24 **Abstract**

25 The ability of a single genome to express multiple phenotypes is key to understanding social
26 evolution, where individuals with different morphologies perform different tasks. In social
27 insects, phenotypes are typically determined during larval development and depend on the social
28 environment. Here, we used the bumble bee *Bombus impatiens* to examine the social regulation
29 of body size variation and caste by manipulating the identity (queen/worker) and the number of
30 caretakers tending for the brood. Eggs of females and males were kept in cages with (1) a single
31 queen; (2) a single worker; (3) three workers; or (4) ten workers. We measured larval weight,
32 developmental length, and the resulting caste (in females) throughout the brood development of
33 >2000 individuals. We found differences in larval mass when reared by varying number of
34 workers, but not when reared by a single worker compared to a queen. Additionally, in contrast
35 with previous findings in *B. terrestris*, none of the female eggs reared by workers developed into
36 gynes (new queens), indicating that the mechanisms regulating caste determination in *B.*
37 *impatiens* is not solely dependent on the queen presence as in *B. terrestris*. Adult males were
38 slightly larger than workers and developed for a longer period in the presence of the queen.
39 Overall, we suggest that body size in *B. impatiens* is determined by the number of caretakers and
40 is likely mediated by the amount of provision. The hypothesis that the queen's presence
41 manipulates female caste was not supported by our data.

44 **Introduction**

45 Phenotypic plasticity, the ability of one genome to produce multiple variations of behavioral and
46 morphologic forms, is a fascinating phenomenon that is crucial for understanding how societies
47 of social insects have evolved (Corona et al. 2016; West-Eberhard 1989). Diversity of
48 phenotypes, such as females of various sizes and morphologies, is critical for sustaining social
49 organization as they determine the female's life trajectory as reproductives or helpers.

50

51 Social insect societies contain three main castes: queens, workers, and males, while workers can
52 differentiate even further to individuals of different sizes and morphologies (e.g., soldier workers
53 in ants and termites). These differences have been documented in numerous social species
54 (Miura 2005) and form the basis for their social organization. While in many cases, differences
55 between female castes (queens and workers) are limited to body size (Alford 1975; Plowright
56 and Jay 1968; Richards and Packer 1996; Treanore et al. 2020a; Tribble and Kronauer 2017;
57 West-Eberhard 1969), female castes in some species exhibit additional morphological
58 differences in the foraging organs or in the spermatheca (Gotoh et al. 2016; Gotoh et al. 2013;
59 Khila and Abouheif 2010). Variation in worker body size and morphology is more common and
60 is often associated with task allocation and reproductive roles. For example, in leaf-cutter ants,
61 the smallest individuals specialize in tending the fungus garden and are more resistant to
62 parasitic fungi (Poulsen et al. 2006; Wilson 1980). Likewise, individuals of the guard caste of the
63 stingless bee, *Tetragonisca angustula*, are generally heavier, have smaller heads and larger legs
64 than forager bees (Smith et al. 2008a). A morphologically-distinct soldier caste responsible for
65 nest defense is also common among termites where soldiers have a sclerotized head, enlarged

66 mandibles, a stopper-like shape, or frontal glands which produce defensive secretions (Roisin
67 2000). The majority of these morphs are determined during early development.
68
69 Body size and caste in social insects are influenced by the environment, genetics, or a
70 combination of both (Schwander et al. 2010). In some ant species, such as *Wasmannia*
71 *auropunctata* and *Vollenhovia emeryi*, caste is genetically determined with the worker caste
72 being produced through sexual reproduction while queens are produced through parthenogenesis
73 (Fournier et al. 2005; Kobayashi et al. 2008; Ohkawara et al. 2006). In Meliponine bees, caste is
74 influenced by a combination of genetic and environmental factors. There, genetic markers in
75 larvae are associated with the queen phenotype but require adequate nutritional input to develop
76 into gynes (future queens) (Hartfelder et al. 2006; Kerr 1950). The same applies to the Florida
77 harvester ant, *Pogonomyrmex badius*, where larval diet differs between castes but patrilineage
78 also influences the resulting caste (Smith et al. 2008b). In many other social species, however,
79 caste and body size are determined solely by environmental factors such as diet, feeding regime,
80 thermoregulation, and colony social conditions (Eyer et al. 2017; Mao et al. 2013; Mutti et al.
81 2011). In *Vespula maculifrons*, for example, both caste and body size are primarily determined
82 by environmental factors and are not affected by the genetic patriline (Goodisman et al. 2007).
83 Despite extensive study of phenotypic plasticity (Leimar et al. 2012; Libbrecht et al. 2013; Miura
84 2005; Simpson et al. 2011; Weiner and Toth 2012), our knowledge of the environmental factors
85 determining development, size, and caste is partial and is limited to selected model organisms,
86 primarily ants and some termites, wasps, and bees.

87

88 The social regulators of caste and body size are often mediated by the adults, who take care of
89 the immobile young. Adults dictate larval diet, clean and thermoregulate the brood (Jandt et al.
90 2017; Molet et al. 2017; Yaguchi et al. 2019), and can manipulate not only the larval health but
91 also their life trajectory. Differential feeding in the honey bee, for example, determines whether a
92 female larva develops into a worker or a queen (Eyer et al. 2017; Mao et al. 2013; Mutti et al.
93 2011), and thermoregulation of brood in social insects has been shown to influence broods'
94 metabolic rate, growth, caste determination, and health (Howard and Jeanne 2004; Jones and
95 Oldroyd 2006; Kadochová and Frouz 2014; Vogt 1986). The amount of care adults provide
96 depends on the resources available for them, which are driven by the colony size, age and
97 seasonality (Chole et al. 2019; DeGrandi-Hoffman et al. 2018; Hoover et al. 2006; Korb and
98 Hartfelder 2008; Molet et al. 2017; Quezada-Euán et al. 2011; Villalta et al. 2016), but also by
99 their reproductive interests, a theory known as “parental manipulation” in which the caretaker
100 limits the provisioning of the brood to generate smaller or submissive individuals (Alexander
101 1974b). Parental manipulation by the queen was demonstrated in *Polistes fuscatus* wasps where
102 queens influence larval physiology and caste with vibrational signals in combination with
103 nutritional input (Jeanne and Suryanarayanan 2011; Mignini and Lorenzi 2015; Suryanarayanan
104 et al. 2011). Queens provide wasp larvae fewer vibrational signals, resulting in larvae with a
105 lower likelihood of developing into gynes (Suryanarayanan et al. 2011). Similar works in *Apis*
106 *mellifera* (Le Conte and Hefetz 2008), *Bombus terrestris* (Cnaani et al. 1997) and *Solenopsis*
107 *invicta* (Fletcher and Blum 1981) showed that the presence of the queen inhibits the
108 differentiation of larvae to gynes, presumably using pheromones. In some species of termites, the
109 queen is the only individual in the colony able to provide the nutrients larvae require in order to

110 develop as sexuals (Korb and Hartfelder 2008; Yaguchi et al. 2019). Overall, the care received
111 by adults is a strong regulator of larval development and caste in social insects.

112

113 Bumble bees are an excellent system for examining the social regulation of body size and caste,
114 because both factors are influenced by the social environment (Cnaani et al. 2000b). However,
115 despite some progress in the field (see below) the mechanisms underlying caste determination
116 are not fully understood. Bumble bee colonies undergo several transitions during the colony life
117 cycle that may result in young receiving differential care. When a bumble bee queen founds a
118 colony, she is the sole caretaker of the brood until the first workers emerge. Female brood in
119 bumble bees is laid by the queen, whereas male brood can be laid by both the queen and the
120 workers (Amsalem et al. 2015). Male and workers brood develop for 24 days, on average, while
121 queens require 36-37 days, on average, in both *B. impatiens* and *B. terrestris*. Eggs hatch within
122 5 days and go through 4 larva instars, after which they pupate and emerge (Cnaani et al. 2000b;
123 Cnaani et al. 2000c; Cnaani et al. 2002; Tian and Hines 2018). Castes differ mostly in body size
124 (Goulson 2010; Michener and Michener 1974), with queens being 3-4 times larger than workers,
125 whereas males are slightly larger than workers (Goulson 2010; Michener and Michener 1974;
126 Plowright and Jay 1968). Bumble bee workers' body mass within the same colony can vary up to
127 tenfold (Couvillon and Dornhaus 2010; Cumber 1949), and size variation is often associated with
128 task specialization (Holland et al. 2021; Jandt et al. 2009).

129

130 The mechanisms determining female caste and size in bumble bees are not fully understood and
131 the existing data point to a substantial variation across species and sometimes to conflicting data.
132 In *B. terrestris*, the species that was investigated the most, diet composition of provisions is not

133 different for queens and workers (Pereboom 2000). However, queens are fed more frequently
134 than workers in the later stages of larval development (Ribeiro et al. 1999), although this has not
135 been confirmed in a later study (Pereboom et al. 2003). Furthermore, diploid eggs develop to
136 gynes in the absence of the queen, as long as they are separated from the queen before the critical
137 period for differentiation (approximately 5 days after larvae hatch) (Cnaani et al. 1997; Cnaani et
138 al. 2000c). A similar critical period during early development was found in *B. terricola*
139 (Plowright and Pendrel 1977; Röseler 1970), but a much later critical point for differentiation
140 was found in *B. hypnorum*, *B. rufocinctus*, and *B. ternarius*. In these species it was further
141 suggested that queen determination depends on food quantity and feeding regimes during
142 development (Plowright and Jay 1977; Plowright and Pendrel 1977; Röseler 1970). Queens and
143 workers in these species have similar growth rates but queens are supplied additional food for
144 longer (Röseler 1976).

145
146 The frequency of larval feeding in *B. terrestris* and *B. terricola* influences not only caste, but
147 also worker body mass (Pendrel and Plowright 1981; Pereboom et al. 2003). A study that
148 manipulated the pollen intake of *B. terricola* colonies found that reduced food intake of colonies
149 resulted in smaller-bodied workers (Sutcliffe and Plowright 1988). Furthermore, larvae on the
150 periphery of *B. impatiens* colonies are fed less frequently than larvae towards the center of the
151 colony, also resulting in smaller individuals. Variation in worker size is also affected by the
152 presence of the queen. A previous study in *B. terrestris* showed that brood reared by a queen was
153 significantly smaller than brood reared by a worker (Shpigler et al. 2013). A similar study in *B.*
154 *impatiens* examined development in brood reared by five workers vs. one queen, and found that

155 the queen produced smaller individuals, although whether the effect is due to the identity of the
156 caretaker or their number is not clear (Costa et al. 2021).

157

158 In this study, we examined how the social environment, specifically, the identity/caste and the
159 number of the caretaking females affect larval body mass, duration of development and caste in
160 the bumble bee *B. impatiens*. Phylogenetically, *B. impatiens* is much closer to bumble bee
161 species where caste and body size are determined by diet and later in development than to *B.*
162 *terrestris* where these factors are influenced solely by the presence of the queen (Cameron et al.
163 2007), but mechanistic details of caste determination in this species are still lacking . To examine
164 this, we grouped female and male eggs with a queen or a varying number of workers (1, 3 and
165 10). We anticipated that the identity of the caretaker (i.e., queen or worker) would affect female
166 caste. We also expected the number of the caretakers to positively correlate with body size and
167 brood development. Finally, we hypothesized that a selective effect by the queen on females'
168 body size and development, but not on males, would indicate a parental manipulation aiming to
169 control the resulting female caste and generate submissive and sterile workers.

170

171 **Methods**

172

173 *Bumble bees rearing*

174 Colonies of *B. impatiens* were obtained from Koppert USA, Inc. (Romulus, MI) and were used
175 as a source for caretakers (workers and queens) and egg laying females producing male and
176 female egg batches. Bumble bees lay eggs in batches, containing up to 10 eggs each, and seal
177 them with wax (Amsalem et al. 2015). In all experiments, groups containing 1 and 3 caretakers

178 were kept in small plastic cages (11 cm diameter × 7 cm tall) whereas groups containing 10
179 caretakers were kept in larger plastic cages (19 x 16.5 x 14 cm) (i.e., to maintain similar density
180 of worker across treatments). Group sizes were chosen based on a previous study showing that
181 reproductive division of labor in groups of 10 workers is similar to a colony (~40% of the
182 females activate their ovaries and lay eggs), as opposed to smaller groups containing 3 and 5
183 individuals, where reproduction is monopolized by a single bee (Amsalem and Hefetz 2011). All
184 bees were kept in a dark environmental chamber, at 28-30° C and 60% relative humidity and
185 provided an unlimited supply of pollen and 60% sugar solution.

186

187 *Social condition treatments*

188 To examine how caretaker identity affects brood development, we set up cages (n=97)
189 containing an egg-layer queen or a random-age worker together with a single 4-days-old egg
190 batch of either females or males. To examine how the number of caretakers affect brood
191 development, we set up 141 cages with 1, 3, and 10 random-age workers together with a 4-days-
192 old egg batch of either female or male brood. Cages were sampled at different time points,
193 covering the entire duration of brood development (egg to adult). In each cage, we measured
194 larval weight, duration of development, sex, and caste. Caretaker workers were taken from
195 young colonies which were not producing males or young queens. Caretaker queens were taken
196 from colonies upon emergence. They were mated with unrelated males and treated with CO₂ to
197 induce transition to egg laying as in (Treanore et al. 2021). They were then placed in individual
198 cells until they confirmed to lay eggs. Female eggs were laid by mated queens while male eggs
199 were laid by unmated queens or workers. Cages producing eggs were checked for eggs every 24
200 hours and were photographed and tagged to keep track of the date eggs were laid. Egg batches

201 were then gently transferred to a treatment cage (i.e., with caretakers) 4 days after they were laid,
202 thus, before hatching and before the earliest critical period for determination (5-6 days after
203 larvae hatch) found in *B. terrestris* (Cnaani et al. 2000b). Workers may lay eggs in the absence of
204 the queen (Amsalem et al. 2015), thus, new egg batches laid by the caretakers after the onset of
205 the experiment were removed daily. Caretakers and egg batches were unrelated across both
206 experiments, since brood care in *B. impatiens* is not affected by relatedness (Starkey et al. 2019).

207

208 *Larval development duration, weight, and caste*

209 Brood (eggs, larvae, pupae) or newly-emerged adults were collected daily between days 6 to 26
210 after the onset of egg laying. At least 10 individuals were collected for each day across all cages
211 in the treatment groups and overall, 2001 brood and newly-emerged adults were collected in the
212 study. The brood was frozen and removed from their wax cases. The developmental stage of the
213 brood (eggs, larvae, pupae, or newly-emerged adults) was determined, individuals were weighed,
214 and the caste was determined for female individuals based on body mass. Workers and males
215 weigh approximately up to 300 mg, while queens weigh >450 mg and can reach up to 1 g.
216 Usually, there is no overlap in the body mass of workers and queens (Amsalem et al. 2015)

217

218 *Statistical analysis*

219 Statistical analyses and data visualizations were performed using JMP Pro 16. The effects of the
220 treatments (1, 3, 10 workers or a queen), the time (days since egg laying), and sex (female, male)
221 on the body mass and duration of development of the brood were compared using ANOVA
222 mixed model. Post-hoc comparisons between treatment groups were conducted using Tukey
223 HSD test. The growth rate of larvae across treatments and sexes was compared using indicator

224 function parameterization. Data are presented as means \pm S.E.M. Statistical significance was
225 accepted at $\alpha=0.05$.

226

227 **Results**

228 We monitored the development, body mass and caste of 2001 individual brood in the study and
229 examined how the two sexes are affected by the number and identity of the caretaker. Most
230 larvae hatched within 6 days, a slightly older age than in *B. impatiens* (Cnaani et al. 2002),
231 although this could be explained by the method of counting (i.e., whether the first day eggs are
232 found is considered day 0 or 1). The youngest age of larvae was 6 days (from egg laying) while
233 the oldest was 18 (Table 1). The earliest pupation occurred on day 14 and lasted, to the latest,
234 until day 26. All brood emerged on days 24-26 (males and workers) and none of the developed
235 brood was of queens. The development of larvae and pupae in this study is similar to the one
236 reported previously for males and workers of *B. impatiens* (Cnaani et al. 2002) and *B. terrestris*
237 females (Cnaani et al. 2000c).

238

239 Body mass of female larvae, pupae and adults throughout the development was affected by the
240 time (days after egg laying, Mixed model, Two-way ANOVA $f_{1,1024}=628.5$, $p<0.0001$) and by
241 the treatment (1, 3, 10 workers or a queen, $f_{3,1024}=39$, $p<0.001$), however a post-hoc test for the
242 variable treatment showed that the significant impact is attributed to the number of caretakers
243 and not to their identity (post-hoc Tukey HSD $p<0.01$ for all comparisons except one queen vs.
244 one worker, $p=0.08$, Figure 1A). A queen and a single worker produced approximately similarly-
245 sized larvae (on average 189 ± 13 and 195 ± 10 mg at the peak of development, $n=10$ and $n=15$ for
246 one worker and a queen, respectively, means \pm SE), while 3 and 10 worker groups produced

247 much larger larvae (on average 231 ± 6 and 252 ± 17 mg at the peak of development, $n=10$ and
248 $n=10$ for 3 and 10 worker groups, respectively, means \pm SE). The ‘peak of development’ refers
249 to the timepoint (day) with the highest body mass of larvae.

250

251 Body mass of male larvae, pupae and adults was also affected by the time (Mixed model, Two-
252 way ANOVA $f_{1,973}=614.9$, $p<0.0001$) and the treatment ($f_{3,973}=59.8$, $p<0.001$), and a post-hoc
253 test showed similar results to females with a significant effect by the number of caretakers but
254 not their identity (post-hoc Tukey HSD $p<0.001$ for all comparisons except one queen vs. one
255 worker, $p=0.64$, Figure 1B). Male larvae were overall slightly larger than females (on average
256 179.4 ± 9 , 179.3 ± 10 , 243.8 ± 13 , and 280 ± 20 mg at the peak of development, $n=14$, 11, 13, 11 for
257 queen, groups of 1, 3 and 10 workers, respectively, means \pm SE), but this difference was not
258 statistically significant (Mixed model with time, sex and treatment as fixed effects, $f_{1,1999}=
259 1243.4$, $p<0.0001$ for time; $f_{3,1999}=97$, $p<0.0001$ for treatment, and $f_{1,1999}=0.68$, $p=0.4$ for sex, Fig
260 2).

261

262 We also separately analyzed the data of female and male larvae to examine differences in their
263 growth rate during the feeding period when reared by a queen and varying numbers of workers.
264 To perform this analysis, we included all the brood that was still larvae at the time of collection
265 (Table 1). This included 523 female and 472 male larvae. The fit of the mass gain curves over
266 time in all treatments and in both sexes was linear ($R^2>0.74$). Comparison of slopes in females
267 and male returned similar results to the comparison of the means above, confirming once again
268 that the number of caretakers but not their identity affects body mass gain in larvae (indicator
269 function parameterization for queen vs. one worker: estimate: -3.2, Std Error: 3.66, t-ratio: -0.9,

270 $p=0.37$; for queen vs. 3 workers: estimate: 9.3, Std Error: 3.8, t-ratio: 2.45, $p=0.01$; and for queen
271 vs. 10 workers: estimate: 18.9, Std Error: 3.7, t-ratio: 5.1, $p<0.001$, Fig 3A). Similar analysis of
272 male larvae returned similar results (indicator function parameterization for queen vs. one
273 worker: estimate: 5.8, Std Error: 4.9, t-ratio: 1.18, $p=0.23$; for queen vs. 3 workers: estimate:
274 13.1, Std Error: 4.8, t-ratio: 2.7, $p=0.007$; and for queen vs. 10 workers: estimate: 35.1, Std
275 Error: 4.9, t-ratio: 7.05, $p<0.001$, Fig 3B).

276

277 Finally, we analyzed the effect of treatment and sex on the weight gain and development
278 duration of the brood that emerged throughout the experiment (Fig. 4). This included 47 and 48
279 female and male adults, respectively (Table 1). Treatment had a significant effect on body mass
280 of females ($f_{3,45}=27.15$, $p<0.001$ followed by Tukey HSD post-hoc test $p=0.6$ for one worker vs.
281 a queen and $p<0.004$ for all the rest) and males ($f_{3,46}=26.8$, $p<0.001$ followed by Tukey HSD
282 post-hoc test $p=0.98$ for one worker vs. a queen and $p<0.03$ for all the rest). Within each
283 treatment, females and males differed in the 10 workers ($p=0.01$) and the queen ($p=0.009$)
284 treatments but not in the one worker ($p=0.68$) or 3 worker ($p=0.34$) treatments.

285

286 The treatment also affected the duration of development in females ($f_{3,45}=3.37$, $p=0.02$ followed
287 by Tukey HSD post-hoc test $p=0.03$ for 10 workers vs. a queen and $p>0.064$ for all the rest) and
288 males ($f_{3,46}=3.77$, $p=0.01$ followed by Tukey HSD post-hoc test $p=0.04$ for 3 workers vs. a
289 queen, $p=0.01$ for 10 workers vs. a queen and $p>0.1$ for all the rest). Within each treatment,
290 females and males differed in the queen treatment ($p<0.001$) but not in any of the other
291 treatments ($p>0.33$).

292

293 **Discussion**

294 This study investigated how the social environment affects brood development in *B. impatiens*.
295 We examined the effect of caretaker identity and their number on brood developmental duration,
296 body mass, and resulting caste. Overall, we found that body size is affected by the number of
297 caretakers but not their identity. Additionally, all the female eggs in our study developed into
298 workers, regardless of the identity or the number of the caretakers, indicating that the mechanism
299 determining caste in *B. impatiens* is different than the one in *B. terrestris* and is not solely
300 dependent on the presence of the queen. It is important to note that gynes are typically produced
301 in full-size colonies of *B. impatiens* towards the end of the life cycle, but there is high variability
302 across colonies and the reasons for it are unknown. In a recent study (Santos et al. 2022), we
303 have shown that increasing the amount of the brood in the colony also increases the number of
304 gynes produced by the colony, while decreasing the amount of brood results in colonies
305 specializing in producing males. As far as we know, nobody was able to produce gynes in *B.*
306 *impatiens* in a setting that is not a full-size colony. These results are fundamentally different
307 from *B. terrestris* where ~80% of the eggs that were transplanted between queenright and
308 queenless colonies developed into gynes (Cnaani et al. 1997; Cnaani et al. 2000c) and gynes
309 were produced also in small groups of workers (Shpigler et al. 2013). To our knowledge, this is
310 the first time these questions are examined experimentally in *B. impatiens* or in any other species
311 of *Bombus* that is not *B. terrestris*.

312

313 The number of caretakers influenced brood development in a positive way, with an increase in
314 the growth rate and emergence weight as the number of caretakers increased. Similar impacts of
315 the colony size have been observed in other social insect species (Korb and Hartfelder 2008;

316 Molet et al. 2017; Plowright and Jay 1968; Plowright and Pendrel 1977; Ramalho et al. 1998).
317 These effects are likely mediated via an increase in feeding frequency, attributed to the number
318 of caretakers (Pereboom et al. 2003; Ribeiro et al. 1999). Interestingly, the size differences
319 between female and male brood were minor and apparent only in the adults reared by the queen
320 and not throughout development (Fig. 4). In contrast, *B. terrestris* males were reported to be
321 larger and fed more frequently than workers (Ribeiro et al. 1999; Shpigler et al. 2013). However,
322 an analysis of *Bombus* species found a large overlap in the size range of males and workers, and
323 although males are generally larger in *B. terrestris*, this is not the case in *B. impatiens* (Del
324 Castillo and Fairbairn 2012).

325

326 We found no effect of caretaker identity on the developmental time, growth rate, and weight at
327 emergence, with the brood reared by a single worker being similar in all parameters to the brood
328 reared by a queen. Based on the parental manipulation hypothesis, it is predicted that the queen
329 would manipulate brood development to produce smaller workers in order to reduce competition
330 with her offspring (Alexander 1974a). Accordingly, we expected that queen-reared brood would
331 develop quicker and be smaller than worker-reared brood as was found in *B. terrestris* (Shpigler
332 et al. 2013). However, since the queen has no competition with males, we expected this effect to
333 be specific to female eggs. Conversely, we found that a queen-reared brood was not significantly
334 smaller nor developed faster than a worker-reared brood. The difference in body size of brood
335 reared by workers and queens in *B. terrestris* could be the result of worker rearing gynes in the
336 absence of the queen. However, decreased developmental time in individuals reared by the queen
337 was observed even when no gynes were produced, suggesting that in *B. terrestris*, but not in *B.*
338 *impatiens*, the queen is able to manipulate worker size. In line with these findings, a previous

339 study in *B. impatiens* also found no differences in the developmental time of female brood reared
340 by a queen versus brood reared by five workers (Costa et al. 2021). However, this study did find
341 that a single queen produced smaller individuals compared to the worker social condition, but
342 this finding may be confounded by the number of caretaker (a single queen versus 5 workers)
343 (Costa et al. 2021). Potentially, both queens and workers in *B. impatiens* may preferentially
344 produce smaller individuals when there are a few caretakers because it may be less costly and
345 require less provisioning to produce smaller individuals (Cnaani and Hefetz 2001; Couvillon and
346 Dornhaus 2010).

347
348 Regardless of caretaker identity or number, no gynes were produced in any of the social
349 condition treatments. The absence of a queen has been shown to incite rearing of gynes in
350 several social insects such as the ant species *Aphaenogaster senilis* and *Atta sexdens* and honey
351 bees (Boulay et al. 2009; Tarpay et al. 2000; Winston 1991). Additionally, in *B. terrestris*, close to
352 80% of the female brood that was reared in the absence of the queen and that was transplanted
353 before the critical period for differentiation, developed into gynes or intercastes in both full-size
354 colonies (Cnaani et al. 2000a), and also in small groups of 10 workers (Shpigler et al. 2013), and
355 increased colony size affected the production of new gynes in several studies (Bloch 1999;
356 Pereboom et al. 2005). However, in this study we found an increase in brood body mass (within
357 the range of a worker) with the increase in the number of caretakers but did not observe gyne
358 production even in the ten-caretaker condition, meaning that the queen is not the sole factor
359 affecting caste determination and gyne production.

360

361 That being said, a group of ten workers may not be sufficient for inducing gyne production in *B.*
362 *impatiens* and an increase in the number of nurses combined with the absence of the queen may
363 have resulted in gyne production. A previous study in several bumble bee species has suggested
364 a certain worker/larva ratio needs to be achieved for gyne production (Plowright and Jay 1968).
365 This ratio, however, may vary across bumble bee species. In some ant species it has been
366 reported that the number of workers constrained reproductive decisions, and the production of
367 gynes was lower in smaller than in larger groups. In the instances of low worker numbers,
368 rearing gynes may require an overhead that small worker groups cannot afford (Ruel et al. 2012).
369
370 Since we observed no difference in brood reared by one worker and one queen, our data do not
371 indicate that there is an active manipulation of the queen on worker body mass or duration of
372 development. The data further show that no gynes were produced in any of the worker cages,
373 questioning whether the queen's presence is as important for gyne production in *B. impatiens* as
374 it is in *B. terrestris*. Data in *B. impatiens* support a much simpler model in which worker size
375 (and maybe also caste) are dependent on the number of caretakers and consequently, the amounts
376 of resources. Size variation in workers can be explained along the same lines with the production
377 of relatively smaller individuals either early in the season, when fewer caretakers are available,
378 or very late in the season, when resources are no longer available (Treanore et al. 2020b). *B.*
379 *impatiens* may have a similar caste determination mechanism to that seen in *Bombus hypnorum*,
380 *Bombus rufocinctus*, and *Bombus ternarius*, to which they are more closely related (Cameron et
381 al. 2007) and where caste determination depends on food quantity and feeding regimes during
382 development (Plowright and Jay 1977; Plowright and Pendrel 1977; Roseler, 1970; Roseler and

383 Roseler 1974). However, the detailed mechanisms determining gyne production in this species
384 are yet to be explored.

Caption to figures

Figure 1: Body mass of female (A) and male (B) larvae and pupae across treatments. Egg batches of either females (laid by a queen) or males (laid by workers) were reared by a single queen or by varying number of workers (1, 3 and 10) and were sampled every day during the entire development period between egg and adult. The sample size per treatment ranges between 235 to 309 individuals (see Table 1 for details).

Figure 2. Body mass of female and male larvae and pupae across all treatments. Egg batches of either females (laid by a queen) or males (laid by workers) were reared by a single queen or by varying number of workers (1, 3 and 10) and were sampled every day during the entire development period between egg and adult.

Figure 3: The growth rate of female (A) and male (B) larvae reared by a single queen or by varying number of workers (1, 3 and 10). All larvae were included in the analysis (110-165 individuals per treatment, see Table 1 for details). Larvae hatched on day 6 (after eggs were laid) and pupated on days 13 (the earliest) to 18 (the latest). Most larvae (>95%) pupated on days 15-16.

Figure 4. The average body mass (A) and duration of development (B) of all the adults emerging in the study (10-15 individuals per treatment, see Table 1 for details). The body mass was measured upon emergence and duration was counted from the day eggs were laid until the emergence of the adult. Asterisks denote significance at $p < 0.001$ (***) and $p < 0.01$ (**).

Table 1 - The total sample size in the study split into treatments and sex, and the minimum and maximum values for the larvae and pupae duration of development.

	Care takers	Total n	Min and Max of larva age (n)	Min and Max of pupa age (n)	Min and Max of adult age (n)
Females	1 worker	238	6-17 (n=127)	14-24 (n=100)	24-26 (n=11)
	3 workers	238	6-16 (n=110)	13-25 (n=115)	24-26 (n=13)
	10 workers	241	6-18 (n=121)	14-25 (n=109)	23-26 (n=11)
	Queen	309	6-17 (n=165)	13-23 (n=132)	24-25 (n=12)
Males	1 worker	247	6-16 (n=116)	13-24 (n=116)	24-26 (n=15)
	3 workers	235	6-16 (n=128)	17-26 (n=97)	24-26 (n=10)
	10 workers	244	6-15 (n=112)	16-25 (n=120)	24-26 (n=12)
	Queen	249	6-17 (n=116)	13-25 (n=122)	24-26 (n=11)
