Abstract. With the high mutation rate in viruses, a mixture of closely related viral strains (called viral quasispecies) often co-infect an individual host. Reconstructing individual strains from viral quasispecies is a key step to characterizing the viral population, revealing strain-level genetic variability, and providing insights into biomedical and clinical studies. Reference-based approaches of reconstructing viral strains suffer from the lack of high-quality references due to high mutation rates and biased variant calling introduced by a selected reference. De novo methods require no references but face challenges due to errors in reads, the high similarity of quasispecies, and uneven abundance of strains.

In this paper, we propose VStrains, a de novo approach for reconstructing strains from viral quasispecies. VStrains incorporates contigs, paired-end reads, and coverage information to iteratively extract the strain-specific paths from assembly graphs. We benchmark VStrains against multiple state-of-the-art de novo and reference-based approaches on both simulated and real datasets. Experimental results demonstrate that VStrains achieves the best overall performance on both simulated and real datasets under a comprehensive set of metrics such as genome fraction, duplication ratio, NGA50, error rate, *etc*. VStrains is publicly available at https://github.com/MetaGenTools/VStrains.

Keywords: De Novo Assembly · Viral Quasispecies · Assembly Graph · Path Extraction

1   Introduction

Viruses are the most abundant biological entities on Earth and have high mutation rates, up to a million times higher than their hosts [10,25]. Variations in viral genetic sequences lead to the emergence of new viral strains during evolution and are also known to be associated with many diseases [30]. One challenge in viral studies is to analyze a mixture of closely related viral strains, referred to as viral quasispecies. The reconstruction of viral strains in individual patients provides a signature of genetic variability and thus informs us about disease susceptibilities and evolutionary patterns of distinct viral strains [9].

The problem of inferring individual viral strains from sequencing data is called strain-aware assembly or viral haplotype reconstruction. Next-generation sequencing (NGS) data for viral quasispecies usually consists of many copies of short fragments (called reads) from a mixture of viral strains. A major challenge is to distinguish sequencing errors in reads from rare variations from highly similar strains. Moreover, unknown population sizes and imbalanced abundances pose additional difficulties [32]. Various approaches have been proposed to infer individual viral strains from NGS data and can mainly be classified into two categories [14], reference-based and de novo (or reference-free). Reference-based approaches (such as PredictHaplo [29] and NeurHap [35]) rely on the alignment between reads and references, and thus suffer from the lack of high-quality references due to high mutation rates [8], and biased variant calling introduced by a selected reference [3,33]. De novo approaches directly assemble viral strains from sequencing reads without references and have the potential to identify novel viral strains and provide deep insights for viral genetic novelty [30].

While de novo (meta)-genomic assemblers such as SPAdes-series [1,5,7,23,27] could be applied to assemble individual strains, they tend to produce fragmented contigs rather than complete viral strains, or collapsed contigs ignoring differences between strains, as they are not specifically designed to distinguish closely related viral strains. Specialized de novo assemblers such as SAVAGE [3], viaDBG [11], Haploflow [12] and PEHaplo [8] directly assemble reads into strains from viral quasispecies and have achieved promising results. More recently, VG-Flow [4] was proposed to extend pre-assembled contigs (produced by the specialized assembler SAVAGE [3]) into full-length viral strains using flow variation graphs and significantly outperformed other approaches on recovering viral strains from mixed samples. While VG-Flow [4] guarantees its runtime to be polynomial in the genome size, all the recovered viral strains must be selected from a set of candidate paths inferred by greedy path extraction strategies and thus some viral strains not covered by the candidate set are infeasible to be reconstructed.

We propose VStrains, a de novo approach for reconstructing strains from viral quasispecies. VStrains employs SPAdes [5] to build the assembly graph from paired-end reads and incorporates contigs and coverage information to iteratively extract distinct paths as reconstructed strains. We benchmark VStrains against multiple state-of-the-art de novo and reference-based approaches on both simulated and real datasets. Experimental results demonstrate that VStrains achieves the best overall performance on both simulated and real datasets under a comprehensive set of metrics such as genome fraction, duplication ratio, NGA50, error rate, etc. In particular, in more challenging real datasets, VStrains achieves remarkably improvements in recovering viral strains compare to other methods.

2   Methods

2.1   Preliminary

An assembly graph generated by SPAdes [5] is a directed graph $G = (V, E)$. Each vertex $v \in V$ represents a double-stranded DNA segment where its forward and reverse strands are denoted

by $seq(v^+)$ and $seq(v^-)$, respectively. A distinctive feature of assembly graphs built by SPAdes (with iterative k-mer sizes up to k_{max}) is that each $(k_{max}+1)$-mer appears in at most one vertex and thus can be used to uniquely identify the corresponding vertex in the assembly graph. Two vertices u and v can be connected by an edge $e = (u^{o_u}, v^{o_v}) \in E$, where $o_u, o_v \in \{+, -\}$ denote the strandedness of u and v, respectively. Note that suffix of u^{o_u} overlaps k_{max} positions with the prefix of v^{o_v} under the de Bruijn graph model [28] behind SPAdes. Moreover, the assembly graphs built by SPAdes also contain contigs information, $i.e.$, a contig in $G(V, E)$ is defined as a path of vertices together with their strandedness information. Let $cov(v)$ and $cov(c)$ denote the estimated coverage of DNA segment of a vertex v or a contig c, respectively.

2.2   Algorithm Overview

VStrains takes paired-end reads from mixed viral strains as the input and aims to recover individual viral strains. During pre-processing, VStrains first employs SPAdes to construct an assembly graph and contigs from paired-end reads, then canonicalizes the strandedness of vertices and edges, and further complements the assembly graph with additional linkage information from paired-end reads. After pre-processing, VStrains makes use of the contigs, paired-end links, and coverage information to perform branch split and non-branching path contraction to disentangle the assembly graph. Finally, VStrains outputs strain-specific sequences from the assembly graph via iterative contig-based path extraction. Refer to Fig. 1 for an overview of our algorithm. Details of each step are explained in the following sections.

Fig. 1. The framework of VStrains

2.3   Preprocessing

2.3.1   Canonicalizing Strandedness Recall that each vertex in the assembly graph produced by SPAdes represents both the forward and reverse strands of a DNA segment, and thus contigs reported by SPAdes may refer to two different strands of the same DNA segment. Therefore, there is no obvious correspondence between a viral strain and a directed path in the assembly graph. To unravel this correspondence, VStrains performs the strandedness canonicalization to choose the strandedness $o_v \in \{+, -\}$ for each vertex $v \in V$ where all adjacent edges only use v^{o_v}. VStrains first chooses an arbitrary vertex $s \in V$ as the source and fixes

its strandedness to o_s. Let $\bar{o}_s$ denotes the opposite strandedness of o_s, i.e., $\bar{o}_s = \{+, -\} \setminus \{o_s\}$. VStrains flips its adjacent edges if necessary to ensure these edges only use s^{o_s}, e.g., $(u^{o_u}, s^{\bar{o}_s})$ and $(s^{\bar{o}_s}, u^{o_u})$ will be flipped into $(s^{o_s}, u^{\bar{o}_u})$ and $(u^{\bar{o}_u}, s^{o_s})$, respectively. VStrains iteratively perform the above step until all the vertices have a fixed strandedness or one vertex has to use both strandedness. VStrains resolves the latter case by splitting this vertex into a pair of vertices, representing its forward and reverse strands, respectively. As a result, $seq(v^{o_v})$ can be simplified to $seq(v)$ where o_v is the chosen strandedness of v, and $(u^{o_u}, v^{o_v}) \in E$ can be simplified to (u, v), where o_u and o_v are the chosen strandedness of u and v, respectively. The vertices without any in-coming edges are defined as *source* vertices, whereas the vertices without any out-going edges are defined as *sink* vertices.

2.3.2   Inferring Paired-end Links While SPAdes [5] uses paired-end reads to construct contigs as paths in the assembly graph, VStrains uses unique k-mers of vertices in the assembly graph to establish mappings between paired-end reads and pairs of vertices and thus infers paired-end links.

VStrains uses minimap2 [19] to find exact matches of $(k_{max}+1)$-mers between pairs of vertices in the assembly graph produced by SPAdes (with iterative k-mer sizes up to k_{max}) and paired-end reads. Assume u and v are a pair of vertices in the assembly graph. A PE link is added between u and v if a paired-end read contains at least one $(k_{max}+1)$-mer in u and at least one $(k_{max}+1)$-mer in v. Note that $(k_{max}+1)$-mer can uniquely identify the corresponding vertex and thus makes it extremely unlikely to produce false-positive PE links unless errors in reads coincide with rare variations between strains. Since $(k_{max}+1)$-mer is usually smaller than the read length, even erroneous paired-end reads may infer paired-end links as long as they still contain error-free $(k_{max}+1)$-mers.

Note that paired-end reads are commonly used to infer paired-end links between vertices in the assembly graph. For example, overlap-graph-based assemblers, such as SAVAGE [3] and PEHaplo [8], use pairwise alignments between paired-end reads to build overlap graphs [26], and thus face challenges to choose appropriate parameters (*e.g.*, the overlap length cutoff along with allowed mismatches) to distinguish false-positive links between perfect reads from different strains and true positive links between erroneous reads from the same strain in overlap graphs. De Buijn graph-based assemblers, such as SPAdes [5] and viaDBG[11], split paired-end reads into k-bimers [5] or bilabel [22], pairs of k-mers of exact (or near exact) distances, one from the forward read and the other from the reverse read. Although this split strategy helps adjust k-bimers/bilabel distances [5,22] and efficiently construct de Bruijn graphs, it does not make full use of all available k-mer pairs (with varying distances) between forward and reverse reads to further simplify their assembly graphs. To overcome this limitation, VStrains uses all available k-mer pairs without any distance constraints between forward and reverse reads to create PE links between vertices in the assembly graph, which unravels its potential to further simplify the assembly graph produced by SPAdes.

2.4   Graph Disentanglement

After pre-processing, paired-end link information has been incorporated, and viral strains are expected to correspond to directed paths in the assembly graph. However, strains may share vertices and edges, and thus result in an entangled assembly graph. In this section, the graph disentanglement iteratively split branching vertices and contract non-branching paths as follows.

2.4.1   Branching vertex split A vertex $v \in V$ is called a *branching vertex* if either the in-degree or out-degree of v is greater than 1. A branching vertex is *non-trivial* if both its in-

Fig. 2. Graph disentanglement of VStrains. (a) P is a balanced branching vertex. (b) P is split into P_1 and P_2 in a balanced split corresponding to O↔R(contig path) and N↔Q (*PE* link). (c) A trivial branching vertex L in (b) is split into L_1 and L_2 in a trivial split, and thus previously unbalanced branching vertex K becomes a balanced branching vertex. (d) K is split into K_1, K_2 and K_3 in a balanced split, corresponding to three one-to-one mappings, I↔L_1NP_1Q (contig path), J↔L_2OP_2R (*PE* link), and H↔M (coverage compatible pair). D and G are not split during graph disentanglement.

degree and out-degree are greater than 1, and *trivial* otherwise. For example, vertex L is a trivial branching vertex while vertices D, G, K, and P are non-trivial branching vertices in Fig. 2(a).

Without loss of generality, assume a trivial branching vertex v has multiple in-coming edges $\{(u_i, v) \in E \mid i = 1, \ldots, n\}$. In a trivial split, vertex v will be replaced by vertices $\{v_1, \ldots, v_n\}$ without passing on its *PE* links, and each in-coming edge (u_i, v) will be replaced by (u_i, v_i), respectively. The coverage of v_i and the capacity of (u_i, v_i) are set to the capacity of (u_i, v). If

v has an out-going edge (v, w), (v, w) will be replaced by edges $\{(v_i, w)|i = 1, \ldots, n\}$ where the capacity of (v_i, w) is set to the coverage of v_i.

A non-trivial branching vertex v is called *balanced* if v has the same number of in-coming edges $\{(u_i, v) \in E \ |i = 1, \ldots, n\}$ and out-going edges $\{(v, w_j) \in E \ |j = 1, \ldots, n\}$. For example, vertex P is a balanced branching vertex in Fig. 2(a). Let $U = \{u_i|i = 1, \ldots, n\}$ and $W = \{w_j|j = 1, \ldots, n\}$. In a balance split, the balanced branching vertex v will be replaced by vertices $\{v_1, \ldots, v_n\}$ without passing on its PE links, and each in-coming edge (u_i, v) and out-going edge (v, w_i) will be replaced by (u_i, v_i) and (v_i, w_i), respectively. The above balanced split of v corresponds to a bijection between U and W, and most of these one-to-one mappings can be perfectly inferred by contigs and PE links, *i.e.*, they are both contained in at least one contig or connected by a PE link. For example, a balanced split of P from Fig. 2(a) to (b) corresponds to two one-to-one mappings, O↔R and N↔Q, inferred by the contig and PE link information, respectively. In case U and W form an partial bijection using contigs and PE links information, VStrains further uses coverage information and aims to find more one-to-one mappings. For the $u_i \in U$ and $w_j \in W$ not in the current partial bijection, an one-to-one mapping is established between u and w if and only if u_i and w_j form a *coverage compatible pair*, *i.e.*, $u_i = \arg\min_u |cap(v, w_j) - cap(u, v)|$ and $w_j = \arg\min_w |cap(v, w) - cap(u_i, v)|$. For example in Fig. 2(c) to (d), vertices H and M form a coverage compatible pair, together with two other one-to-one mappings I↔L_1NP_1Q (from contig path) and J↔L_2OP_2R (from PE link), lead to a balanced split on the balanced branching vertex K in Fig. 2(d).

Note that not all non-trivial branching vertices are balanced (*e.g.*, vertex K is an unbalanced branching vertex in Fig. 2(a)). For such unbalanced vertex v, VStrains performs a trivial split on its adjacent trivial branching vertices and aim to convert v into a balanced vertex. For example, after performing a trivial split on vertex L in Fig. 2(b) to (c), vertex K now becomes a balanced branching vertex in Fig. 2(c) and becomes a candidate for a balanced split. VStrains performs a balanced split on v if the above bijection can be established by contigs, PE links and coverage information.

2.4.2   Non-branching path contraction The above branch split operation in the assembly graph creates non-branching paths, i.e., path $p = (v_1, v_2, \ldots, v_n), v_i \in V \ \forall i = 1, \ldots, n$, where the in-degree of $v_2, \ldots v_n$ and the out-degree of $v_1, \ldots v_{n-1}$ are all 1. Following the similar idea of graph simplification in SPAdes [5], VStrains contracts all the non-branching paths. For example, the above non-branching path p is contracted into one vertex v_p, and each in-coming edge (u, v_1) of v_1 is replaced by (u, v_p) and each out-going edge (v_n, w) is replaced by (v_p, w) with the same capacity, the coverage of v_p is set to be the average coverage of $v_1, \ldots, v_n$. Moreover, v_p inherits all the PE links of vertices in non-branching path p. For example in Fig. 2(d), three non-branching paths in three different colors on the right are contracted, respectively.

2.5   Contig-based Path Extraction

While VStrains effectively disentangles the assembly graph through branching vertex split and non-branching path contraction in the above step, there still exist branching vertices (*e.g.*, D and G in Fig. 2(d)) which may introduce ambiguity in distinguishing full paths that correspond to individual viral strains.

Recall SPAdes outputs contigs as paths of vertices on the assembly graph, which are usually sub-paths of viral strain induced paths on the assembly graph. The remaining problem is to extend these contigs (sub-paths) into corresponding viral strains (full paths) on the assembly graph. Note that a full path on the assembly graph starts from a *source* vertex and ends at a

Fig. 3. The contig-based path extraction of VStrains. (a) Assembly graph after graph disentanglement with three contigs: I→K_1→L_1→N, O→P_2→R, K_3→M. (b) The longest contig I→K_1→L_1→N is firstly extended to I→K_1... →P_1→Q (terminated at I due to the lack of coverage compatible pair with respect to 200x). Afterwards, the second longest contig O→P_2→R is extended to J→K_2→ . . . →P_2→R (terminated at J due to the lack of coverage compatible pair with respect to 300x). At last, the shortest contig K_3→M is extended to C→D_1→ . . . →K_3→M (thanks to the coverage compatible pairs with respect to 400x) (c) Contigs J→ . . . →R and I→ . . . →Q are extended to full path (thanks to the path extraction and coverage/topology update in (b)).

sink vertex or is a cyclic path (*i.e.*, its first and the last vertex coincide). Ideally, the strain-specific (not shared by multiple viral strains) contigs should be extended and extracted first. The longer a contig is, the more likely that this contig is strain-specific.

Therefore, VStrains iteratively selects the longest contig and extends its corresponding sub-path on both ends. Without loss of generality, consider the right extension of the current contig $C = (v_1, v_2, \ldots, v_n)$. If v_n has only one out-going edge (v_n, v_{n+1}), the current contig will be extended into $(v_1, \ldots, v_n, v_{n+1})$. If v_n has multiple out-going edges $\{(v_n, v_{n+1}^1), \ldots, (v_n, v_{n+1}^m)\}$, we follow the same strategy in Section 2.4.1 to look for one-to-one mapping between v_{n-1} and $\{v_{n+1}^1, \ldots, v_{n+1}^m\}$ using contigs, paired-end reads and coverage information. If v_{n-1} forms the one-to-one mapping with v_{n+1}', the current contig will be extended into $(v_1, \ldots, v_n, v_{n+1}')$, otherwise, the extension to the right terminates. If v_n is a sink vertex (without any out-going edges), the extension to the right terminates. If v_n is a visited vertex during extension on the other end, the extension to the right terminates and a cyclic path is obtained by combining both left and right extensions.

If the currently selected contig can be extended into a full path, VStrains will include this extended path as one of the output strains. Otherwise, VStrains will contract this extended path as a single vertex, and wait for confident extension in the future step. VStrains will also update the coverage information of the assembly graph. More specifically, VStrains estimates

the path coverage as the median coverage of all the non-branching vertices along the path, and reduce the path coverage from all the traversed vertices. For example, VStrains extends the contig $H \rightarrow K_3 \rightarrow M$ into the full path $C \rightarrow D_1 \rightarrow \ldots \rightarrow K_3 \rightarrow M$ (using coverage compatible pairs $F \leftrightarrow H$ and $C \leftrightarrow F$ described in Section 2.4.1) in Fig.3(b).

By iteratively extending and extracting the contig from the assembly graph, VStrains obtains a set of distinct paths as the final viral strains. This iterative strategy contracts/extracts the most confident sub-paths/full-paths first, and updates topology and coverage information of the assembly graph on the fly, which in turn reveals more strain-specific paths in the updated graph and facilitates the subsequent path extractions. For example, after extracting the full path $C \rightarrow D_1 \rightarrow \ldots \rightarrow K_3 \rightarrow M$ in Fig.3(b), the (sub)-paths $I \rightarrow K_1 \rightarrow \ldots \rightarrow P_1 \rightarrow Q$ and $J \rightarrow K_2 \rightarrow \ldots \rightarrow P_2 \rightarrow R$ are able to further extend to the left (using coverage compatible pairs $A \leftrightarrow I$ and $B \leftrightarrow J$) into two full paths $A \rightarrow D_3 \rightarrow \ldots \rightarrow P_1 \rightarrow Q$ and $B \rightarrow D_2 \rightarrow \ldots \rightarrow P_2 \rightarrow R$.

Note that the iterative path extraction strategy in VStrains overcomes the limitation of the greedy path finding strategies [4,8,12]. For example, VG-Flow [4] employs three greedy strategies (maximum capacity, minimum capacity, shortest paths) to derive the set of candidate paths, from which the final output strains will be selected. However, such greedy strategies are directly applied on the original flow-variation graph, making it likely to find erroneous paths (e.g., the maximum-capacity path $C \rightarrow D \rightarrow E \rightarrow G \rightarrow H \rightarrow K_3 \rightarrow M$ and the minimum-capacity path $A \rightarrow D \rightarrow F \rightarrow G \rightarrow I \rightarrow \ldots \rightarrow P_1 \rightarrow Q$ in Fig.3(a) are both erroneous paths).

3   Experimental Setup

3.1   Experimental Datasets

3.1.1   Simulated Datasets To evaluate the performance and scalability of VStrains, we used three simulated viral quasispecies datasets from [3] consisting of 6 Poliovirus, 10 HCV, and 15 ZIKV mixed strains, respectively. These datasets were commonly used to benchmark strain-aware viral assemblers and simulated from known reference genomes using SimSeq [6] with the default error profile, and each dataset consists of Illumina MiSeq reads (2x250 bp) with 20,000x total sequencing coverage.

3.1.2   Real Datasets Two real datasets with different coverages are obtained from the NCBI database. The first 5-HIV-labmix (20,000x) dataset [13] is a lab mix of 5 known real HIV strains with accession number SRR961514. The second 2-SARS-COV-2 dataset [36] is a mixture of 2 real SARS-COV-2 (4,000x) strains (BA.1 and B.1.1), with accession number SRR18009684 and SRR18009686, respectively. Two independently assembled strains, BA.1 from SRR18009684 and B.1.1 from SRR18009686, are used as the ground-truth for evaluation.

Refer to Section S1 in the Supplementary Materials for more details on datasets.

3.2   Baselines and Evaluation Metrics

VStrains was benchmarked against the state-of-the-art methods on assembling viral strains including SPAdes [5], SAVAGE [3], VG-Flow [4], PEHaplo [8], viaDBG [11], Haploflow [12], and PredictHaplo [29]. Three recent reference-based machine-learning approaches GAEseq [16], CAECseq [15] and NeurHap [35] are not included for comparison because all of them have only been applied to a gene segment of viral strains in their experiments and failed to handle the above datasets on whole viral strains (*i.e.*, memory usage exceeding 300G). All above tools

under evaluation use default settings unless specified otherwise. Refer to Section S6 in the Supplementary Materials for detailed description of baselines.

Similar to previous studies, we employ MetaQUAST [24] to evaluate all assembly results of viral strains. As viral quasispecies contains highly similar strains, we run MetaQUAST with the "--unique-mapping" option to minimize ambiguous false positive mapping.

4   Experimental Results

In this section, we show the performance of VStrains and other baselines on both simulated and real datasets. In consistent with previous observations [4,11], we found that SPAdes [5] in general outperforms metaSPAdes [27] and other specialized versions [1,7,23] (refer to Section S2 in the Supplementary Materials for detailed comparison among SPAdes-series assemblers) and thus is employed to build assembly graphs for VStrains. Section S3 in the Supplementary Materials also provides the comparison between VStrains and PredictHaplo [29] (a reference-based approach).

4.1   Performance on Simulated Datasets

Table 1 summarizes the performance of different de novo approaches on reconstructing viral strains in three simulated datasets. Note that specialized strain-aware assemblers such as PEHaplo [8], HaploFlow [12], viaDBG [11] and SAVAGE [3] typically outperform the general-purpose assembler SPAdes [5], especially in genome fraction and NGA50. One possible reason is that SPAdes [5] is not designed to distinguish highly similar viral strains. When two or more strains share long and identical sequences, SPAdes may result in fragmented assemblies (*i.e.*, low NGA50) and keep only one copy of such shared sequences (*i.e.*, low genome fraction). VG-Flow [4] uses assembled contigs from SAVAGE [3] (VG-Flow+SAVAGE) and SPAdes [5] (VG-Flow+SPAdes) to build flow-variation graphs and effectively improves their genome fraction and NGA50. While the greedy strategies in building candidate paths make VG-Flow tractable, VG-Flow may be forced to use more (incorrect) paths to cover all strains (*i.e.* high duplication ratio and error rate) when not all the ground-truth paths have been included in its selected candidate set. VStrains uses contigs, paired-end reads, and coverage information to extracts strain-specific paths from assembly graphs built by SPAdes [5] (VStrains+SPAdes) and achieves the best overall performance on a comprehensive set of metrics (including genome fraction, duplication ratio, NGA50, error rate and number of contigs). It is worth noting that VStrains is able to adapt the general-purpose assembler SPAdes [5] to assemble highly similar strains and even outperform existing specialized strain-aware assemblers.

4.2   Performance on Real Datasets

Table 2 summarizes the performance of VStrains and other de novo approaches on two real datasets, 5-HIV-labmix [13] and 2-SARS-COV-2 [36]. While viaDBG [11] results in high genome coverage and low error rate, it comes at a cost of (extremely) high duplication ratio and excessive number of contigs, making it infeasible to distinguish correct and incorrect contigs from its output.

Similar to the performance on the simulated datasets, SPAdes [5] results in very fragmented assemblies with low genome fraction (49.11%) and NGA50 (614) for 5-HIV-labmix (20,000x) dataset. SAVAGE as a specialized strain-aware assembler produces almost double the genome fraction (87.34%) and NGA50 (1397) compare to SPAdes. While VG-Flow+SAVAGE increases the NGA50 to 7245, it decreases the genome fraction to 77.7%, doubles the duplication ratio

SPAdes	66.71%	**1.00**	6447(11)	0.037%	27
VG-Flow+SPAdes	-	-	-	-	-
VStrains+SPAdes	**98.87%**	**1.00**	**10130(15)**	0.068%	**16**

Table 1. The performance on three simulated datasets, 6-Poliovirus, 10-HCV, and 15-ZIKV. '-' indicates that the corresponding approach failed to complete on the given dataset or exceeded the memory limit (500 GB) or runtime limit (800 hours). Refer to Section S4 Table S4.1, S4.2 and S4.3 in the Supplementary Materials for the detailed strain-level results reported by MetaQUAST [24].

(from 1.56 to 3.12), and significantly increase the error rate from 0.115% to 1.038%, which indicates its limitation on handling real datasets. On the other hand, VStrains+SPAdes significantly improves the overall performance on SPAdes, *e.g.*, increase genome fraction from 49.11% to 86.42%, NGA50 from 614 to 7583, and decreases the error rate from 0.515% to 0.237%. Note that VG-Flow+SPAdes fails to achieve such an improvement as VG-Flow is mainly designed to couple with SAVAGE [3]. However, SAVAGE [3] typically assumes at least 10,000x total coverage of viral sequencing data (quote from its GitHub site), which limits the application of VG-Flow on datasets without ultra-high coverage (e.g., on the 2-SARS-COV-2 dataset with only 4,000x coverage).

4.3   Runtime, Memory and Implementation Details

We observe that Haploflow [12] is much more efficient than all other approaches in runtime and memory, but may not be a preferred tool due to its extremely high error rate and low genome fraction. The general-purpose assembler SPAdes [5] is more efficient than specialized strain-aware assemblers such as PEHaplo [8], HaploFlow [12], viaDBG [11] and SAVAGE [3] in terms

5 HIV-labmix Strains	Genome Fraction (GF)	Duplication Ratio	NGA50(# ref strains >50% GF)	Error Rate (mis+indel+N's)	# Contigs (> 500 bp)
PEHaplo	84.19%	1.55	1915(5)	0.300%	41
Haploflow	56.80%	1.26	4832(4)	**2.675%**	18
viaDBG	**92.80%**	**13.54**	5942(5)	**0.071%**	**228**
SAVAGE	87.34%	1.56	1397(5)	0.115%	72

Table 2. The performance on two real datasets, 5-HIV-labmix (20,000x) and 2-SARS-COV-2 (4,000x). '-' indicates that the corresponding approach failed to complete on the given dataset or exceeded the memory limit (500 GB) or runtime limit (800 hours). Refer to Section S4 Table S4.4 and S4.5 in the Supplementary Materials for the detailed strain-level results reported by MetaQUAST [24].

of runtime and memory. VG-Flow is dominated by the contig variation graph construction step [4] and lead to higher peak memory and runtime compare to VStrains. Refer to Section S5 and Section S6 in the Supplementary Materials for the detailed runtime, memory information and command lines used in the above experiments, respectively.

5 Conclusion and Discussion

In VStrains, we first introduce a strategy to canonicalize the strandedness of assembly graphs from SPAdes [5], which reduces the strain reconstruction problem into the path extraction problem. Secondly, we use all available k-mer pairs in paired-end reads to infer PE links in the assembly graph produced by SPAdes. Thirdly, we propose an effective way to incorporate PE links together with contigs and coverage information to disentangle the assembly graphs. Finally, we demonstrate how to extract confident strain-specific paths via iterative contig-based path extraction. Experimental results on both simulated and real datasets show that VStrains achieve the best overall performance among the state-of-the-art approaches.

Currently, VStrains relies on both assembly graphs and contigs from SPAdes [5] and thus cannot couple with assemblers which does not explicitly output assembly graphs such as SAVAGE [3]. The current implementation of VStrains requires additional alignments of paired-end reads to vertices in assembly graphs to infer PE links. It is worth exploring how to make VStrains more flexible and efficient.

With the advance of third-generation sequencing (TGS), multiple approaches (including Strainline [21], Strainberry[34], VirStrain [20], viralFlye [2], *etc.*) have been proposed for strain-aware assembly using TGS data. VStrains has the potential to be extended to handle TGS data by taking advantages of assembly graphs built from Canu [18], Flye [17], wtdbg [31] and others.
