25 **Abstract: Temperate understory plant species are at risk from climate change and**
26 **anthropogenic threats that include increased deer herbivory¹⁻³, habitat loss⁴, pollinator**
27 **declines⁵ and mismatch^{6,7}, and nutrient pollution^{8,9}. Recent work suggests that spring**
28 **ephemeral wildflowers may be at additional risk due to phenological mismatch with**
29 **deciduous canopy trees^{10,11}. The study of this dynamic, commonly referred to as**
30 **“phenological escape”, and its sensitivity to spring temperature is limited to eastern North**
31 **America¹⁰⁻¹⁶. Here, we use herbarium specimens to show that phenological sensitivity to**
32 **spring temperature is remarkably conserved for understory wildflowers across North**
33 **America, Europe, and Asia, but that canopy trees in North America are significantly more**
34 **sensitive to spring temperature compared to in Asia and Europe. Our findings reveal that**
35 **advancing tree phenology will lead to decreasing spring light windows in North America**
36 **while spring light windows will be maintained or even increase in Asia and Europe in**
37 **response to projected climate warming.**

38 **Introduction**

39 Temperate deciduous forests are a dominant biome in the northern hemisphere, covering
40 extensive regions in eastern Asia, continental Europe, and eastern North America¹⁸. They are
41 characterized by winter-deciduous plant species, and the phenology of leaf out and flowering on
42 all three continents is sensitive to variation in average spring temperature¹⁹⁻²². Furthermore,
43 recent research has found disparities in phenological sensitivity among plants from different
44 continents^{19,23}, suggesting that climate change may affect temperate forests differently depending
45 on location.

46 Previous studies indicate differences in spring phenological sensitivity between woody
47 and herbaceous plants in forests, with direct comparisons available for plants in Asia²⁰ and North

48 America^{10,22}. Evidence in Europe similarly suggests differences in sensitivities between woody
49 and herbaceous plants^{24,25}. Herbaceous plants may be less sensitive to spring temperature than
50 trees because the former often overwinter underground and therefore may not respond to the
51 same phenological cues as the latter, which have extensive aboveground structures^{15,26}, but this
52 mechanism has only been studied in North American forests. This potential phenological
53 mismatch is important because spring-active wildflowers in temperate deciduous forests, as well
54 as some woody understory species^{12,13,27,28}, often rely on leafing out before the canopy closes in
55 order to assimilate 40-100% of their annual carbon budget¹¹. The success of this strategy to
56 maximize the spring light window, referred to as “phenological escape”^{13,14}, is directly
57 associated with patterns of growth^{13–15,29,30}, survival^{13,29–31}, flowering^{14,31}, and reproductive
58 output^{14–16,32}. Recent studies suggest that the duration of spring light windows in eastern North
59 America is likely to be significantly altered with warming climates^{10,12}, with herbaceous species
60 generally expected to experience shorter spring light windows in the coming decades.

61 Experimental evidence for such mismatches, however, has generally been limited to
62 comparisons of woody plants located in common garden experiments, which are limited in
63 geographical and temporal extent and have not evaluated mismatch with understory species. For
64 example, Zohner and Renner^{23,33} have contributed valuable insights into interspecific variation in
65 plant phenology using woody plants growing in European botanical gardens. It is unknown,
66 however, if the variation in woody plant phenology found in common garden experiments are
67 also observed at large scales, for forest trees growing in their natal environment, and across long
68 time periods³⁴. It is similarly unknown whether understory herbaceous plant phenological
69 sensitivity varies across large spatial and temporal scales.

70 Here we assess intercontinental, long-term data of the phenological sensitivity of canopy
71 and understory forest plants and the potential for phenological mismatch across temperate forests
72 in North America, Europe, and Asia. We evaluate the spring phenology of 5,522 herbarium
73 specimens collected between 1901 and 2020, representing 22 common tree and 18 common
74 wildflower species found in temperate deciduous forests on three continents (six wildflower
75 species per continent and six, six, and ten tree species in Europe, North America, and Asia,
76 respectively; see full species list in Table S1 and distribution of observations in Fig. S1).
77 Herbarium collections provide data from across large temporal (centuries) and spatial
78 (intercontinental) scales difficult to match with other methods. Following previously validated
79 methods^{35,36}, we model Leaf Out Date (LOD) of overstory canopy trees and First Flowering Date
80 (FFD) of spring-blooming understory wildflowers (perennial herbaceous species that leaf out at
81 approximately the same time as they flower in the early spring) in response to average spring
82 (March-April) temperature of the collection year and location. This period is chosen because
83 most (> 99%) of the observed phenology occurred during or following this period (Fig. 1a;
84 means and standard deviations are listed in Table S2) and because initial variable analysis
85 identified this temperature variable as the best for predicting tree and wildflower spring
86 phenology. Additionally, owing to the absence of daily weather records for many years and
87 locations, we were unable to calculate and analyze finer-resolution temperature data for all
88 geographic locations within the dataset (see Supplement). We use estimated model parameter
89 values to compare phenological sensitivities of trees and wildflowers among continents and to
90 project how spring light window duration will change by the end of the current century based on
91 projected climate trends. Our results suggest that there are important differences in the sensitivity
92 of trees (but not wildflowers), with North American trees significantly more sensitive to spring

93 temperature than Asian or European trees. This difference has important implications for
94 phenological escape and the future conservation of the species-rich herbaceous layer in
95 temperate deciduous forests as the climate continues to change.

96

97 **Results/Discussion**

98 We used a hierarchical Bayesian modeling approach to evaluate the relationship between
99 spring phenology of tree and wildflower species and various climate drivers (see Methods).
100 Following model selection, our final model structure included fixed effects of average spring
101 (March-April) temperature, and elevation as well as species-level random effects. We show
102 continental distributions of spring temperature values in Fig. 1b (means and standard deviations
103 are listed in Table S2). We report estimates for spring temperature sensitivities from the final
104 model structure in the main text. Parameter estimates for elevation sensitivities and model
105 performance of other potential drivers and combinations of drivers are reported in Tables S3 and
106 S4.

107

108 *Sensitivity differences by strata*

109 Tree leaf out phenology (LOD) was significantly more sensitive to average spring
110 temperature in North America (mean = -3.62 days °C⁻¹; 95% credible interval (CI) = [-3.76, -
111 3.49]) than in Europe (mean = -2.79; CI = [-3.27, -2.30]) and Asia (mean = -2.62; CI = [-2.97, -
112 2.26]; Fig. 2). These values are consistent with previously reported phenological sensitivities in
113 North America¹⁰ (-5.5 to -3.3 days °C⁻¹) and Europe²⁴ (-4.1 to -3.0 days °C⁻¹), as the credible
114 intervals from our results overlap with the reported credible intervals of prior studies. However,
115 the Asian LOD sensitivity was less sensitive than previously reported³⁷ (-3.50 to -3.03 days °C⁻¹)

116 ¹), potentially owing to differences in species selection³⁸ or model structure. Previously reported
117 sensitivities were determined in separate studies using either observational data^{10,24} or long-term
118 observation-based weather station data³⁷. The general consistency between our findings suggests
119 that phenology data from herbarium collections are good indicators of patterns in natural
120 systems³⁹⁻⁴¹, a point supported by a recent study of phenological sensitivity derived from
121 herbaria and from observed citizen science data⁴². These herbarium-based results provide some
122 of the first evidence that phenological sensitivity differs across the temperate forest biome (but
123 see ref⁴³ for evidence of differences in response to warming and chilling accumulation). Our
124 study is also the first to directly contrast overstory and understory phenology across multiple
125 continents, and therefore the first to find differences in phenological sensitivity between trees
126 and forest wildflowers across continents. We recommend future studies explore these differences
127 using alternative approaches and methodologies that focus on the physiological basis for and
128 mechanisms that underlie these patterns.

129 In contrast to trees, wildflower sensitivity to spring temperature was similar across all
130 three continents and exhibited no statistically significant differences among continents (means
131 and 95% credible intervals in brackets: North America = -3.14, [-3.28, -3.00]; Europe = -3.02, [-
132 3.48, -2.56]; Asia = -3.12, [-3.36, -2.86]; Fig. 2). These values are also generally consistent with
133 those reported elsewhere in the literature (i.e., 95% credible intervals overlap with those reported
134 in other studies; -2.2, [-3.7, -0.76] days °C⁻¹ in North America¹⁰ and -3.6, [-4.04, -3.18] days °C⁻¹
135 in Europe²⁵), although we are unaware of any studies that have estimated phenological sensitivity
136 for Asian forest wildflowers in days °C⁻¹. Ge et al.²⁰ reports herbaceous plant sensitivity of -5.71
137 days per decade in Asia (\pm 7.90 standard deviation; based primarily on long-term observational
138 data), which appears to be roughly consistent with our model results, although the difference in

139 units makes this more speculative than the other comparisons. Discrepancies in mean responses
140 between this study and others may be due in part to different types of data (herbarium specimens
141 versus field observations) and to choice in focal taxa, as temperature sensitivity has been shown
142 to vary widely across taxa³⁸.

143 Particularly noticeable in our results was that r^2 coefficients of predicted versus observed
144 phenology were much higher in North America (0.70 and 0.76 for wildflower and tree models,
145 respectively) compared to Asian (0.40 and 0.44, respectively) and European models (0.41 and
146 0.25, respectively). This difference in model performance could be due to the higher interannual
147 variability of spring temperatures in North America⁴³, leading to greater selective pressure for
148 strong sensitivity to spring temperatures in North American plants. This difference could explain
149 why North American species exhibit higher correlation of phenology with average spring
150 temperatures (Table S4). Alternatively, European and Asian species may have stronger
151 phenological responses to other spring forcing cues, like winter chilling temperatures or
152 photoperiod, relative to the March-April period used in this study (see Methods). We think the
153 latter explanation is unlikely given the strong correlations of phenology with spring temperature
154 across all continents (see Supplement).

155 Herbarium-based phenological models may be improved by accounting for spatial
156 autocorrelation within the dataset. For example, Willems et al.²⁵ found that including spatial
157 autocorrelation significantly improved predictability of European herbaceous phenology, even
158 when accounting for multiple drivers of spring phenology. We followed a similar approach as
159 their study and found similar improvements in model performance (Tables S3-4) that had
160 substantial positive effects on r^2 values of Asian and European models. However, spatial
161 distributions of specimens differed substantially among continents (see Fig. S2-S4), and these

162 differences could lead to artifacts and make results unreliable to interpret (see Supplemental
163 Information). Therefore, we focus here on results for models without spatial autocorrelation but
164 acknowledge that spatial aggregation of herbarium specimens in Europe and Asia may be
165 partially responsible for the relatively lower r^2 values. We encourage other researchers to explore
166 this question further both with our data set and other data sets.

167

168 *Climate change and spring light windows*

169 The relative difference between wildflower and tree sensitivity varied substantially
170 among continents, with wildflowers being approximately equally as sensitive to spring
171 temperature as trees in Asia and Europe but significantly less sensitive than trees in North
172 America (Fig. 2). Importantly, these differences were driven by changes in tree phenological
173 sensitivities among continents and resulted in different expectations for spring light window
174 duration (i.e., the difference in time between estimated wildflower flowering date and canopy
175 tree leaf out date) on different continents under current climate conditions (Fig. 3), based on
176 modeled leaf out and flowering under a climate scenario derived from average climate conditions
177 from 2009-2018 (Fig. S5).

178 Interestingly, the time between leaf out and flowering in North America is greater in the
179 north than in the south (Fig. 3), indicating a greater spring light window duration at higher
180 latitudes. In addition, although there was regional variation in spring light window duration on
181 each continent, there was broad overlap in duration among continents estimated under current
182 environmental conditions (North America light window duration averages 11.7 ± 4.1 s.d. days;
183 European duration averages 14.7 ± 3.0 s.d. days; and Asian duration averages 8.0 ± 4.6 s.d.
184 days). This suggests that under current climate conditions wildflowers across all continents

185 experience similar length of spring light windows, but the impact of warming on shrinking
186 window size will differ among continents with unknown impacts on wildflower populations.

187 To that end, differences among continents resulted in different projections for how spring
188 light window duration will respond to climate change over the coming century (Fig. 4). We used
189 climate change projections for 2081-2100 (assuming an extreme climate change scenario; Institut
190 Pierre-Simon Laplace CM6A-LR climate model – shared socioeconomic pathway 585; see
191 Methods for more details) to forecast wildflower flowering date and canopy tree LOD for the
192 end of the current century (Fig. S8) and then calculated the difference between forecasted
193 wildflower flowering and tree leaf out phenology for the period of 2081-2100 (future spring light
194 window duration; Fig. S9). To estimate the change in spring light window duration between now
195 and the end of the century (Fig. 4), we subtracted the forecasted future light window duration
196 from the modeled light window duration under current climate conditions.

197 Dramatic differences in the projected change in spring light window duration emerged,
198 ranging from increasing spring light windows for wildflowers in Asia, to minimal change in
199 spring light window length in Europe, to decreasing spring light window length in North
200 America. Importantly, these differences in phenological escape trajectories are primarily
201 attributable to differences in phenological sensitivities between overstory and understory species
202 and not to differences in projected spring temperature changes among continents. Projected
203 changes in March-April temperature broadly overlapped across continents (mean \pm s.d. of
204 projected change in spring temperature is 5.41 ± 1.87 °C, 6.36 ± 2.36 °C, and 5.04 ± 2.92 °C in
205 Asia, Europe, and North America, respectively; Fig. S10). Intracontinental differences, however,
206 such as the more extreme projected changes in phenological escape in the northern regions of

207 each continent, are due to projected spring temperature change across latitudes, with higher
208 latitude regions expected to experience greater spring warming relative to lower latitudes^{44,45}.

209 The North American results are consistent with findings from a previous study which
210 similarly predicted reduction in access to spring light at a single site in the U.S. Northeast¹⁰.
211 Although no previous studies have specifically addressed phenological escape in Asia, our
212 results are consistent with previous research that found higher sensitivity to spring temperature
213 for Asian herbaceous plants compared to Asian woody trees and shrubs²⁰. Similarly, we are not
214 aware of European studies that have directly compared phenological sensitivity between
215 wildflowers and trees nor that have quantified phenological escape, but our estimates of
216 sensitivity are consistent with previously reported values^{24,46}. Together, this supports our
217 conclusion that the duration of spring light windows will be differently affected by climate
218 change on different continents.

219 The different response of forest plant phenology among continents is important because it
220 suggests that the performance of understory wildflowers will be affected more or less severely
221 depending on the continent. Previous studies have linked access to spring light before canopy
222 closure with the growth^{13–15,29,30}, survival^{13,29–31}, flowering^{14,31}, and reproductive output^{14–16,32} of
223 understory plant species. Therefore, reductions in access to light in North America are expected
224 to lead to reduced performance under climate change while these metrics would be expected to
225 be maintained (Europe) or improved (Asia) on other continents.

226

227 *Conclusions and future directions*

228 The herbaceous layer accounts for more than 80% of plant species in temperate forests
229 worldwide⁴⁷ and provides a critical role in the functioning of these ecosystems⁴⁸. Understory

230 wildflower species face many threats that include deer herbivory¹⁻³, habitat loss⁴, pollinator
231 declines⁵ and mismatch^{6,7}, presence of nonnative, invasive plants^{49,50}, and nutrient pollution^{8,9}.
232 Furthermore, there is substantial evidence that many of these species are limited in their dispersal
233 ability^{4,51} and populations are likely unable to shift their distributions as rapidly as regional
234 climates are predicted to warm. Our results show that mismatch between understory and
235 overstory phenology, specifically in North America, is another concern for this already
236 threatened group^{47,52}. Reductions in spring light windows will likely lead to reduced carbon gains
237 each year for spring forest wildflowers^{10,11}, which may ultimately lead to population decline as
238 plant fitness declines. Therefore, we suggest that future conservation efforts also consider the
239 impact of loss of spring light in restoration planning, with simultaneous studies of overstory and
240 understory responses together⁴⁸. Furthermore, this information may assist conservation
241 practitioners in their decisions of where to focus management or conservation efforts based on
242 projected changes to future forest ecosystems.

243 The patterns examined in this study point to fascinating distinctions in plant phenological
244 responses among continents, but they cannot provide a mechanistic explanation for why these
245 differences exist. Wildflowers and trees advance their phenology with warming spring
246 temperatures, for example, but why are North American trees more responsive than co-occurring
247 wildflower species to warming? Some speculate it is because perennial wildflowers overwinter
248 underground whereas tree buds overwinter aboveground; trees may therefore be more affected
249 by air temperature relative to wildflowers^{15,26}. Future empirical studies should directly test this
250 theory. Similarly, what are the mechanisms that allow North American trees to be more sensitive
251 to spring temperature than trees in Europe and Asia? Studies using dormant twigs, potted
252 seedlings, and trees growing in botanical gardens are possible methods for investigating this.

253 Common garden experiments with manipulated treatments may provide a more mechanistic
254 understanding of our observations, including to rule out potentially confounding variables such
255 as intercontinental differences in soil properties, precipitation, and photoperiod.

256 Other recent research highlights the growing need to assess the potential for nonlinear
257 phenological responses to spring warming. As reviewed by Wolkovich et al.⁵³, future
258 phenological responses to spring warming may be nonlinear owing to a number of reasons
259 (including threshold responses to extreme environmental conditions and interactions among
260 drivers besides spring forcing). Accounting for factors that might drive nonlinearities in plant
261 phenological response to warming will necessitate controlled experiments^{53,54}, which was not
262 possible with the observational herbarium dataset used in our study. We did not find evidence for
263 nonlinear responses to spring temperature, but we acknowledge that experimental studies that
264 can experimentally manipulate and test for the impacts of spring forcing, winter chilling, and
265 photoperiodic effects on plant phenology could further illuminate how nonlinearity affects
266 phenological escape.

267 Our study represents an early attempt to address phenological questions using herbarium
268 specimens at the intercontinental level. Digitization of herbarium specimens and other historical
269 data and citizen science programs like iNaturalist and iSpot are making data increasingly
270 available and enabling new research⁵⁵. We encourage others to reach out to international herbaria
271 and to collaborate to synthesize these data at a global scale to address pressing ecological and
272 climate change questions.

273 **Methods**

274 *Phenological data*

275 Herbarium specimens from North America (see Miller et al.²²), East Asia, and Europe
276 were evaluated for common species of deciduous overstory tree species and understory
277 deciduous wildflowers, prioritizing congeneric species living on more than one continent when
278 possible, and with genus and family in mind when not possible. Specimens were scored for
279 either Leaf Out Date³⁵ (LOD, tree species) or First Flowering Date^{36,41} (FFD, wildflower
280 species), consistent with previous studies comparing phenology across forest strata^{10,56}. This
281 approach assumes that herbaceous species flowering time is tightly correlated with timing of leaf
282 out for these species¹⁰. This approach is currently widely accepted to be the best we have to
283 assess shifts in phenology using herbarium specimens⁴¹, but see also Buonaiuto et al.⁵⁷. In
284 particular, we selected wildflower species that flowered and leafed out at approximately the same
285 time in early spring.

286 Specifically, we searched digitized repositories of herbarium collections on each of the
287 three target continents. Digitized Asian herbarium specimens were provided by the Chinese
288 Virtual Herbarium (<https://www.cvh.ac.cn/>) and Chinese Field Herbarium
289 (<http://english.ib.cas.cn/>). European specimens were located and collated using the Global
290 Biodiversity Information Facility (gbif; <https://www.gbif.org/>). In North America, digitized
291 specimens were collated from seven online repositories, further detailed in Miller et al.²². We
292 conducted searches for each species independently, prioritizing spring ephemeral wildflowers
293 and deciduous tree species with the highest number of available observations across most of the
294 relevant geographic range. We then filtered our initial searches by phenophase (scored by hand),
295 making sure we only included observations that were flowering (for the wildflowers) or newly
296 leafed out (trees). Next, we identified specimens that were missing information but for which
297 digitized images of the specimen sheet were available. For these individuals, we entered missing

298 phenological and georeferencing data when available (see below). Individuals with missing
299 information and that either were not fully digitized or that did not include the necessary
300 information on the digitized herbarium sheet were excluded from further study.

301 Specimens were georeferenced by researchers fluent in the languages in which the
302 specimen data were collected in. Georeferencing was completed using the most precise
303 geographic scale recorded at time of collection (i.e., prioritized by exact coordinates,
304 town/locality, county). Specimens that did not identify location to at least county (in North
305 America) or locality-level (in Asia and Europe) were excluded from this analysis, which is
306 common practice in herbarium studies given the lack of precise geolocation data for some older
307 specimens. Only specimens collected within each species' native range were used. Specimens
308 collected prior to 1901 were excluded because climate estimates were not available prior to this
309 year⁵⁸. In total, after accounting for specimens that were excluded from our original search, we
310 collected data for a total of 40 species (22 tree species and 18 herbaceous species; Table S1)
311 consisting of 5,522 individual specimens. The complete dataset of herbarium specimens used in
312 this analysis is available [upon publication].

313

314 *Climate data*

315 Climate data were extracted from the Climate Research Unit gridded Temperature Series
316 (CRU TS) data set⁵⁸ v4.05 using the georeferenced location for each specimen. Spring
317 temperature was calculated as the average of the March and April average monthly temperatures
318 for the year and location associated with each specimen. This metric is consistent with other
319 studies which found this period to be important in cueing temperate plant phenology^{10,13,22,56} and
320 preliminary analysis indicated that this was the best spring temperature metric for modeling plant

321 phenological responses in our dataset (see Supplemental Information for more details). Daily
322 weather records were not available for many years and many locations.

323

324 *Models and analysis*

325 We modeled the day of observed phenological event (OPE) for individual i of species j
326 using a normal likelihood distribution:

327

$$328 \quad OPE_{i,j} \sim N(\mu_{i,j}, \sigma^2)$$

329

330 The mean, μ , was modeled with an intercept term (β_0), slope terms representing phenological
331 sensitivity to average spring temperature (β_1) and elevation (β_2), and species random effects (α_j):

332

$$333 \quad \mu_{i,j} = \beta_0 + \beta_1 \times SpringT_i + \beta_2 \times Elevation_i + \alpha_j$$

334

335 We used slightly informative priors to estimate parameters: $\beta_0, \beta_1, \beta_2, \alpha_j \sim N(0, 1E-3)$;
336 $1/\sigma^2 \sim Uniform(0, 100)$. Other potential drivers of leaf-out and flowering phenology were
337 explored in preliminary analysis (i.e., winter temperatures, annual precipitation, and spring
338 precipitation), but these drivers did not generally improve model performance (Table S3) and
339 were thus excluded from the model structure.

340 Models were run separately for each stratum (i.e., tree vs. herbaceous) x continent
341 combination using the *R2jags* package⁵⁹ (v0.7-1) in R v4.1.0. Parameter values (means,
342 variances, and covariances) were estimated from posterior distributions and are considered

343 significantly different if the 95% credible intervals (CIs) of their posterior distributions do not
344 overlap. Model code and data used to fit each model are publicly available [upon publication].

345

346 *Climate Change Modeling*

347 To forecast changes in the duration of spring light windows, we compared FFD and LOD
348 from two different climate simulations. The first simulation represented current environmental
349 conditions and was estimated by taking the average of spring (March-April) temperatures from a
350 recent ten-year period (2009-2018). Climate and elevation data were downscaled from the CRU
351 TS 4.03⁵⁸ dataset using WorldClim 2.1⁶⁰ for bias correction at a resolution of 2.5 minutes.
352 Average monthly temperature for each month and each year was calculated as the mean of
353 monthly minimum and maximum temperatures.

354 The second simulation represents projected environmental conditions under climate
355 change at the end of this century (2081-2100). Climate data used in this simulation were
356 downscaled (using WorldClim 2.1⁶⁰) from the Institut Pierre-Simon Laplace (IPSL) CM6A-LR
357 climate model^{44,61}, which is part of the ongoing Climate Model Intercomparison Project⁴⁵
358 (CMIP6). We specifically used forecasts based on the Shared Socioeconomic Pathway (SSP)
359 585, which is analogous to the Representative Concentration Pathway (RCP) 8.5 from CMIP5
360 and earlier. This SSP is the most extreme, “business as usual”, pathway used by the
361 Intergovernmental Panel on Climate Change (IPCC). Therefore, projections made using this
362 pathway represent the extreme threshold of climate change effects by the end of the century.

363 Model output is presented for regions where land-use is classified as > 1% temperate
364 deciduous forest type according to a consensus of four global land-use models¹⁸ (uncropped
365 versions of figures can be found in the supplement). Herbarium specimens were included in the

366 above analyses regardless of the land-use classification of the respective georeferenced locations.
367 We did not find consistent effects of land-use on phenological sensitivity, so we did not include
368 this variable as a fixed effect in the final model. Still, we only present output for land areas
369 currently covered by deciduous forests as those are so far the only systems where phenological
370 escape has been shown to be important^{10–13,15,22}.

371 Approximations of FFD and LOD (for wildflowers and trees, respectively), were
372 calculated using posterior mean estimates of the slopes, intercepts, and species-level random
373 effects of our models (Tables S4-S7). Spring light window length was then calculated as the
374 difference (in days) between FLD and LOD in each simulation X continent combination. Data
375 processing and handling was completed primarily using the *ncdf4*⁶², *stars*⁶³, and *sp*⁶⁴ packages in
376 R v4.1.0.

377

378 **Inclusion and ethics statement:** The work presented here is the culmination of international
379 collaboration and facilitation. Herbarium specimens were collated across three continents by
380 researchers in those locations who spoke the language(s) in which information was recorded. All
381 researchers who led these efforts are coauthors on this manuscript and their employees and lab
382 members who assisted in this effort are listed in the Acknowledgements section. Local and
383 regional studies have been cited throughout this document, further acknowledging the
384 contributions of global scholars to our work and to science as a whole.

385

386 **Data availability statement:** Data used in this analysis is freely available [upon publication].

387

388 **Code availability statement:** Examples of code used in this analysis is freely available [upon
389 publication].

546 **Acknowledgements**

547 We thank A. Helmling, L. de Castro Machado de Souza, P.Y. Lai, C. Terry, and M. Rothendler
548 (North American specimens); I. Vogler, M. Schramm, V. Bastian, K. Adler, and B. Müller
549 (European specimens); and Z. Yang, C. Tan, L. Wang, and X. Huo (East Asian specimens) for
550 their efforts in databasing and georeferencing the herbarium specimens analyzed for this project.

551 We also thank C. Römermann, E. Welk, and B. Liu for their suggestions on the European and
552 Asian species list. We are grateful to the Chinese Virtual Herbarium and Chinese Field
553 Herbarium for providing the East Asian specimen data and digitized photos and to the
554 *Metasequoia* funding of Nanjing Forestry University which helped fund the Asian data
555 extraction. We thank F Lindgren and F Willems for providing guidance on INLA methodology
556 for the models with spatial autocorrelation. BR Lee, TK Miller, JM Heberling, SE Kuebbing, and

557 RB Primack were funded by National Science Foundation Grants Nos. DEB 1936971, 1936877,
558 and 1936960. We acknowledge the World Climate Research Program, which, through its
559 Working Group on Coupled Modelling, coordinated and promoted CMIP6. We thank the climate
560 modeling groups for producing and making available their model output, the Earth System Grid
561 Federation (ESGF) for archiving the data and providing access, and the multiple funding
562 agencies who support CMIP6 and ESGF. We thank Abe Miller-Rushing and Amanda S. Gallinat
563 for providing valuable feedback on this manuscript.

564

565 **Author contributions:** JMH, SEK, and RBP initially conceived of this project. TKM, CR, and
566 YY collected, scored, and georeferenced the herbarium collections used in this analysis. BRL
567 conducted the statistical analysis and wrote the article. All authors contributed equally to
568 reviewing and editing the manuscript.

569

570 **Competing interests statement:** The authors declare no competing interests.

571

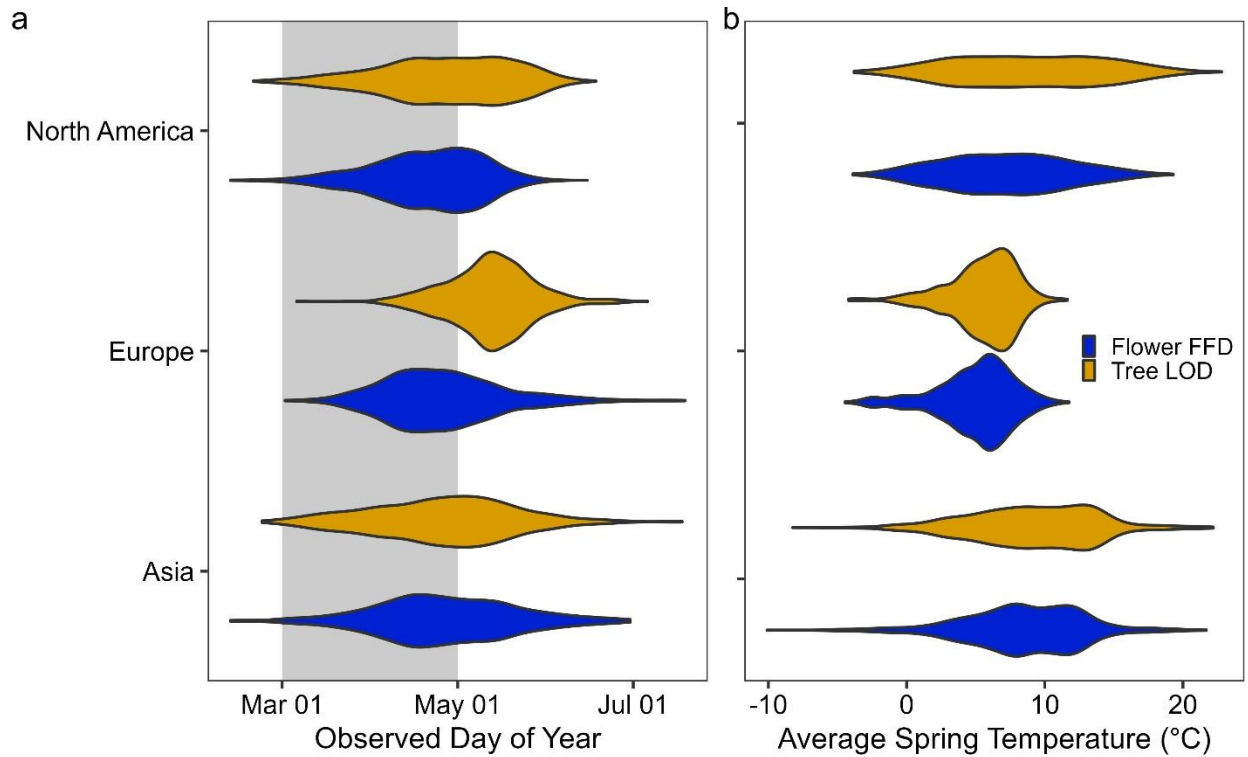

572 **Additional information:** Supplementary Information is available for this paper. Correspondence
573 and requests for materials should be addressed to Benjamin R. Lee (LeeB@CarnegieMNH.org).

574 Reprints and permissions information is available at www.nature.com/reprints.

575

576 **Figures:**

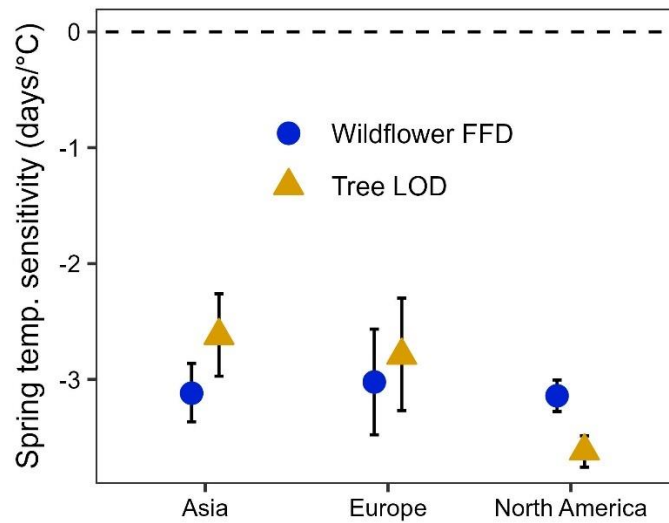

577 **Figure 1:** Distributions of observed understory wildflower flowering (blue) and canopy tree leaf
578 out (gold) in temperate forests in Asia, Europe, and North America by (a) observed date of
579 phenology and (b) average spring (March-April) temperature (°C). Grey shading behind the
580 violin plots in panel a indicates the March-April period used to model and forecast phenology.

581

582

583 **Figure 2:** Posterior estimated means and 95% credible intervals for spring temperature
584 sensitivity. Shapes represent parameter estimates for wildflower First Flower Date (FFD, blue
585 circles) and canopy tree Leaf Out Date (LOD, yellow triangles). Estimates are considered
586 statistically significant from 0 if credible intervals do not overlap the dashed 0 line and are
587 considered significantly different from each other if credible intervals do not overlap.

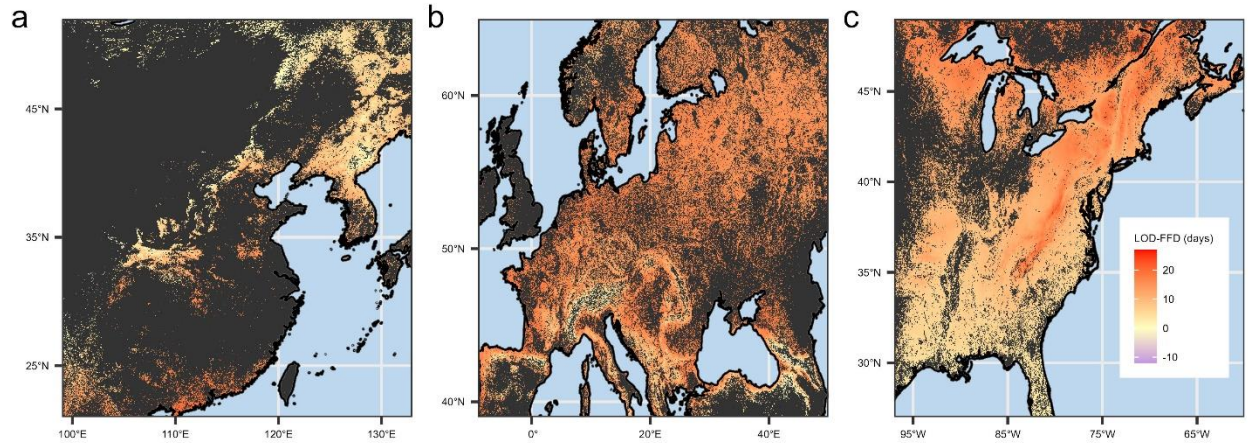

588

589

590

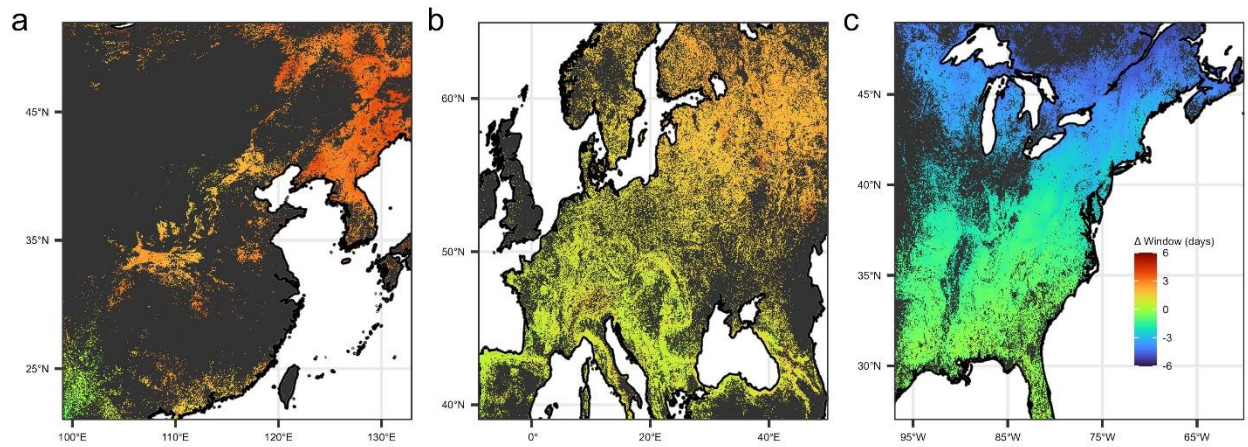

591 **Figure 3:** Estimated mean difference between wildflower First Flower Date (FFD) and canopy
592 tree Leaf Out Date (LOD) (in days) under current climate conditions (averaged from 2009-2018,
593 see methods) in a) Asia, b) Europe, and c) North America. Negative values indicate tree LOD is
594 estimated to occur before wildflower FFD. Estimations were cropped by estimated area of
595 broadleaf and mixed-broadleaf forest (see methods). Dark gray regions indicate areas where the
596 consensus land classification is < 1% deciduous or mixed deciduous forest cover. An uncropped
597 version of this figure is available in Fig. S6.
598

599

600

601 **Figure 4:** Projected changes in spring light window duration (Δ Window) between current
602 climate conditions and conditions projected for the end of the current century. Positive values
603 indicate regions where light window duration is expected to increase with spring warming
604 (particularly in northern Asia) and negative values indicate where it is expected to decrease
605 (particularly in northern North America). Dark gray regions indicate areas where the consensus
606 land classification is < 1% deciduous or mixed deciduous forest cover. An uncropped version of
607 this figure is available in Fig. S7.
