## 18 **Abstract**

### 19 **Background:**

20 The social disparities in obesity may originate in early life and adult social class. There are various developmental  
21 trajectories of overweight/obesity in adulthood. It is unclear how the intergenerational mobility of socioeconomic  
22 status influences adult overweight/obesity in China.

### 23 **Methods:**

24 We used longitudinal data from ten waves of the China Health and Nutrition Survey (CHNS) between 1989 and  
25 2015 for our analysis. The group-based trajectory modeling was used to identify BMI trajectories in adulthood.  
26 Multinomial logistic regression was adopted to assess the associations between SES and adult BMI trajectories.

### 27 **Results:**

28 Among a total of 3,138 participants, three latent clusters, including normal-stable BMI (51.4%), progressive  
29 overweight group (39.8%), and progressive obesity group (8.8%), were identified. High father's occupational  
30 position, high participants' occupation position and educational attainment, respectively, were associated with  
31 greater obesity risk. Compared to a stable low life course SES trajectory, a stable high life course SES trajectory  
32 was associated with a 2.35-fold risk of obesity, and upward and downward social mobility trajectories increased the  
33 risk for overweight/obesity. Individuals in the highest relative to the lowest life course cumulative socioeconomic

1 score group had around twice risk of obesity.

## 2 **Conclusions:**

3 The results emphasize the role of the high SES in early life and life-course SES accumulation, in the obesity  
4 intervention in China.

## 5 **Funding:**

## 8 **Introduction**

9 Obesity has recently been a public health concern around the world, due to its strong association with many  
10 negative physical and mental health outcomes, including hypertension, diabetes, cancer and depression as well as  
11 mortality(1-3). Recent studies suggest that in China between 2015 and 2019, the prevalence of overweight and  
12 obesity in adults have reached 34.3% and 16.4%, respectively(4). The obesity and overweight epidemic have been  
13 influenced by both personal and environmental factors, such as genes, diet culture and behavioral patterns(5). The  
14 bulk of evidences show that socioeconomic status (SES), such as education, occupation and income, very often  
15 lead to social differences in the prevalence of obesity and overweight(6, 7). The majority of studies from western  
16 countries find an inverse relationship between SES and obesity(8, 9). In the developing countries, this  
17 interrelationship shows a strong positive correlation between those. Previous study in Chinese juvenile and adult  
18 population found higher income contributed to the risk for obesity(10, 11). With the rapid development of China's  
19 economy, the relationship between SES and obesity is becoming increasingly complex. Hence, understanding SES  
20 disparities in obesity is presently an essential element for Chinese government in establishing public health

1 priorities.

2 Socioeconomic disparities seem to have their origins in early life and perhaps even in earlier generations. In the

3 United States, for example, a longitudinal 19-year study suggests that higher SES in childhood protects against

4 weight gain at age 18 and in adulthood(12). Furthermore, it is now well established that adults suffer from gain

5 weight and excess adiposity mostly in this period from young to middle adulthood, while weight remain fairly

6 stable from middle to late adulthood, suggesting that there are various developmental trajectories of

7 overweight/obesity in adulthood(13). In developing countries, however, studies on the relationship between the

8 SES in early life and adult BMI trajectory are scarce, and it is also unclear whether early life course SES still has an

9 impact on adult BMI. Therefore, it is necessary to investigate the developmental characteristics of adult

10 overweight/obesity across different SES in developing countries, particularly across early life SES trajectory, to

11 provide measures to reduce future disease burdens.

12 In this study, we extracted data from a 20-year longitudinal survey, the China Health and Nutrition Survey (CHNS),

13 to assess the influence of life-course SES on adult obesity development. Our main objectives are to evaluate: (1)

14 latent effects of early life socioeconomic circumstances on adult obesity; (2) the effect of SES over the life course

15 on BMI trajectory in adulthood.

## 16 **Methods**

### 17 **Study population**

1 The data was extracted from China Health and Nutrition Survey (CHNS), which is an ongoing cohort study to  
2 explore how a series of economic, sociological, and demographic factors influence health and nutritional status of  
3 interest in China's population. The first wave of CHNS began in 1989, and subsequently the surveys were tracked  
4 in 1989, 1991, 1993, 1997, 2000, 2004, 2006, 2009, 2011 and 2015. A multistage random cluster sampling method  
5 was adopted in the survey, covering 239 communities from nine of China's 31 provinces. The survey was approved  
6 by institutional review boards at the University of North Carolina, Chapel Hill (Chapel Hill, NC), and China Center  
7 for Disease Control and Prevention (Beijing, China), and each participant provided written informed consent. A  
8 more detailed description of the design and procedures of CHNS has been described elsewhere(14, 15).

9 We used longitudinal data from ten waves of the CHNS between 1989 and 2015 for our analysis. The flow diagram  
10 of the study cohort is summarized in Figure 1. Initially, a total of 38,536 participants were extracted from the  
11 original surveys. Then approximately 35398 participants were excluded due to the following reasons: < 18 years  
12 old (n=7,870), less than 2 visits of BMI in adulthood (n=11,768), missing father's occupational position (n=15,604),  
13 missing education (n=29) and economic status in adulthood (n=92), and pregnant women (n=35). Finally, a total of  
14 3,138 participants with 11440 visits were included in the study.

## 15 **Outcome assessment**

16 In the study, the weight was measured using a balance-beam scale with an accurate to 0.1 kg, when participants  
17 wore only light clothing. The height measurement was conducted with participants barefoot on a portable  
18 stadiometer that was accurate to 0.1 cm. BMI was calculated as weight (in kilograms) divided by the square of

1 height (in meters). According to the Working Group on Obesity in China (WGOC), the BMI based definition of  
2 overweight or obesity for the Chinese population is lower than that for the European or North American population.  
3 In the study, thus, overweight and obesity were defined as  $BMI \geq 24 \text{ kg/m}^2$  and  $BMI \geq 28 \text{ kg/m}^2$ , respectively(16).  
4 To represent the development of BMI in adults, all BMI measurements from 1989 to 2015 were utilized to explore  
5 BMI trajectories with the age in the survey year as the timeline.  
6 Group-based trajectory model (GBTM) was adopted to analyze the dynamic changes of adult BMI during  
7 follow-up and identify potential clusters with similar trajectories(17). These trajectories were summarized by a  
8 finite set of different polynomial functions of age or time, determining the form and number of groups that best fit  
9 the data. Briefly, GBTM provides a statistical method to identify the trajectory of each group and the form of each  
10 trajectory, and estimates the probability for each individual of group membership and assign them to one of the  
11 trajectories for which they have the highest estimated probability. GBTMs with different numbers of latent classes  
12 were compared using information criteria (IC)-based fit statistics, including Akaike Information Criteria (AIC),  
13 Bayesian Information Criteria (BIC), Log-Likelihood G2. Lower values on these fit statistics were used for the  
14 best-fitting model selection. The value of average posterior probability (entropy) was commonly used to assess  
15 whether individuals are accurately classified into their most likely class, of which the value ranges from 0 to 1, with  
16 scores higher than 0.7 reflecting classification more accurate. At the same time, each latent class with a reasonable  
17 sample size was also considered for model selection, which will make sure interpretability of results. GBTM was  
18 conducted using Stata 12.0 with the traj procedure.

## 1 **Socioeconomic indicators**

2 We collected three indicators at the baseline survey, including father's occupation position, the participant  
3 educational attainment and adult occupation position, to represent individual socioeconomic status over the life  
4 course. Father's occupational position commonly indicated SES of participants in childhood, which was assessed  
5 retrospectively with the question "What is/was your father's main job". Similarly, the participant occupational  
6 position in adulthood was acquired by the question "What is/was your main job", which is the most used indicators  
7 of adult SES(18). According to the classification criteria of socioeconomic classification scheme(19), father's and  
8 participant's occupational positions were categorized into high (social classes I–II), medium (social classes III–IV)  
9 and low (social class V) (Table S1, Supplementary file 1), coded from 0 (low) to 2 (high).

10 The participant educational attainment was considered as a main indicator of SES in his own early life, especially  
11 in young adulthood(6). Education was defined as the highest qualification in full-time education, was obtained by  
12 the question "How many years of formal education did you have in formal school?" In the study, education was  
13 also grouped into three categories: high ( $\geq 12$  years formal education), medium (8-11 years formal education), and  
14 low (<8 years formal education).

15 Two indicators were established to represent participants' life-course SES, including life-course socioeconomic  
16 trajectories and a cumulative SES score. The cumulative life-course SES score was sum of paternal occupational  
17 position and participant's education and adult occupational position, ranging from 0 to 6, with higher values  
18 corresponding to greater life-course advantage. The life-course socioeconomic trajectories from childhood to

1 adulthood were computed using information on the father's occupational position and adult occupational position,  
2 both of them were dichotomized as high (social class I-IV) and low (social class V). Four possible combinations of  
3 socioeconomic trajectories across the life course were generated (Table S2): high SES in childhood and high SES  
4 in adulthood (stable high, n = 1524), low SES in childhood and high SES in adulthood (upward, n = 581), high SES  
5 in childhood and low SES in adulthood (downward, n = 292), and low SES in childhood and low SES in adulthood  
6 (stable low, n = 741).

## 7 **Covariates**

8 According to previous studies and a priori knowledge about our data(20), a set of covariates were considered as  
9 potential confounders, including gender, age, place of residence, smoking/drinking habits, total daily energy intake  
10 (TDEI) and physical activity level (PAL) were used as covariates in this study. Place of residence was determined  
11 by the question "Where do you live now, urban or rural?", and was further classified into two groups (urban or  
12 rural). Smoking was obtained by the question "Have you ever smoked cigarettes (including hand-rolled or  
13 device-rolled)?" and were divided into two categories, "yes" (smoking currently) or "no" (not smoking currently).  
14 Drinking was acquired by the question "How often do you drink?", and was also categorized into "yes" (drinking  
15  $\geq 1$  per month last year) or "no" (drinking  $< 1$  per month).

16 The total dietary energy intake (TDEI) was assessed at the household and individual levels, with individual's intake  
17 collected using a weighing method in combination with three consecutive 24-h recalls (on 2 weekdays and 1  
18 weekend day). TDEI was calculated based on the China Food Composition Table(21), which was used to

1 determine the energy content in each food item consumed by the individual. The caloric value of all food items was  
2 summed to calculate a daily total, finally taking the average of total energy intake for 3 days. Physical activity level  
3 was derived in the survey, including very light PAL (sitting at work, such as office workers, watch repairers, etc.),  
4 light PAL (standing at work, such as sales clerks, laboratory technicians, teachers, etc.), moderate PAL (students,  
5 drivers, electricians, metal fabrication workers, etc.), heavy PAL (farmers, dancers, steel workers, athletes, etc.) and  
6 very heavy PAL (loaders, lumberjacks, miners, masons, etc.). PAL was reclassified into 3 groups: very light and  
7 light PAL activities were combined into light PAL group, moderate PAL included moderate PAL activities, and  
8 heavy and very heavy PAL activities was combined into heavy PAL group.

## 9 **Statistical analysis**

10 The baseline characteristics were presented and compared across different socioeconomic status among participants.  
11 Continuous variables if normally distributed, were expressed as mean  $\pm$  standard deviation and if not normally  
12 distributed, median and interquartile range was provided. Categorical variables were expressed as frequency and  
13 percentage. All univariate comparison of these variables across different subgroups was conducted by ANOVA,  
14 Wilcoxon rank-sum test, and Chi-square test.

15 A multinomial logistic regression model was used to explore the association between life-course socioeconomic  
16 status and adult BMI multi-class trajectories adjusting for some possible confounders. Adjusted odds ratios (OR)  
17 and 95% CI (confidence interval) were calculated for the different BMI trajectories. Each life-course SES indicator  
18 was first entered into a basic model, including gender, age and place of residence (Model 1). Smoking and drinking

1 were further added in Model 2. Model 3 was further adjusted for variables in Model 2, plus physical activity level.  
2 Model 4 was further adjusted for variables in Model 3, plus total daily energy intake. Model 5 included all  
3 covariates from model 1 to model 4. Multicollinearity was checked using variance inflation factor (VIF). In the  
4 study, there are no variables with  $VIF > 4$ , representing no multicollinearity of the variables.  
5 After the risk factors of interest were entered into Model 1 (gender, age and place of residence), the percent  
6 attenuation in the  $\beta$  coefficient for SES was calculated to express the contribution of risk factors in explaining the  
7 SES-BMI trajectory association. The formula was expressed as “ $100 \times (\beta_{\text{Model 1}} - \beta_{\text{Model 1 + risk factors}}) / (\beta_{\text{Model 1}})$ ”.  
8 The 95% CI of the percentage attenuation was calculated using a bootstrap method with 1000 re-samplings.  
9 A series of sensitivity analysis were conducted to test the robustness of the results. Firstly, we excluded participants  
10 who developed diabetes, hypertension, myocardial infarction, stroke or cancer at baseline from the sample, to  
11 minimize the possible reverse causation caused by these diseases. Secondly, we used the multiple imputation by the  
12 chained equations models to deal with missing covariates. We generated 20 imputed data sets, as the maximum  
13 missing amount of these variables was lower than 5%. The multinomial logistic regression analyses were repeated  
14 using each of the augmented data sets, and parameter estimates were averaged in the 20 sets. The adjusted OR  
15 values before and after multiple imputation were shown in the forest plot. All statistical analyses were performed  
16 with Stata version 12.0 and R version 4.1.3, and statistical significance was set at a 2-sided  $p < 0.05$ .

## 17 **RESULTS**

## 1 **Long-term BMI trajectories across adulthood**

2 The group-based trajectory models (GBTM) with 1-5 latent classes were fitted to select a reasonable model. When  
3 latent classes increased, AIC, BIC and Log-Likelihood  $G^2$  all continued to go down, and the decrease in the  
4 three-latent-class model leveled off (Figure S1, Supplementary file 1). Entropy was higher than 0.7 except for the  
5 four-latent-group model. Considering the interpretability of results, a frequency of >5% was preferred for each  
6 latent class (Table S3). Finally, the three-latent-class model was considered optimal (Figure 2): (1) normal-stable  
7 BMI (N=1613, 51.4%) with a consistently normal BMI, (2) progressive overweight (N=1249, 39.8%) with  
8 continuously increasing BMI from normal to overweight, and (3) progressive obesity (N= 276, 8.8%) with elevated  
9 BMI from overweight to obesity.

## 10 **Baseline characteristics of participants**

11 Among 3,138 participants (909 women), the mean BMI of participants and education years were  $21.2 \pm 2.7$  and 9.6  
12  $\pm 3.2$ , respectively, and the median of age on years was 20(19-22) at baseline. The majority of participants (66.0%)  
13 lived in rural areas. Table 1 showed the baseline characteristics of the participants across different SES indicators.  
14 The age of participants with a high SES were higher than those with a low SES ( $p < 0.001$ ). Compared to  
15 participants with middle and high SES, the participants with low SES were likely to reside in rural areas. With  
16 regards to lifestyles behaviors, the total daily energy intake and the percentage of smoking progressively decreased  
17 with the increment of SES. In the low SES group, the participants had more heavy physical activities than those in  
18 other two SES groups ( $p < 0.001$ ). The proportion of drinking was higher among participants with high education

1 and occupational position compared to those with low education and occupational position.

2 According to three latent class BMI trajectories, it was found that the total daily energy intake and the proportions  
3 of smoking and drinking were higher among participants in progressive obesity group, in comparison with other  
4 groups (Table S4). From normal-stable BMI group to progressive obesity group, heavy and moderate physical  
5 activities gradually decreased. In progressive obesity group, there were higher adult occupational position and  
6 parental occupational position, but no significant difference in participant's education across the three trajectories  
7 (Figure 3).

8 Through monomial logistic regression, participants with smoking (OR=1.35, 95% CI: 1.15-1.58; OR=1.53, 95% CI:  
9 1.17-1.99) and drinking (OR=1.59, 95% CI: 1.22-2.06; OR=1.34, 95% CI: 1.16-1.57) were more likely to suffer  
10 from progressive obesity and overweight rather than normal-stable weight (Table 2). The females vs the males had  
11 much less risks for progressive obesity (OR=0.59, 95% CI: 0.44-0.77) and overweight (OR=0.62, 95% CI:  
12 0.52-0.73). Participants in rural areas were more likely to develop into progressive overweight (OR=1.19, 95%CI:  
13 1.02-1.40) in contrast with those in urban areas.

#### 14 **Association of socioeconomic status in early life and adult life with BMI trajectories**

15 Table 3 showed that participants with the highest education attainment (OR=1.57, 95% CI:1.05, 2.35) or the  
16 highest adult occupational position (OR=1.17, 95% CI:1.01, 1.36), were more likely to have progressive obesity  
17 development than those with the lowest education attainment or adult occupational position. High father's

1 occupation vs low father's occupation (OR=1.91, 95% CI:1.36, 2.69) was more likely to contribute to progressive  
2 obesity compared to normal-stable BMI. Similarly, apart from father's occupation, high participant education  
3 (OR=1.33, 95% CI:1.05, 1.69) and adult occupational position (OR=1.20, 95% CI:1.10, 1.31) were more likely to  
4 increase the risk for progressive obesity in comparison with low participant education and adult occupational  
5 position after adjustment for all potential confounders. In the study, multiple adjustments resulted in some changes  
6 of these estimates but the pattern of association persisted (Table 3). We also found that the risk of obesity was  
7 lower in the smoking group and drinking increased the risk of obesity, compared to the normal-stable BMI (Figure  
8 S2 - S4, Supplementary file 1)

### 9 **The association of life-course socioeconomic trajectories with BMI trajectories**

10 Two socioeconomic indicators were combined to represent the socioeconomic trajectory from childhood to  
11 adulthood, including stable high, downward, upward, stable low groups. Table 4 presented the association of  
12 life-course socioeconomic trajectories with BMI trajectories. For progressive overweight vs normal-stable BMI, the  
13 odds ratio of participants with low SES in childhood but high SES in adulthood relative to a stable-low SES  
14 trajectory (low SES in both childhood and adulthood) was 1.56 (95% CI: 1.45, 1.68) after adjustment for potential  
15 confounders. Participants who were socially downwardly mobile (high SES in childhood and low SES in adulthood)  
16 or stable high in both childhood and adulthood, had a 1.26 and a 1.40-fold increased risk of progressive overweight,  
17 respectively, compared to those who had a stable-low SES trajectory. Physical activity explained 6.17% to 14.53%  
18 of the association between life-course socioeconomic trajectories with progressive obesity trajectory, TDEI

1 explained 1.50 % to 1.95% of the association, and all risk factors explained 2.09% to 7.55% of the association.  
2 The risks for progressive obesity trajectory in participants with stable-high SES trajectory (OR=2.35, 95% CI:  
3 2.06-2.67) was higher than that in participants with stable-low SES trajectory. Participants in downwardly SES  
4 trajectory had 1.93 times (95% CI: 1.61-2.31) higher risk for progressive obesity, and participants in upwardly SES  
5 trajectory had a 1.21 (95% CI: 1.04-1.41) times risk of progressive obesity, compared to the stable-low SES  
6 trajectory. Physical activity explained 4.49% to 10.55% of this increased risk for progressive obesity with  
7 life-course SES trajectories, TDEI explained 4.14% to 6.93% of the association, and all risk factors explained  
8 8.19% to 19.42% of the association.

### 9 **The association of cumulative socioeconomic score with BMI trajectories**

10 Table 5 showed that individuals with the highest life-course cumulative SES compared to those with the lowest  
11 life-course cumulative SES score, were 2.01 times (95% CI: 1.12; 4.00) more likely to be in progressive obesity  
12 trajectory. Physical activity (9.9%) could explain the highest proportion of this gradient. All risk factors combined  
13 attenuated by 1.8% for the OR of progressive obesity in the highest vs the lowest cumulative score groups.  
14 However, no significant associations between life-course cumulative SES and progressive overweight were found.

### 15 **Sensitivity Analyses**

16 After excluding 121 participants who developed diabetes, hypertension, myocardial infarction, stroke or cancer at  
17 baseline (Table S5), we had a total of 3017 participants. The results indicated that association of socioeconomic

1 status in early life and adult life with BMI trajectories did not significantly change before and after excluding  
2 chronic diseases (Figure S2 - S4). There is no difference in the association of socioeconomic status in early life and  
3 adult life with BMI trajectories before and after multiple imputation, suggesting the robustness of the results  
4 (Figure S5 - S7).

## 5 **DISCUSSION**

6 In the study, we built two indicators of life-course social class: a measure of social trajectories from childhood to  
7 adulthood and a cumulative score of individual socioeconomic indicators through life time. Our study established  
8 the BMI development trajectory in adulthood to reflect the dynamic change, and identified three patterns of the  
9 BMI trajectories among Chinese adults, including normal-stable BMI, progressive overweight, progressive obesity.  
10 High SES in early and adult life contributed to the increased long-term risk of obesity in Chinese adults. We  
11 explored the relationship between life-course SES and BMI development trajectory in China. Social disparities in  
12 BMI over the adult life course, may increase the future health risks associated with obesity in these populations as  
13 they age. Therefore, targeted interventions for these groups, especially early in the life course, have important  
14 public health implications.

15 Our study found that the hazards of the obesity increased with father's occupational position in early life,  
16 participants' occupational position and educational attainment in adult life. Higher SESs in developed countries  
17 generally had lower hazards of obesity(9, 22), but this pattern does not apply to China. Low SES limited the  
18 opportunities available for excess to food consumption and increases physical labor, while high SES increased

1 access to excess food and avoids physical labor. These conditions contribute to the differences in weight gain  
2 between low SES groups and wealthy individuals in developing countries. Studies have showed that socioeconomic  
3 status in early life and perhaps even in earlier generations have significant influence on adult obesity  
4 development(23-25). However, this relationship still varies across countries with different levels of development. A  
5 cohort study from China reported a positive association between childhood SES and waist circumference in  
6 adulthood among the males(26). Low SES in childhood tended to have reduced risk of general obesity in adulthood  
7 among Hong Kong Chinese adults(27). Our findings were consistent with previous studies. There are several  
8 explanations for how exposure to low SES in childhood influence health later in life. Firstly, in different  
9 developmental stages, the impact of SES-related factors on health varied, with the greatest effects in specific stages  
10 (e.g. in utero, early childhood, adolescence). A cohort study US showed that in the prenatal period and the first year  
11 of life, the SES had significant effect on adult BMI but not in other periods of childhood(28). Secondly, the effect  
12 of poor SES in early life on adult health varied with the intensity and duration of exposure to socioeconomic  
13 disadvantage. Studies found that a longer duration of exposure to early childhood poverty would experience  
14 accelerated BMI growth trajectories in future(29).

15 The life-course socioeconomic trajectory reflects the intergenerational mobility of socioeconomic status between  
16 parents and children, from a life-course perspective, drawing attention to the powerful connections between  
17 individual lives and the historical and socioeconomic contexts of those live(30). Our results showed the individuals  
18 with higher life course SES, had a higher risk for long term obesity trend compared with individuals with

1 stable-low SES. Upwardly mobile participants were more likely to fall into obesity than participants remaining in  
2 stable low social class. The associations observed in our study were consistent with previous studies in low-middle  
3 income countries showing positive correlation between life-course SES and obesity(31, 32). For example, a  
4 cross-sectional study in five middle-income countries (China, South Africa, India, Russia, and Mexico) found that  
5 life-course stable high or declining SES was associated with increased risks of overweight/obesity(31). In addition,  
6 our results contradicted findings in some previous studies conducted mostly in developed countries(33-35). For  
7 example, Albrecht and Gordon-Larsen reported upward education mobility was associated with low adult mean  
8 BMI(33); Sinead and Timothy found downwardly SES mobility were significantly more likely to be  
9 overweight/obese compared with those who remained of high SES(34). Thus, the relationship between life course  
10 SES and obesity seems to vary depending on the culture and socioeconomic development stage of the sample.  
11 Furthermore, those whose parents have high SES, may have the resources to increase consumption of fast food,  
12 high-sodium diets, and high-calorie beverages, which are thought to be significant dietary changes that promote  
13 obesity(36).

14 The accumulation model proposes that adverse exposures over the life course cause cumulative damage to  
15 biological systems. A positive association between cumulative socioeconomic score and obesity was found in our  
16 study, although some studies of Chinese populations did not find significant differences in obesity between groups  
17 with the greatest and the least cumulative disadvantage(27, 37). According to previous researches, a positive  
18 association with SES and obesity was shown in adults(10, 31), but the future burden of overweight and obesity may

1 shift to populations with lower socioeconomic status. Further research is still needed to clarify the relationship  
2 between the socioeconomic transition occurring in China and obesity and related chronic diseases in adulthood.  
3 Moreover, the potential mechanisms explaining the association between life-course SES and overweight/obesity  
4 also include socially patterned behavioral factors, such as alcohol use, dietary quality and physical activity(20).  
5 Current alcohol drinking was associated with obesity in our analyses. Alcohol consumption has a greater acute  
6 effect on calorie intake than other lifestyle factors(38). Furthermore, metabolic evidence also suggests that alcohol  
7 consumption may be associated not only with a higher urge to drink, but also with less restrictive eating behaviors,  
8 which further cause higher BMI(39). Due to the economic transition and introduction of the western lifestyle in  
9 China, people's work and dietary patterns have changed dramatically. According to our analysis, people of low  
10 socioeconomic status are more likely to be engaged in moderate and heavy work, although they have a higher  
11 average daily energy intake compared to people of high socioeconomic status.

12 Considering the study data from a 20-year follow-up cohort in China, we are able to clearly confirm the association  
13 between life-course socioeconomic status and the risk of overweight/obesity. Additionally, we constructed the BMI  
14 development trajectories, which was a more stable and reliable indicator to reflect the long term BMI change. In the  
15 meanwhile, the two measures of life-course SES (life-course socioeconomic trajectories and a cumulative SES  
16 index) were also adopted to explore their origins of SES disparities in early life and long term effect of SES on  
17 obesity.

18 In this study, some limitations should be noted in the explanation of the results. Firstly, the socioeconomic level

1 and lifestyle were mainly self-reported, and only baseline information was used, thus recall bias was inevitable.  
2 Second, because of lacking of parents' income, education and other related SES indicators to represent the SES in  
3 early life of participants, the life course SES variable was constructed only using on paternal occupation and  
4 personal occupation position. Future studies with more reliable indicators in early life are preferred. Third, we  
5 excluded those with major chronic diseases at baseline, and then got robust results. However, the possibility of  
6 reverse causation and residual confounding may still exist in our study, due to many other unmeasured diseases.  
7 Fourth, our results may be subjected to other potential confounders that were not observed in the study.

## 8 **Conclusion**

9 This study confirmed that socioeconomic status played an important role in the development of overweight and  
10 obesity. These patterns suggest that the effect of SES on adult BMI may act during critical periods in early life and  
11 accumulate throughout the lifespan. Physical activity and total daily energy intake partially explain this gradient,  
12 showing that both play an important role in obesity interventions. When implementing prevention measures of  
13 obesity in targeted groups, attention should be paid to the high socioeconomic status, especially in early life, such  
14 as childhood, adolescence.

15

## 16 **Access to research materials/Data sharing**

17 China Health and Nutrition Survey data are available in a public, open access repository. Original data are available  
18 in Carolina Population Center of the University of North Carolina at Chapel Hill  
19 (<https://www.cpc.unc.edu/projects/china>).

## SUPPLEMENTARY MATERIALS

Table S1. Social class based on self-reported primary occupation

Table S2. Definition of life-course socioeconomic trajectories

Table S3. Tabulated Bayesian Information Criterion (BIC) for all participants

Table S4. Participant characteristics across BMI trajectories groups

Table S5. Details about participants with chronic diseases at baseline

Table S6. Details about missing covariates

Figure S1. Model Fitting Indicators of Group-based trajectory model (GBTM)

Figure S2-S4. Sensitivity analysis of the associations between BMI trajectories and SESs (before & after exclude chronic diseases)

Figure S5-S7. sensitivity analysis of the associations between BMI trajectories and SESs (before & after multiple imputation)

**Table S1.** Social class based on self-reported primary occupation

<b>Social class</b>	<b>Primary occupation</b>
Class I	1. Senior professional/technical worker
Class II	1. Junior professional/technical worker 2. Administrator/executive/manager 3. Army officer, police officer
Class III-M (skilled manual)	1. Skilled worker
Class III-NM (skilled non-manual)	2. Office staff 3. Soldier, policeman 4. Athlete, actor, musician
Class IV (semi-skilled)	1. Driver 2. Service worker
Class V (unskilled)	1. Farmer, fisherman, hunter 2. Non-skilled worker

**Table S2.** Definition of life course socioeconomic trajectories

<b>Father's occupational position</b>	<b>Adult occupational position</b>	
	Low	High
Low	stable low	upward
High	downward	stable high

**Table S3.** Tabulated Bayesian Information Criterion (BIC) for all participants

Number of groups	BIC <sup>1</sup>	BIC <sup>2</sup>	AIC	G <sup>2</sup>	Entropy	Group Membership Probabilities
1	-29209.11	-29207.17	-29198.09	-29195.09	-	(100.00%)
2	-27113.79	-27109.26	-27088.08	-27081.08	0.759	(70.91%/29.08%)
3	-26325.60	-26318.49	-26285.21	-26274.21	0.737	(51.40%/39.80%/8.80%)
4	-26023.02	-26012.67	-25964.26	-25948.26	0.677	(28.79%/41.79%/23.37%/6.03%)
5	-25879.80	-25866.86	-25806.35	-25786.35	0.714	(41.50%/26.43%/24.42%/6.62%/1.01%)

BIC<sup>1</sup>=Bayesian information criterion (for the total number of observations).

BIC<sup>2</sup>=Bayesian information criterion (for the total number of participants).

Abbreviations: BIC, Bayesian information criterion; AIC, Akaike information criterion.

**Table S4. Participant characteristics across BMI trajectory groups (n = 3138)**

	Normal-stable BMI	Progressive overweight	Progressive obesity	
Characteristics				<i>p</i>
participants(n)	1613(51.4)	1249(39.8)	276(8.8)	
Baseline age(years)	22.0(6.0)	23.0(9.0)	25.00(9.0)	<0.001
Gender				
Male	1068(66.2)	949(76.0)	212(76.8)	<0.001
Female	545(33.8)	300(24.0)	64(23.2)	
Residential areas				
Urban	573(35.5)	394(31.5)	101(36.6)	0.054
Rural	1040(64.5)	855(68.5)	175(63.4)	
BMI(Kg/m <sup>2</sup> )	19.6±1.5	22.1±2.1	25.8±3.2	<0.001
<i>Socioeconomic indicators</i>				
Father's occupational position				
Low	668(41.4)	571(45.7)	83(30.1)	<0.001
Medium	520(32.2)	332(26.6)	103(37.3)	
High	425(26.3)	346(27.7)	90(32.6)	
Adult occupation				
Low	554(34.3)	405(32.4)	74(26.8)	0.029
Medium	683(42.3)	533(42.7)	115(41.7)	
High	376(23.3)	311(24.9)	87(31.5)	
Adult education				
Low	373(23.1)	298(23.9)	63(22.8)	0.843

Medium	733(45.4)	546(43.7)	119(43.1)	
High	507(31.4)	405(32.4)	94(34.1)	
<i>Health-related behaviors</i>				
Smoking	467(29.0)	442(35.4)	106(38.4)	<0.001
Drinking	528(32.7)	494(39.6)	120(43.6)	
PAL				
Light PA level	403(25.5)	272(22.2)	82(30.5)	0.043
Moderate PA level	638(40.4)	528(43.1)	105(39.0)	
Heavy PA level	540(34.2)	426(34.7)	82(30.5)	
TDEI (kcal)	2348.6±660.4	2460.5±558.5	2479.±557.5	<0.001

<sup>a</sup>Data were expressed as numbers or percentages and presented as mean with standard deviation of the mean. Non-normally distributed data like baseline age reported as median (IQR)

All univariate comparisons across subgroups were evaluated using ANOVA, Chi-square test, and Kruskal-Wallis as appropriate.

BMI: body mass index; PAL: physical activity level; TDEI: total daily energy intake

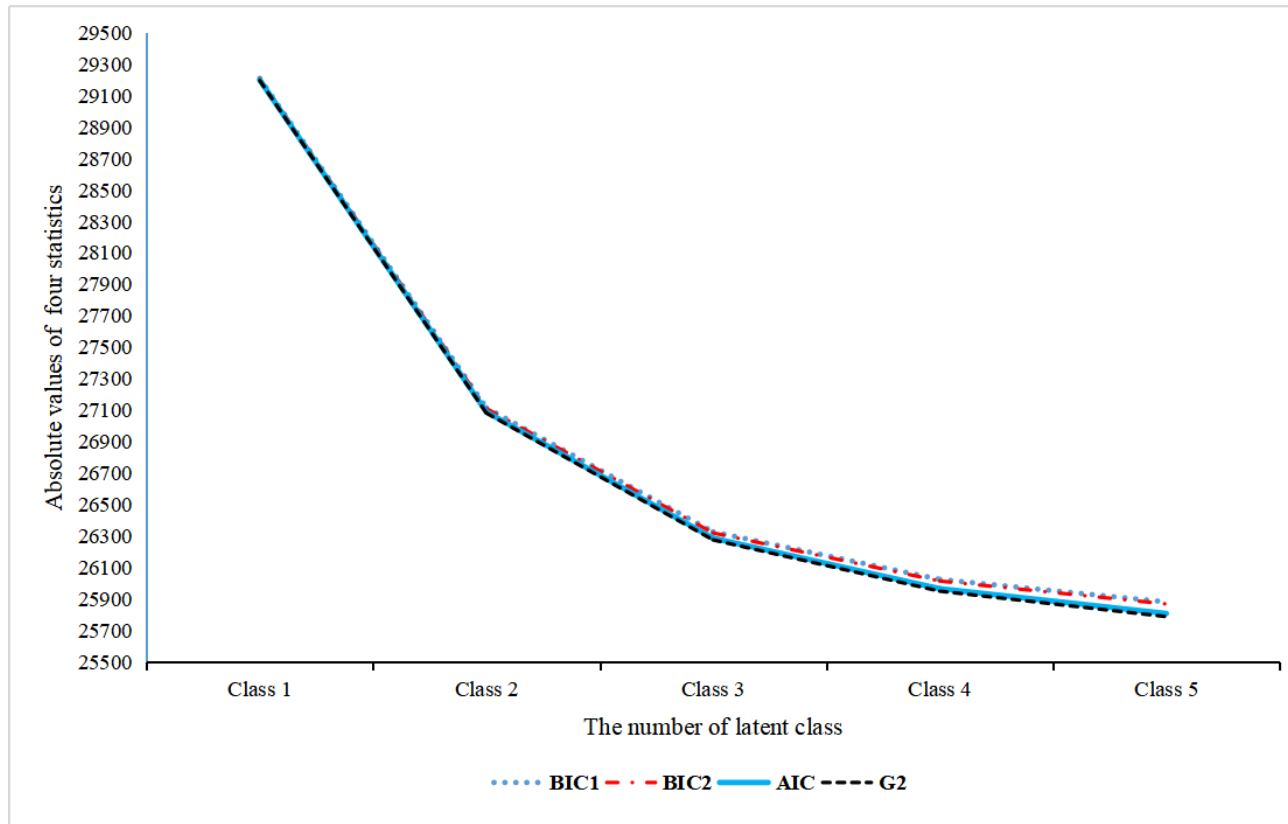

**Table S5. Details about participants with chronic diseases at baseline(n=121)**

Chronic Disease	Number (%)
HYPERTENSION	79(2.5)
DIABATES	29(0.9)
STROKE	7(0.2)
MYOCARDIAL INFARCTION	5(0.2)
ASTHMA	9(0.3)
CANCER	6(0.2)

Note: There were 14 participants with two or more chronic diseases in the total sample(n=3138).

**Table S6. Details about missing covariates**

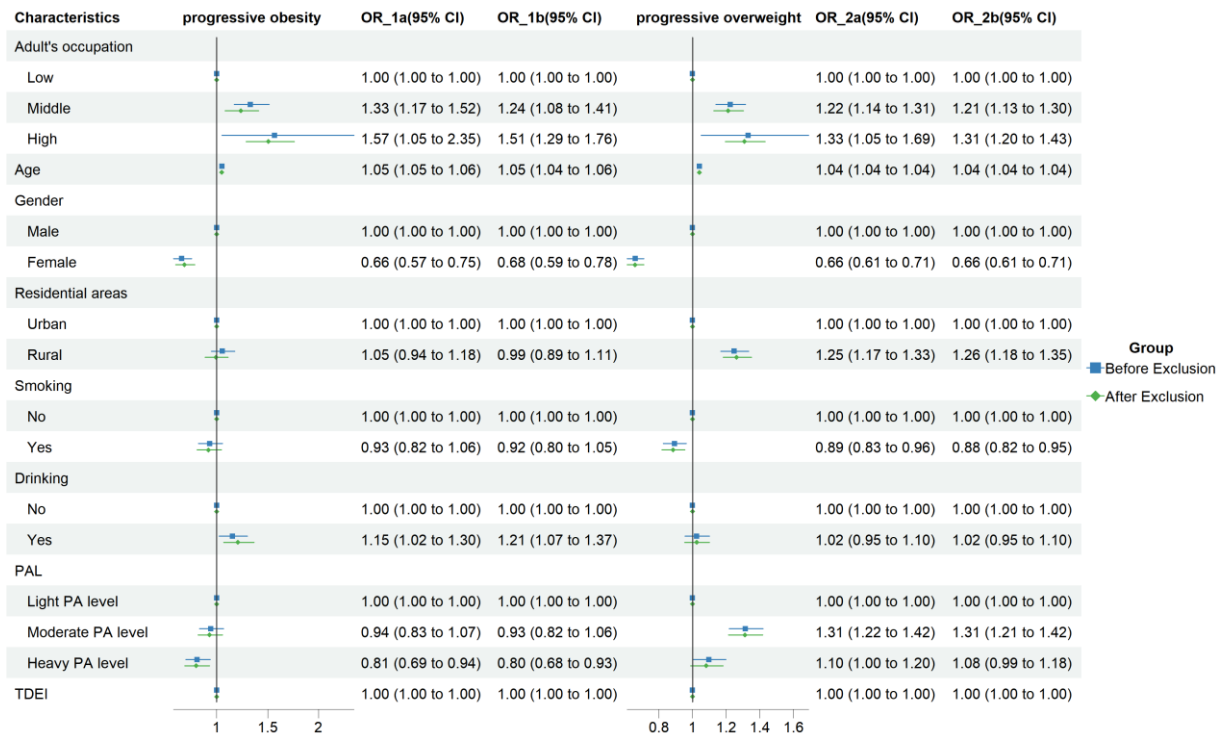

<b>Variable</b>	<b>Missing ratio (%)</b>
Smoking	1 (0. 1)
Drinking	3 (0. 1)
Physical activity level	62 (2. 0)
Total daily energy intake	77 (2. 5)
