintained in a globular conformation (Figure 2b, supplementary Figure 1a). PMA behaves similarly to PEA in terms of surface wettability and stiffness[44], but with increased adsorption of FN (Figure 2c). The fluorescent detection of antibodies that recognise total FN (Figure 2d, supplementary Figure

1b), FN's arginine-glycine-aspartic acid (RGD)-containing HFN7.1 integrin-binding domain (Figure 2e), and its P5F3 GF-binding domain (Figure 2f) demonstrates the significantly increased availability of these FN domains when absorbed on PEA, relative to PMA. The P5F3 domain of FN in particular has high binding affinity for several GF families[45]. Here, we show that exogenous BMP-2 binds to PEA-FN (Figure 2g) allowing us to present low levels of this endosteal-related GF to cells. Although similar amounts of BMP-2 also bind to PMA, our previous work has shown that BMP-2 does not co-localise with FN on PMA, leading to its faster release[35,36]. Thus, in this study, we use PEA to present FN and BMP-2 to recreate the milieu of the endosteal surface that supports HSC quiescence (maintenance) in our BM model.

Control of PerSC phenotype

The stromal population of the BM niche is highly heterogeneous[11]. Reported expression of markers, such as nestin, neural-glial antigen 2 (NG-2) and leptin receptor (LEPR), indicate that PerSCs and MSCs have a phenotype that supports HSC regulation[12–14]. Here, we focus on the LT-HSC regulating PerSCs that line the endosteal arterioles[12,13,18], and on nestin. Nestin is a cytoskeletal intermediate filament (IF) protein traditionally associated with neural progenitor cells[46]. *In vivo* murine BM studies have shown that nestin[+ve] PerSCs express high levels of factors involved in HSC maintenance, such as stem cell factor (SCF)[39]. Previous seminal work has also shown that stromal cells express nestin in response to soft materials[19]. We therefore used low-stiffness collagen type I hydrogels, a major constituent of the BM ECM[40,47], to study

the role of nestin expression in human PerSCs and to investigate how this influences their interactions with HSCs *in vitro*. We note that PerSCs have similar multipotency to MSCs (supplementary Figure 2).

The collagen gels, with a Young's modulus of ~80 Pa to mimic BM HSC niche stiffness[20], were overlayed onto PerSCs cultured on PEA/FN/BMP-2 surfaces (Figure 3a, b, supplementary Figure 3). We also used PEA/FN/BMP-2 with a lowered oxygen tension (1% O_2, hypoxia), since hypoxia is considered to be important for maintaining the stromal HSC supporting phenotype in the BM environment[24] (Figure 3a). We observed in our bioengineered PEA/FN/BMP-2 niches with hydrogels (denoted as +gel) that nestin was significantly upregulated by day 7 in PerSCs (Figure 3c), with enhanced nestin expression continuing to day 14 (supplementary Figure 4a). By contrast, nestin was expressed at a basal level in PEA/FN/BMP-2 niches without hydrogels (denoted as -gel), in the PEA/FN/BMP-2 hypoxic niches and in PMA/FN/BMP-2 niches with and without gels (supplementary Figure 4a). We used PerSCs on glass coverslips as a culture control since they do not attach to highly hydrophobic PEA without a protein interface (Fig 3c,d,e and f). Thus, nestin expression was induced only when the gel was included on PEA-unfolded FN. Nestin is a type IV IF protein incapable of self-polymerisation. It, therefore, co-polymerises with other type II and IV IFs [46]. We therefore examined vimentin expression, as an IF protein expressed in mesenchymal-lineage cells, and found no significant differences in vimentin expression or its morphology (Figure 3d).

Next, PerSCs were treated with brefeldin A for the final 24h of culture to prevent protein export and SCF levels were monitored by immunofluorescence. SCF production correlated with the observed increase in nestin expression in PEA +gel niches (Figure 3e, supplementary Figure 4b & c). CXCL12 expression was also detected in PerSCs on all substrates, with no significant differences between the bioengineered models (supplementary Figure 4d).

Phenotypic analysis by flow cytometry of the different environments showed that PerSCs in +gel niches expressed important stromal niche markers CD90, NG2, CD146 and CD51, but that expression was lost in -gel niches[13,16,18] (Figure 3f, supplementary Figure 5). Interestingly, the introduction of hypoxia also led to expression of these markers, and also increased expression of LEPR. LEPR is a marker of stromal cells that line hypoxic sinusoids, and supports our attempt to recreate an arteriolar/endosteal niche in which stromal cells are reported to be nestin[+ve]/LEPR[-ve] [12,14,39] (Figure 3f, supplementary Figure 5).

Next, we performed RNA-seq on PerSCs cultured in the PEA/FN/BMP-2 -gel, +gel and hypoxic niches. RNA-seq identified transcripts related to niche (Figure 3g) or regulation of differentiation (Figure 3h). Importantly, cells from the +gel niche had an up-regulation of niche genes and a concomitant down-regulation of differentiation genes, compared to control and other conditions (-gel and hypoxia) (Figure 3g, h). The known functions of these genes are listed in supplementary Tables 1 & 2.

Using principal component analysis (PCA), the -gel/+gel/hypoxic conditions were clearly distinguishable from each other by RNA-seq (supplementary Figure 6a). Analysis of significant gene changes revealed that most unique changes occurred in the +gel niche, and that the +gel and hypoxic models had more changes in common, relative to the -gel model (Figure 4a). Gene ontology (GO) clustering analysis indicates that a range of changes occurred in response to the different engineered ECM environments (-gel / +gel) (supplementary Figure 6b). Changes in integrins, adhesion molecules, ECM interactions, cytoskeleton and to the BMP-2 milieu, were evident in response to these ECM changes, as were changes to members of the canonical BMP signalling family, including TGFβs and SMADs (Figure 4b). Clustering analysis of the four top networks of actin cytoskeleton, cell adhesion and ECM, illustrated that in the +gel niches, the PerSCs had decreased levels of cytoskeletal transcripts and increased levels of cell adhesion and ECM transcripts, compared to the -gel models (Figure 4c). The hypoxic niche, however, both up-regulated and down-regulated ECM transcripts, and strongly repressed adhesion and actin related transcripts, relative to the other models (Figure 4c, supplementary Figure 6c).

Another feature of the naïve stromal stem cell phenotype is the ability to modulate the immune system[48]. We therefore compared the expression profiles of inflammation-related marker genes across the three different niches. Several markers up-regulated in PerSCs in the +gel niche, compared to the -gel model, are implicated in immunomodulatory properties of the stromal phenotype, including interleukin 6 (IL-6)[49], prostaglandin-endoperoxide synthase 2 (PTGS2), prostaglandin E2 receptor 2 (PTGER2)[50], CD44, tumour necrosis factor α-induced protein 3 (TNFAIP3) [51] and ephrin type-A receptor 2 (EPHA2)[52] (Figure 4d). PerSCs in the hypoxic and -gel models showed reduced expression of these immunomodulatory transcripts, with little difference between them, whereas +gel niches led to enhanced expression of these transcripts when compared to both -gel and hypoxic niches (Figure 4d). Together, these findings help demonstrate that a naïve PerSC phenotype is retained in the +gel niches.

Metabolic regulation in the BM niche

In order to elucidate further the role of hypoxia in the BM niche, we investigated the role of hypoxia and stiffness on stromal niche phenotypes by using our modular platform to compare the effects of hypoxia in our bioengineered models. HIF1α is a master regulator of metabolism. It regulates both glycolysis and oxidative phosphorylation, including anaerobic glycolysis[53]. As such, we evaluated the expression pattern of HIF1α in PerSCs in our bioengineered niches after 3, 7 and 14 days of culture. HIF1α is constitutively produced but is hydroxylated in normoxia which inhibits its transcriptional activity and targets it for ubiquitination and degradation in most cells[53]. However, in hypoxia, it becomes stable, translocates to the nucleus and activates the transcription of hypoxia-responsive genes. We,

therefore, chose to investigate nuclear expression of HIF1α (Figure 5a, supplementary Figure 7a - c). By this measure, all three bioengineered models led to increased nuclear expression of HIF1α protein in PerSCs. Interestingly, however, cells in the +gel niches displayed significantly more nuclear HIF1α, expression compared to the -gel and hypoxic models at all time points; the +gel niche also supported PerSCs with the most niche-like phenotype (Figure 3c-h).

Although some hypoxic response genes are up-regulated in PerSCs in the +gel niches (supplementary Figure 6c), our investigation of HIF1α downstream targets, such as of VEGF (Figure 5b), lactate and lactate dehydrogenase (LDH) (supplementary Figure 7d & e), did not reveal an increase in expression. To determine if the PerSCs in the +gel niches were experiencing low oxygen tension, we next used pimonidazole, a hypoxia probe. The probe revealed that while PerSCs cultured in the low oxygen tension models are clearly hypoxic, cells in the -gel models and +gel niches were not (Figure 5c). This indicates that PerSCs in the +gel niche that were expressing nuclear HIF1α were not doing so in response to lowered oxygen tension.

To identify changes in the metabolism of PerSCs in the niche models, liquid chromatography-mass spectrometry (LC-MS) was performed to identify alterations in the metabolome at 7 and 14 days of culture. PCA of all metabolites demonstrated that all three culture conditions clustered with no overlap in PC 1 vs PC 2, and with some overlap between +gel and hypoxic niches at day 14 in PC 2 vs PC 3. (Figure 5d, supplementary Figure 8). Then, focussing only on glycolysis and TCA cycle metabolites (Figure 5e), revealed an expected increase in clusters of glycolytic metabolites in the hypoxic model, as well as the upregulation of TCA-associated metabolites in the -gel model, as would be expected with active differentiation[54]. Interestingly, for the +gel niche, we observed a general down-regulation of glycolysis and oxidative phosphorylation rather than an increase in glycolysis (Figure 5e).

HIF activity in non-hypoxic conditions is a distinguishing feature of the Warburg effect, in which cancer cells switch to rely on oxidative glycolysis to generate energy[55]. The metabolic profile of PerSCs cultured in the +gel niche appears to be more quiescent than glycolytic, however. This finding was confirmed by tracing the conversion of C^{13} labelled glucose using LC-MS in PerSCs (Figure 5f). In the +gel niches, PerSCs still retained significantly more labelled glucose compared to other conditions, indicative of lowered respiration. In the -gel models, significantly less glucose was detected at the end of the analysis, and it was not reduced to pyruvate or lactate but there was an increase in ATP levels, indicative of more normal respiration (Figure 5e). In hypoxic models, significant levels of C^{13} labelled pyruvate and lactate remained in the PerSCs, indicative of anaerobic respiration, as would be expected[55]. Taken together, these observations indicate that PerSCs in the +gel niche are not responding as if in hypoxic conditions, but are attenuating respiration. This is despite the increased expression and prolonged nuclear presence of HIF1α, which may be acting in a BM niche-specific role.

Figure 5 | Bioengineered niches promote a hypoxic-like metabolic phenotype. a, *Nuclear HIF1α levels were compared at day 3 by immunofluorescence microscopy. HIF1α levels increased in cells in all models, and significantly increased in +gel niches. Nestin is required for metabolic regulation in the niche

Little is known about why nestin is highly expressed in BM niche stromal cells. We have already shown that while nestin levels are increased in +gel niches (Figure 3c), IFs (as measured using vimentin) are not (Figure 3d). To confirm this observation, we assessed the incorporation of nestin into IF networks using an antibody against p(Thr316)-nestin. This site, when phosphorylated, drives disassembly of nestin from IF fibres[56]. We observed a significant up regulation of p(Thr316) nestin in PerSCs in the +gel niche, indicating that not all nestin is incorporated into the cytoskeleton. This suggests that the function of nestin in stromal cells in our engineered BM niche does not entirely depend on its structural involvement in the cytoskeleton (Figure 6a, supplementary Figure 9).

Because of our HIF1α observation and because soluble nestin has been linked to cytoprotection in other cell types[56–58], we next investigated two possibilities: (1) that nestin expression is linked to the HIF1α positive PerSC phenotype, and (2) that nestin is linked to cytoprotection. Linking PerSC nestin expression and cytoprotection is perhaps important as naïve stromal cells are linked to increased caspase expression (involved in regulation of apoptosis), and enhanced ability to undergo cell death[59] and so perhaps these cells need to be protected by their niche.

To address these questions, nestin expression was reduced by siRNA knock-down in PerSCs to test links between HIF1α expression and cytoprotective effects (Figure 6b, supplementary Figure 10a). Interestingly, in the +gel niche, nestin knock-down led to a concomitant decrease in the levels of nuclear-localised HIF1α, demonstrating a link between nestin and HIF1α (Figure 6c, supplementary Figure 10b). We note that a recent study indicated that nestin binds to HIF1α to protect it from degradation and showed nestin knockdown leads to loss of HIF1α, as we show here[60]. To evaluate if this link was involved in cytoprotection, oxidative stress and apoptosis was induced in PerSCs by exposure to hydrogen peroxide and changes in viability measured using propidium iodide (PI) uptake. In the +gel niches, where PerSCs express high levels of nestin, cell death in response to oxidative stress was low (Figure 6d). Reducing nestin by siRNA knock-down resulted in an increased sensitivity to oxidative stress, with a significant increase in PI positive cells observed for cells in +gel niches (Figure 6e & supplementary Figure 10c & d; note that all conditions are with H_2O_2). These results align with reports on the effects of oxidative stress on neuronal progenitors, where nestin positive cells were more resistant to oxidative stress driven by H_2O_2-induced apoptosis[58].

Engineered Niches Maintain LT-HSCs ex vivo.

Next, we investigated whether our bioengineered niches could maintain LT-HSCs. Typically, HSC expansion media contains a cocktail of GFs. Here, we used a defined basic media (0% HSC Media; see Methods), which we supplemented with three necessary GFs (Flt3L (FMS like

tyrosine kinase 3 ligand, 50 ng/mL); SCF (20 ng/mL); and TPO (25 ng/mL)) to make a standardised HSC media (called 100% HSC media). When HSCs were cultured in 100% media in standard tissue culture well plates, we refer to it as the 'gold standard' (GS) condition.

To test the niche conditions on maintenance of the CD34^{+ve}/CD38^{-ve} HSC population, PerSCs were first cultured in the bioengineered models for 14 days in stromal cell media in order to precondition the niches (see Methods). CD34^{+ve} HSCs from human BM were then added to the niches when the media was changed to either 0% HSC media, or 100% HSC media. The cells were co-cultured for a further 5 days (Figure 7a, supplementary Figure 12b), and then released with collagenase for flow cytometry analysis (supplementary Figures 11 & 12). Our strategy (as shown in Figure 7b) excluded PerSCs from this analysis, by gating on CD45 positive cells and then defining and quantifying the CD34^{+ve}/CD38^{-ve} population. This population is commonly referred to as HSCs, but, in fact, contains both LT and ST-HSC populations. GS culture conditions showed a 6-fold increase in CD34^{+ve}/CD38^{-ve} cell numbers after 5 days of culture in the bioengineered models (Figure 7c). When CD34^{+ve} HSCs were co-cultured with PerSCs in -gel models, they expanded to a similar extent in both 0% and 100% HSC media, indicating that the PerSCs could support HSC expansion (Figure 7c). However, when CD34^{+ve} HSCs were co-cultured with PerSCs in hypoxic models or in the +gel niches, no expansion was observed in the CD34^{+ve}/CD38^{-ve} population (Figure 7c).

As previously noted, LT-HSCs are inherently quiescent, making the expansion of this population, without differentiation, difficult[4]. Thus, strategies that robustly maintain LT-HSC functional properties *in vitro* are still unresolved. We therefore investigated if our bioengineered niches could maintain LT-HSC numbers rather than just a CD34^{+ve}/CD38^{-ve} heterogenous population. To enumerate LT-HSCs, long-term culture-initiating cell (LTC-IC) assays were performed to identify the number of naïve LT-HSCs within a CD34^{+ve} mixed population. In this assay, defined culture conditions (feeder layers and media) are used in which ST-HSCs and progenitors die over 6 weeks. The potency of the remaining LT-HSCs was then tested using a colony forming unit assay (CFUs), in which the differentiation potential of individual LT-HSCs were tested in methylcellulose cultures for a further 7 days.

BM CD34^{+ve} cells were co-cultured in engineered niches, and subsequently FACS sorted for CD45^{+ve}/Lin^{-ve}/CD34^{+ve} markers to remove committed progenitors and PerSCs (supplementary Figure 11a). In the -gel condition with 0% or 100% HSC media, increased numbers of CD34^{+ve}/CD38^{-ve} HSCs were observed compared to the starting population (i.e. expansion) (Figure 7c); however, fewer LT-HSCs were preserved compared to the gold-standard conditions (Figure 7d). In the +gel niches with 100% HSC media, no CD34^{+ve}/CD38^{-ve} expansion was noted (Figure 7c) and LT-HSC numbers were reduced demonstrating phenotypic drift (Figure 7d). Importantly, the +gel niche with 0% HSC media maintained both total CD34^{+ve}/CD38^{-ve} cell numbers (Figure 7c) and maintained a significantly higher number of LT-HSCs, similar to the expanded GS population (Figure 7d). This indicates that the CD34^{+ve}/CD38^{-ve} expansion observed in the GS condition must have been in the ST-HSC/progenitor population as it did not lead to an increased number of LT-HSCs compared to +gel 0% (Figure 7c & d). It is noteworthy that the subsequent differentiation profile of LT-HSCs from the +gel niche with 0% HSC media mimics that of the GS cultures, with no loss of lineage commitment, as indicated by the ability to reconstitute all blood cell progenitors (Figure 7e, supplementary Figure 11b).

To confirm this data, we first used extended flow cytometry analysis to identify CD45^{+ve}/CD41a^{-ve}/CD16^{-ve}/CD7^{-ve}/CD38^{-ve}/CD34^{+ve}/CD90^{+ve}/CD45RA^{-ve} (LT-HSCs) from CD45^{+ve}/CD41a^{-ve}/CD16^{-ve}/CD7^{-ve}/CD38^{-ve}/CD34^{+ve}/CD90^{-ve}/CD45RA^{+ve} (ST-HSCs) (supplementary Figure 12a)[61]. This confirmed the 0% +gel niche retained LT-HSCs without expansion in the ST-HSC compartment observed in other conditions. Secondly, *in vivo* engraftment study showed that CD34^{+ve} cells recovered from the niche after culture had engraftment potential similar to that of freshly thawed cells, demonstrating retention of the LT-HSC population (Figure 7f, supplementary Figure 13). It is notable that CD34^{+ve} cells after culture in GS media had significantly reduced *in vivo* engraftment potential (Figure 7f), alongside an increase in proportion of human MPPs to LT-HSCs in the BM (supplementary Figure 13c). Together, this further demonstrates growth accompanied by differentiation in this control condition (Figure 7f, supplementary Figure 13).

PerSC phenotype was next considered with respect to nestin and nuclear HIF1α post-culture with CD34^{+ve} cells, with and without GS media. With use of GS (100%) media in -gel and +gel conditions, only low levels of nestin and HIF1α were observed (supplementary Figure 14a & b) in PerSC phenotype. With use of 0% media, while low levels of nestin and HIF1α were seen in -gel cultures, significant increases in both were noted in +gel cultures (supplementary Figure 14a & b). This data indicates that the PerSCs maintain their niche phenotype best in the condition where best LT-HSC phenotype is maintained (+gel, 0%).

To demonstrate the therapeutic potential of our engineered niches, we also investigated their ability to support CRISPR edited HSCs. The cellular repair of CRISPR-mediated double-strand DNA breaks in dividing cells primarily occurs via canonical non-homologous end-joining (C-NHEJ) or alternative end-joining processes like microhomology-mediated end-joining (MMEJ). It has previously been shown that quiescent LT-HSCs can be CRISPR edited primarily via C-NHEJ, while retaining engraftment potential[62]. As a proof of concept, we targeted the neutral AAVS1 (*PPP1R12C* intron 1) locus (Figure 7g), which can be edited in HSCs without loss of phenotype[62]. Using a NHEJ CRISPR strategy, we transfected primary human CD34^{+ve} BM cells with ribonuclear protein (RNP) complexes of Cas9 and AAVS1 A1 single guide RNA (sgRNA) and seeded the cells into our bioengineered niches immediately after transfection. We then assessed if the different niche microenvironments could improve the survival of CRISPR edited cells by assessing the fractions of edited HSCs after standard culture, or in the -gel and +gel niches, with either 100% or 0% HSC media. As expected, mutagenesis levels were low in these primary human HSCs. We achieved just ~5-6% mutagenesis in 100% HSC media (~2% in 0% HSC media) in both standard and -gel conditions (Figure 7h). However, notably higher levels of CRISPR edited HSCs were retained in the +gel niche, in both 100% and 0% HSC media conditions at ~10% and ~9% respectively (Figure 7h, supplementary Figure 15).

Figure 7 | Engineered niches support LT-HSC maintenance, in vivo reconstitution and CRISPR editing. *a,
Schematic of the experimental set up.* ***b,*** *Representative gating strategy used for HSC identification. Forward
(FSC-A) versus side scatter area (SSC-A) plots were used to identify viable cells; FSC-A versus FSC width (FSC-W)
plots were used to identify single cells. A gate was added on CD45^{+ve} cells to exclude any PerSCs and 3 gates were
used to identify CD34^{+ve}/CD38^{-ve}, CD34^{+ve}/CD38^{+ve} and CD34^{-ve}/CD38^{+ve} populations. The CD34^{+ve}/CD34^{-ve}
population represents both LT- and ST-HSCs, whereas the CD34^{+ve}/CD38^{+ve} and CD34^{-ve}/CD38^{+ve}populations
represent haematopoietic stem and progenitor cells and committed progenitors, respectively.* ***c,*** *Fold change in

The heatmap shows the level of % AAVS1 mutagenesis, n = 2 donors, 3 pooled material replicates.*

Discussion

In this study we set out to show that a combination of materials could be used to organise the ECM, GF presentation and elastic environment of a putative BM niche. *In vivo*, the BM endosteum is densely perfused with a network of thin-walled arterioles[13,24]. These arterioles are closely associated with nestin^{+ve} PerSCs[12,13,18], and HSCs isolated from this area show greater engraftment potential than their central marrow (sinusoidal) counterparts[63]. Here, we report a first attempt to bioengineer this endosteal/arteriolar region of the BM niche, by promoting a niche-like phenotype in PerSCs that can support and maintain LT-HSCs, the HSC population that resembles those isolated from this niche region *in vivo*.

The +gel niche model developed here supports the expression of nestin in PerSCs, a phenotype that has been well-reported to be critical for the stromal-HSC supportive phenotype *in vivo*[12,13,18,27] and has been shown to have increased expression in stromal cells in soft environments[19]. Indeed, expression of nestin by PerSCs correlates with increased expression of other important niche factors, such as HSC maintaining cytokines, decreased oxidative phosphorylation/respiration[39,64], and increased cytoprotection[56–58]. We demonstrate that nestin-linked changes in PerSC respiration were central to the LT-HSC supportive phenotype. Nestin was further implicated in the persistent expression of nuclear HIF1α in the absence of low oxygen tension and without changes in the expression of hypoxia-signalling targets. This has parallels to cancer cells using HIF metabolism without hypoxia in the Warburg effect[55].

This new approach towards LT-HSC maintenance is important, as most studies focus on expansion of the total heterogenous HSC population *in vitro*, and do not separate naïve LT-HSCs from other committed progenitor populations[10,28,30]. Currently, expansion of LT-HSCs and the mechanisms required remain elusive. It is likely that clinically relevant expansions (e.g. 1 donor to multiple recipients) will require genetic manipulations/perturbation as naturally quiescent LT-HSCs will be required to enter the cell cycle and proliferate, then return to the resting state[65]. Until these fundamental principles of LT-HSC dynamics are understood and can be harnessed, systems that focus on their effective maintenance are required to help understand these dynamics and to improve therapeutic applications such as drug development, alloSCT or gene editing.

Here, our data suggests that the use of common exogenous GF supplementation in combination with these niche co-cultures provides excessive stimulation to the HSC population and results in the loss of quiescence. However, by manipulating

microenvironments to tune stromal cell physiology, LT-HSCs can be maintained *in vitro* without any exogenous supplementation. The CFU and *in vivo* data (Figure 7; supplementary figures 11 & 13) indicates that the CD34^{+ve}/CD38^{-ve} expansion (Figure 7c) observed in the GS condition must have been in the ST-HSC/progenitor population, as it did not lead to an increase in CFU number (i.e. LT-HSCs) or to long-term engraftment *in vivo*, in fact, CFUs decreased, and observed engraftment was poor, compared to culture in the +gel niche. As such, we suggest that the use of the optimised +gel niche avoids the unwanted ST-HSC/progenitor expansion that comes with the concomitant sacrifice of LT-HSC numbers.

Furthermore, once we had established a LT-HSC maintenance niche and investigated a role for nestin in PerSC support phenotype, we went on to investigate a potential use for the niches in supporting CRISPR editing. Using a NHEJ-based CRISPR approach that facilitates the targeting of quiescent cells, such as LT-HSCs[62], we demonstrated that our bioengineered niches improve the survival of CRISPR edited HSCs. This is important because of the very low abundance of LT-HSCs and shows that our niches can maintain these cells. For such approaches to be used successfully to gene edit HSCs for therapeutic purposes, CRISPR editing rates in LT-HSCs, and LT-HSC survival, will need to be as high as possible to ensure that enough of the edited population can engraft and rebuild the blood system. Recent work shows that stromal support for gene edited-HSCs (Dexter-like cultures) provides required HSC support factors and can provide better engraftment[66]. Bioengineered niches can be envisaged to offer further enhanced control of the gene edited-LT-HSC phenotype.

Our study has limitations in that it uses a natural hydrogel, collagen. The use of a synthetic hydrogel would have advantages in increased reproducibility/control of viscoelasticity, degradability and biological milieu[67]. Further, while we advocate an approach of LT-HSC maintenance, the ability to robustly expand this population is deeply alluring. In the BM niche, the LT-HSCs are produced or, perhaps, dedifferentiated from ST-HSCs/progenitor cells[65]. Looking to bioengineer the sinusoidal niche, with different ECM constiuents[40,41], different stromal support[13] and different oxygen tension[24], could thus be interesting and rewarding.

Such advances in bioengineering will need to progress in hand with evolving understanding of LT-HSC quiescence and activation. For example, LT-HSCs, themselves, are heterogeneous and this could have practical importance in targeting specific populations of LT-HSCs with materials. CD112^{low} LT-HSCs, are differentially quiescent from CD122^{hi} LT-HSCs and have better-preserved self-renewal and regeneration capacity under regenerative stress[68]. Advancing biochemical information can also provide target pathways for bioengineers to design materials to interact with, as we do with integrins and GFs here. For example, transcription factor EB (TFEB) has been shown to provide lysosomal regulation to drive digestion of membrane receptors, such as transferrin and insulin receptors, in order to limit LT-HSC metabolism and prevent differentiation[69]. The subcellular localization and activity of TFEB are regulated by mechanistic target of rapamycin (mTOR)-mediated phosphorylation, which occurs at the lysosomal surface[70]. Materials platforms have also been implicated in changes in chromatin organisation[71–74] and, for LT-HSCs, understanding chromatin accessibility to suppress CCCTC-binding factor (CTCF), restrains LT-HSCs from transitioning to activated ST-HSCs[75]. These new biological insights guide us for future bioengineered niche developments.

Methods

Preparation of materials and ECM interfaces

Polymer sheets were obtained by radical polymerization of a solution of either MA (methyl acrylate) or EA (ethyl acrylate) (Sigma-Aldrich, UK), using 1 and 0.35 weight percent benzoin (98% pure; Scharlau) as the photoinitiator. Polymerization carried out up to limiting conversion. After polymerization, low molecular mass substances extracted by drying under vacuum to constant weight. PMA and PEA were dissolved in toluene at a concentration of 6% or 9% and 2.5% or 12% dependent on batch. Spin casting was performed on glass coverslips at 2000 rpm for 30 s. Samples dried under vacuum at 60°C for 2 h, and sterilised under UV light for 30 min before use[35]. FN from human plasma (Sigma-Aldrich, F2006) was adsorbed from solutions of 20 μg/ml for 1 h a room temperature (RT) then washed thrice with phosphate-buffered saline (PBS). For GF adsorption, BMP-2 (50 ng/ml; Sigma-Aldrich, H4791) in PBS was used for 2 h at RT. Finally, samples were rinsed in PBS to eliminate non-adsorbed protein.

Atomic force microscopy

FN was prepared in PBS (20 μg/ml) and a 200 μl droplet placed on surface of PEA and PMA coated coverslips. The protein was adsorbed for 10 min and remaining liquid removed from the surface. Surfaces were then washed twice in PBS, once with deionised water and then dried under a stream of nitrogen before imaging. A JPK Nanowizard 4 (JPK Instruments) was used for imaging in tapping mode, using antimony-doped Si cantilevers with a nominal resonant frequency of 75 kHz (MPP-21 220, Bruker). The phase signal was set to 0 at a frequency 5-10% lower than the resonant frequency. Height and phase images were acquired from each scan, the JPK data processing software version 5 was used for image analysis.

FN adsorption assays

To quantify amount of FN adsorbed onto PEA or PMA surfaces substrates were coated with 20 μg/ml FN/PBS solution for 1 h, aspirate was collected and FN quantified using the Pierce™ BCA Protein Assay Kit (ThermoFisher, UK). Quantitative immunofluorescence assays were carried out using the LI-COR in-cell western™ platform. FN (20 μg/ml) was adsorbed as previously described, samples were washed with PBS, blocked with 1% milk protein in PBS, and incubated with primary antibodies for total FN (polyclonal rabbit, Sigma Aldrich), HFN7.1 (monoclonal mouse, Developmental Studies Hybridoma Bank, USA), and P5F3 (monoclonal mouse, Santa Cruz Biotechnology, sc-18827) for 2 h. Substrates were washed 5x 0.5% Tween20 in PBS (PBST), followed by incubation o/n at 4°C with LI-COR secondary antibodies (IRDye 800CW/700CW anti-rabbit/mouse secondary antibody, LI-COR, UK). Samples were

washed 5x with PBST, followed by a final wash in PBS and dried before imaging on LI-COR Sa Odyssey scanner.

BMP-2 adsorption

For quantification of BMP-2 adsorption, (50 ng/ml) BMP-2 solution was added to FN coated polymers and after 2 h incubation solution was aspirated and collected in Protein LoBind Tubes (Eppendorf™). Enzyme-linked immunosorbent assays (ELISA) was then carried out as per manufacturer's instructions (R&D Systems, BMP-2 DuoSet ELISA kit, DY355). Briefly, ELISA plates were coated with capture antibody overnight, then blocked for 1 h with BSA. Standards, original solution, original solution at 20x dilution and sample aspirates were then added to the plate, and bound BMP-2 was detected with biotinylated anti-human BMP-2. Streptavidin-HRP was added to plates for 20 min in the dark, followed by substrate solution (tetramethylbenzidine and peroxide) for 20 min, the reaction was then stopped by adding stop solution. Absorbance measured at 450 nm with wavelength correction at 570 nm.

PerSC isolation

PerSCs were isolated from the adipose tissue of healthy adult donors undergoing cosmetic lipectomy procedures with prior written consent, or from patients undergoing breast reconstruction procedure, using deep inferior epigastric perforators (DIEP), from adult donors. Ethical approval for the collection of tissue and subsequent research was granted by the South-East Scotland Research Ethics Committee 3 (SESREC03, reference no. 10/S1103/45). Incisions were made in the adipose tissue using a scalpel to divide the Scarpa's fascial layer, then tissue was mechanically disrupted, combined with PBS and centrifuged at 445 g for 10 mins at RT, causing phase separation. The 3 phases include the top phase (liquid fat/oil), central phase containing the tissue of interest (adipose tissue), and the bottom phase (blood/fluid). Middle layer was removed and mixed with equal volumes of PBS/2% (v/v) fetal bovine serum (FBS) and centrifuged at 445 g for 10 mins. Supernatant was discarded and the remaining Stromal Vascular Fraction (SVF) pellet, was enzymatically digested with type II-S collagenase 1 mg/ml in DMEM/0.5% (v/v) BSA for 45 mins at 37°C. Samples were centrifuged and supernatant discarded (containing oil and adipocytes) and pellets resuspended and strained through 400 µm, 100 µm and 70 µm cell pluristrainers to remove undigested material. Red blood cell lysis buffer was added to eliminate erythroid cells and SVF pellet resuspended in Fluorescent Activated Cell Sorting (FACS) buffer. Cells sorted on CD146^{+ve}/CD45^{-ve}/CD34^{-ve}/CD31^{-ve} phenotype (anti-CD146 clone P1H12, BV711, 563186; anti-CD45 clone H130, V450, 560367; anti-CD34 clone 581, FITC, 555821; anti-CD31 clone WM59, PE-Cy7, 563651. All BD Biosciences), using BD FACSAria cell sorter (BD Biosciences). Immediately after sorting, cells were then cultured as previously described[16]. Briefly, cells were cultured in endothelial growth medium (EGM-2, Lonza) on 0.1% gelatin-coated plates in a humidified incubator with 5% CO_2 at 37°C until passage 1.

PerSC cell culture

PerSCs, after passage 1, were cultured in Dulbecco's Modified Eagle's Medium (DMEM, Sigma-Aldrich) with 20% FBS (Thermo Fisher), 1% nonessential amino acids (Sigma-Aldrich), 1% 100 mM sodium pyruvate (Sigma-Aldrich) and an antibiotic mix consisting of 10 mg/ml penicillin/streptavidin (Sigma-Aldrich), 200 nM L-glutamate (Sigma-Aldrich), and 0.5% Fungizone (Thermo Fisher). Cells were incubated in a 5% humidified CO_2 atmosphere at 37°C.

For cell culture on polymer substrates, cells were seeded at $1.5 \times 10^3/cm^2$ on 13 mm coverslips in 24 well-plates and cultured in DMEM containing 2% with human AB serum (HS; Sigma Aldrich, H4522) in a 5% humidified CO_2 atmosphere at 37°C. Hypoxic culture carried out in hypoxic workstation (Ruskinn) at an oxygen tension of 1%, CO_2 5% and 37°C. Medium was exchanged every 3 days.

CD34^{+ve} cell isolation

Human CD34^{+ve} cells were isolated from the bone marrow aspirates of patients undergoing joint replacement surgery. The permission to use the residual tissues was given by the Greater Glasgow and Clyde NHS Biorepository. For isolation of CD34^{+ve} cells, mononuclear cells were resuspended with FACS buffer and incubated with CD34^{+ve} microbeads (Militenyi Biotec, #130-046-702) for 30 mins at 4°C. Cell suspensions were transferred to LS Columns (Militenyl Biotec, #130-042-401) and passed through the magnetic Quadromacs Separation Unit (Militenyi Biotec, #130-090-976). Magnetically labelled CD34^{+ve} cells were then collected, counted and cryopreserved.

CD34^{+ve} cell culture

CD34^{+ve} cells from human BM were purchased from CalTag Medystems (experiments related to Figure 7b-e) and STEMCELL Technologies or isolated from BM samples as above (Figure 7f). CD34^{+ve} cells were cultured in serum free medium; Iscove's Modified Dulbecco Medium (IMDM) containing 20% BIT 9500 serum substitute (STEMCELL Technologies), 1% 200 mM L-glutamine (Sigma-Aldrich), 1% 10 mg/ml penicillin/streptomycin (Invitrogen) supplemented with Flt3L (50 ng/ml), SCF (20 ng/ml) and TPO (25 ng/ml) (all recombinant human, Peprotech, 300-19, 300-07, 300-18) (100% medium). CD34^{+ve} cells were thawed, counted and rested overnight in 100% medium at a density of $0.5 \times 10^6/ml$, then recounted, suspended in 100% or 0% media, and seeded into niche models at a density of 5×10^4 cells/ml, with 0.5 ml added to each well of 24 well plate. For conditions containing gels, the HSCs were seeded on top of the gel. Control (100% media only) were seeded into 24 well-plates. Seeded cells were then cultured for 5 days. At least 1×10^3 cells were transferred to an Eppendorf tube and phenotyped at day 0 using flow cytometry.

Collagen gel preparation and rheological measurement

Collagen type I gels were added to relevant (+gel) conditions after either 24h (for short term culture) or 72h (for long term culture). Rat tail collagen type I solution in 0.6% acetic acid (First Link, UK) was combined with human AB serum (HS; Sigma-Aldrich, H4522), 10x DMEM, 2% HS DMEM, adjusted to pH 8.2 using 0.1 M NaOH. 1 ml of solution was then added to 24 well-plates containing PEA coated 13 mm coverslips. Resulting gels were ~1 cm thick. Rheological measurements were carried out using an Anton Paar Physical MCR301 rheometer. A parallel plate geometry (25 mm diameter, sandblasted) and 1.0 mm gap were used to measure time sweeps. The dynamic modulus of the hydrogel was measured as a frequency function, with frequency sweeps carried out between 0.1 – 15 Hz to measure the dynamic shear of the modulus as a function of strain. Measurements were repeated 3 times on gels from 3 different batches. Storage moduli (G´) values were extracted from the accompanying Kinexus software. The Young's modulus was then determined by taking the G´ and multiplying by 3, assuming a Poisson's ratio of 0.5 in accordance with Hooke's law.

Immunocytochemistry

PerSCs were cultured in niches for times indicated and fixed using 10% formaldehyde for 15 mins. For SCF and CXCL12 analysis, cells were cultured with 5 µg/ml brefeldin A (SigmaAldrich, B6542), for the final 24 h of culture before fixation. Cells were then permeabilized with 0.5% Triton-X for 5 mins and blocked using 0.5% BSA/PBS for 2 h at RT. Primary antibodies were then added in blocking buffer: anti-nestin [10C2] 1:200 (mouse monoclonal, Abcam, ab22035); anti-p(Th316)-nestin [a-4] at 1:200 (mouse monoclonal, Santa Cruz Biotechnology, sc-377538); anti-HIF1α [EP1215Y] 1:300 (rabbit monoclonal, Abcam, ab51608); anti-vimentin [SP20] 1:300 (rabbit monoclonal, Thermo Fischer, MA5-16409); anti-CXCL12 1:200 (monoclonal mouse, R & D Systems, MAB350); anti-SCF 1:200 (rabbit polyclonal, Abcam, ab64677). Cells were then washed 5 x 5 mins with PBST and biotinylated secondary antibodies (1:50; Vector Laboratories) were added in blocking buffer for 2 h at RT. Cells were again washed 3 x 5 mins in PBST and incubated with fluorescein isothiocyanate-conjugated streptavidin (1:50; Vector Laboratories) in blocking buffer for 30 mins at RT. Nuclei were stained using VECTASHIELD mountant with 5',6-diamidino-2-phenylindole nuclear stain (DAPI; Vector Laboratories). Samples were then mounted onto glass slides and visualised using an Axiophot microscope or Evos Cell imaging system (Thermo Fischer) and analysed using ImageJ software (National Institute of Health). HIF1α nuclear co-localisation was analysed using a custom developed pipeline on CellProfiler software (version 2.1.1). All images were background corrected and analysis normalised to cell number via DAPI/Hoescht staining, or individual cells measured, as stated in figure legends.

Flow cytometry

To phenotype PerSCs and HSCs after culture, cells were harvested from niche systems using collagenase D (2.5 mg/mL in PBS; Sigma-Aldrich) and TripLE™ (Thermo Fisher). Cells were passed through a 70 µm filter, and stained on ice for 30 mins, using antibodies outlined in supplementary Table 3 and 4 for PerSC and HSC markers, in flow cytometry buffer (PBS supplemented with 0.5% BSA and 0.5 mM EDTA). Cells were then washed twice with PBS and analysed using an BD FACSCanto ll (BD Biosciences). The BD FACSAria Cell sorter was used for CD34[+ve] sorting for LTC-IC and *in vivo* assays. The gating strategy is shown in supplementary Figure 5 & 13. Flow cytometry files were analysed using FlowJo software (version 10.5.3, FlowJo LLC, USA). Single cell suspensions from *in vivo* experiments were prepared for phenotypic analysis by flow cytometry as described previously[76]. All antibodies for *in vivo* analysis are shown in supplementary Table 5. All samples were suspended in 100 µl FACS buffer prior to acquisition. Flow cytometry data were acquired using a FACSCantoII flow cytometer (BD Biosciences) using the FACS Diva software package and analysed using the FlowJo software package (Tree Star, Inc., Ashland, OR).

RNA-seq

Sequencing libraries then prepared from total RNA using the Illumina TruSeq Stranded mRNA Sample Preparation Kit. Libraries were sequenced in 75 base, paired end mode on the Illumina NextSeq 500 platform. Raw sequence reads were trimmed for contaminating sequence adapters and poor quality bases using the program Cutadapt[77]. Bases with an average Phred score lower than 15 were trimmed. Reads that were trimmed to less than 54 bases were discarded. The quality of the reads were checked using the FastQC program (http://www.bioinformatics.babraham.ac.uk/projects/fastqc/) before and after trimming. The reads were "pseudo aligned" to the transcriptome using the program Kallisto[78]. The

differential expression for the analysis groups were assessed using the Bioconductor package DESeq2[79]. This was provided as a service by Glasgow Polyomics Facility. One hypoxic sample failed RNA quality control. Heatmaps in Figure 3g & h were subsequently generated using Cluster 3.0 and Java Treeview 3.0 software, with average linkage clustering method. To assess expression of transcripts related to an immunomodulatory phenotype, the distribution of reads across genomic features was quantified using the R package Genomic Ranges from Bioconductor Version 3.065. Differentially expressed genes were identified using the R package edgeR from Bioconductor Version 3.066. For Figure 4a-c and supplementary Figure 6, analyses were performed within the R statistical computing framework using packages from BioConductor. Feature counts were utilized to quantify reading counts. Human ENSEMBL gene ID to gene symbol conversion was performed in BioTools (https://www.biotools.fr). The DEseq2 BioConductor package was used for outlier detection, normalisation and differential gene expression analyses. Genes passing a threshold of adjusted p-value <0.05 and a log2 fold change > 1 were considered as differentially expressed. The names of differentially expressed genes along with their respective log2fold changes were inputted into PathfindR package. Gene Ontology (GO) enrichment was conducted with PathfindR. Only pathways with FDR < = 0.05 were considered as differentially enriched. The differentially expressed genes involved in every pathway were extracted and their z-scored fold changes in expression were presented as heatmaps.

VEGF ELISA
PerSCs were cultures in niche systems and media supernatant was collected in Protein LoBind Tubes (Eppendorf™) at day 7 and 14 and stored at -20°C. ELISA for VEGF was then carried out as per manufacturer's instructions (R&D Systems, VEGF Quantikine ELISA kit, DVE00). Standards and media aspirate were added to the ELISA plate in duplicate. Absorbance measured at 450 nm with wavelength correction at 570 nm.

Hypoxyprobe™ assay
PerSCs were cultured in niche models for 6 days, medium was then changed to fresh medium containing 200 µM pimonidazole (Hypoxyprobe™, HP1-200kit), and cultured for a further 24 h. Cells were then fixed, permeabilized and blocked as described for immunocytochemistry. Mouse monoclonal anti-pimonidazole (1:200; Hypoxyprobe™, HP1-200kit) was added in blocking buffer and incubated overnight at 4°C. Cells were washed 3 x 5 mins in PBST and incubated with anti-mouse secondary (1:50, Texas Red; Vector Laboratories) for 2 h at RT. Cells were washed 3 x 5 mins in PBST and mounted onto glass slides with DAPI nuclei stain VECTASHIELD mountant (Vector Laboratories). Samples were visualised on Evos Cell imaging system (ThermoFisher) and analysed using ImageJ software (National Institute of Health).

Metabolomics
Whole cell metabolomic analysis was performed on cell lysates isolated from PerSCs cultured in niche systems for 7 or 14 days. Substrates were washed with ice-cold PBS, and cells lysed in extraction buffer (PBS/methanol/chloroform at 1:3:1 ratio) for 60 mins at 4°C with constant agitation. Lysates were then transferred to cold Eppendorfs™ and spun at 13000 g at 4°C for 5 mins to remove debris and stored at -80°C. Cleared extracts were used for hydrophilic interaction LC/MS analysis (UltiMate 3000 RSLC, (ThermoFisher), with a 6 150 x 4.6 mm ZIC-pHILIC column running at 300 µl/min-1 and Orbitrap Exactive). A standard pipeline, consisting of XCMS (peak picking), MzMatch (filtering and grouping) and IDEOM (further filtering, post-

processing and identification) was used to process the raw mass spectrometry data. Identified core metabolites were validated against a panel of unambiguous standards by mass and predicted retention time. Further putative identifications were generated by mass and predicted retention times. Heatmaps of selected metabolites and principle component analysis (PCA) plots were generated using MetaboAnalyst software (version 4.0). This was provided as a service by Glasgow Polyomics Facility.

$^{13}C_6$-Glucose metabolomic tracing

PerSCs were seeded onto PEA/FN/BMP-2 niche systems and allowed to grow for 72 h. Cells were then washed and media was changed to basal media comprising 25% normal glucose and 75% $^{13}C_6$-Glucose (Cambridge Isotopes Ltd). Extraction performed in PBS/methanol/chloroform at 1:3:1 ratio, after 3 days incubation and prepared for LC-MS. The LC-MS platform consisted of an Accela 600 HPLC system combined with an Exactive (Orbitrap) mass spectrometer (ThermoFisher). Two complementary columns were used; the zwitterionic ZICpHILLIC column (150 mm x 4.6 mm; 3.5 μm, Merck) and the reversed phase ACE C18-AR column (150 mm x 4.6 mm; 3.5 μm Hichrom) and in both cases sample volume was 10 μl at a flow rate of 0.3 ml/min. Eluted samples were then analysed by mass spectrometry. Raw data from LC-MS of ^{13}C-labelled extracts was processed to generate a combined PeakML file[80]. Further analysis using mzMatch-ISO in R[81] generated a PDF file containing chromatograms used to check peak-shape and retention time, and a tab delineated file detailing peak height for each isopotologue, which was used to calculate percentage labelling. Samples normalised to cell number. Total $^{13}C_6$-Glucose incorporation was calculated by totalling incorporation excluding up to C2 to eliminate natural incorporation. This was provided as a service by Glasgow Polyomics Facility.

siRNA NES silencing NES

PerSCs were seeded into niche models in antibiotic free 2% HS DMEM, after 24 h media was changed to Opti-MEM™ (ThermoFisher) and siRNA transfection was carried out 24 h later. Pre-designed Silencer™ Select siRNA NES (ID: 21141), or Silencer™ Select negative control number 1 siRNA (both Thermo Fisher), was incubated at RT for 20 mins with Lipofectamine™ RNAiMAX (ThermoFisher) in Opti-MEM™ and added to PerSCs in niches. 6 h later, Opti-MEM™ +2% HS was added to control and -gel conditions. For +gel, media containing siRNA was collected and used to prepare collagen gels as described above. Once collagen had set, Opti-MEM™ +2% HS was added. Cells were then cultured for 72h and either fixed for immunofluorescence analysis or cytotoxicity assays carried out.

Cytotoxicity assay

Cells were cultured in niche models for time points indicated. Collagen gels were removed and 1 mM H_2O_2 added for the final 6 h of culture. Hoechst (33342) nuclear stain (ThermoFisher, R37605) and Propidium Iodide (PI) (Biolegend, 421301) viability stain was then added and imaged on EVOS M7000 imaging system using the on-stage incubator.

LTC-IC assay

LTC-IC assays were carried out on sorted CD45^{+ve}/Lineage^{-ve}/CD34^{+ve} cells harvested after 5 days of culture in niche systems (supplementary Table 4). Engineered stromal fibroblast feeder layers were first established. M2-10B4 (overexpressing IL-3 and G-CSF) and Sl/Sl (overexpressing IL-3 and SCF) were passaged at ~90% confluence (cell lines gifted from

StemCell Technologies). Cells were grown for 2 weeks prior to use in selection agents to select stromal cells expressing long-term cell maintenance factors (M2-10B4, 0.4mg/ml G418 and 0.06mg/ml Hygromycin B; Sl/Sl, 0.8 mg/ml G418 and 0.15 mg/ml Hygromycin B) G418 and Hygromycin B both StemCell Technologies (03812, 03812). Cells at ~80% confluence were irradiated with 8000 cGy, trypsinised. M2-10B4 and Sl/Sl were mixed at 1:1 ratio at a final concentration of 1.5×10^6/ml. Cells were then seeded into collagen coated 24 well plates (Thermo Fisher, A1142802) for 24 h before adding sorted cells. Cultures were then maintained for 6 weeks in MyeloCult™ (StemCell Technologies, 05150) supplemented with 1×10^{-6} M hydrocortisone (StemCell Technologies, 74142), with half media exchanges twice per week.

CFU Assay

Cells were harvested and resuspended in MethoCult™ (StemCell Technologies, 04435) from LTC-IC assays after 6 weeks. 2 replicates were seeded for each condition in 35 mm dishes and incubated at 37°C in 5% CO_2 for 7 days. After 7 days total colonies were counted and phenotyped using a light microscope.

Xeno-transplantations

NOD-RAG-$\gamma c^{-/-}$ mice constitutively expressing human IL3, GMCSF and Steel factor (NRG-3GS[82]) were used as hosts (8 -10 wk old) for transplantation, to establish the lineage potential of human HSCs derived from indicated culture conditions *in vivo*. Human BM CD34[+ve] cells were cultured in GS (n = 5 mice) or PEA +gel (n = 3 mice) niches as previously described and CD45[+ve]/Lineage[-ve]/CD34[+ve] cells harvested after 5 days of culture by FACS. Freshly thawed CD34[+]-enriched HSCs isolated from BM (StemCell Technologies) were used as a positive control for engraftment (n=2 mice). NRG-3GS mice were sub-lethally irradiated with two doses of 1 Gy, 3 h apart. The irradiated mice were transplanted within 24 hr of the last dose with human HSCs via tail vein injection (200,000 cells/mouse). After six weeks, blood sampling (~20 μl) was performed every two weeks to track the progress of human cell engraftment by flow cytometry (hCD45-APC-Cy7 vs mCD45-PerCP), preparing the blood samples for flow cytometry using EasyLyse (Agilent Technologies) following the manufacturer's instructions. After 12 wk, mice were sacrificed and BM, spleen and blood were collected for analyses. Spleens were weighed and cells extracted in FACS buffer (PBS/2% FBS). BM was recovered by crushing the ilia, femurs, and tibia of each mouse using a pestle and mortar in FACS buffer. The cells collected from the BM and spleen were filtered through 70 μm mesh and enriched for haemopoietic lineage cells by density centrifugation using Lympholyte-Mammal (VWR, Lutterworth, UK), centrifuging the cell suspension for 20 min at 625 g at RT. Thereafter the cells were washed in FACS buffer, centrifuged at 500 g for 10 min at RT. Cells were counted using a haemocytometer and prepared for flow cytometry.

Ethical permissions

All mice were housed at the Beatson Research Unit (University of Glasgow, UK). Experimental protocols for working with animals were approved by the local AWERB committee and national Home Office (PD6C67A47).

CRISPR

CD34[+ve] cells were thawed 24 h before electroporation and cultured in IMDM +BIT +100% cytokine media without antibiotics. Ribonucleoprotein (RNP) complexes were prepared by

mixing Cas9 (IDT) at 12 µM and AAVS1_A1 sgRNA (GTCACCAATCCTGTCCCTAG, Synthego) at 12 µM, in electroporation buffer R (ThermoFisher) with 2% glycerol[62], and incubated for 15 min at RT immediately before electroporation. Electroporation was performed using the Neon™ transfection system, with 10 µl tips (ThermoFisher), as per manufacturers protocol. The optimal electroporation conditions for CD34[+ve] cells was 1700 V, 20 ms, one pulse. CD34[+ve] cells were resuspended in buffer R and mixed with assembled RNPs. Electroporated cells were resuspended in either 100% or 0% cytokine IMDM +BIT and 0.5 ml added into niche models at a density of $5x10^4$ cells/ml. Cells were then cultured for 5 days, and harvested as previously described using collagenase D, with final resuspension into 30 µl of Quick Extract™ reagent (Lucigen). For mutagenesis analysis, Quick Extract samples were diluted 1:1 with fresh QuickExtract and heated to 65 °C for 6 mins, vortexed for 15 s, and heated to 98 °C for 2 mins. Genomic PCR was carried out using Herculase II Fusion DNA Polymerase (Agilent) (Forward primer: CCCCGTTCTCCTGTGGATTC, Reverse primer: ATCCTCTCTGGCTCCATCGT). PCR products were run on 1.2 % UltraPure™ Agarose (Invitrogen) gels, purified (QIAquickPCR Purification Kit, Qiagen) and Sanger Sequenced (Eurofins Genomics). Mutagenesis analysis was carried out by TIDE analysis[83] (http://shinyapps.datacurators.nl/tide/) (supplementary Figure 5).

Statistical analysis

Shapiro Wilks normality tests were performed and statistical analysis was by one-way analysis of variance (ANOVA) with Tukey's or Bonferroni's multiple comparison test for normal and non-normal data respectively. T-tests used were indicated in figure legends. All statistical analysis was performed using GraphPad Prism 10 software.

Data availability

Raw data is available at http://dx.doi.org/10.5525/gla.researchdata.1326.
