26

27 Abstract

28 Genome search and/or classification is a key step in microbiome studies and has become 29 more challenging due to the increasing number of available (reference) genomes in 30 recent years and the fact that traditional methods do not scale well with larger databases. 31 By combining a kmer hashing-based genomic distance metric (Probminhash) with a 32 graph based nearest neighbor search (NNS) algorithm (called Hierarchical Navigable 33 Small World Graphs), we developed a new program, GSearch, that is at least ten times 34 faster than alternative tools for the same purposes while maintaining high accuracy. 35 GSearch can identify/classify eight thousand query genomes against all available 36 microbial and viral genomic species within several minutes on a personal laptop, using 37 only ~6GB of memory. Further, GSearch can scale well with millions of database 38 genomes based on a database splitting strategy. Therefore, GSearch solves a major 39 bottleneck in current and future microbiome studies that require genome search and/or 40 classification.

49 Introduction

50 Classifying microbial species based on either universal marker genes (e.g., 16S or 51 18S rRNA genes) or entire genomes represents a re-occurring task in environmental and 52 clinical microbiome studies. However, this task is challenging because i) whether or not 53 microbes (bacteria, fungi) and viruses form discrete population clusters (or species), 54 remains an open question ¹, and ii) the microbial species in nature are still severely undersampled by the available genomes. For instance, there are 10¹² bacterial and fungal 55 species in nature according to a recent estimation² and even more viral species 56 (e.g. $>10^{14}$ species). Yet, only $\sim 17,000$ bacterial species have been described and even 57 fewer (around 15,000) are represented by complete or draft genome ³. Due to the recent 58 59 improvements in DNA sequencing and single-cell technologies, metagenomic surveys 60 can now recover hundreds, if not thousands, of these yet-to-be-described species from 61 environmental or clinical samples^{4,5}, filling in the gap in the described diversity mentioned 62 above. This has created a new challenge, however; that is, identifying these new 63 genomes against the exponentially increasing number of available (described) genomes 64 has become computationally intractable. Nonetheless, the recent high-throughput 65 sequencing of isolate genomes as well as metagenomic studies of natural populations 66 have shown that species may exist and be commonly circumscribed based on a 95% 67 genome-aggregate average nucleotide identity (ANI) threshold, at least for prokaryotes 68 and viruses ^{6, 7}. This threshold represents convenient means in searching and identifying

new genomes against the already descried species and determining whether or not they
 represent novel species ⁸.

71

72 The number of curated draft or complete prokaryotic genomes has reached 73 317,542 in the newest release of the GTDB database, and 2,332,702 in the latest IMG/VR 74 database for viruses, representing 65,703 prokaryotic and 935,122 viral distinct species at the 95% ANI level ^{9, 10}. Searching of guery genomes against these large databases to 75 76 find closely-related database/reference genomes for taxonomy classification based on 77 the traditional brute-force methods, meaning, performing all vs. all searches, has become impractical, even for fast searching algorithms and/or small-to-medium computer clusters. 78 79 For this task, faster search strategies are necessary. In addition to the searching strategy, 80 the actual algorithm used to determine overall genetic relatedness between the guery and 81 the databased genomes is critical. While the traditional blast-based ANI among closely 82 related genomes at the species level, and the genome-aggregate average amino acid 83 identity (AAI) for genomes related at the genus level or above, have been proven to be highly accurate for genetic relatedness estimation across microbial and viral genomes ¹¹⁻ 84 85 ¹³, they are too slow to use when dealing with more than a few dozen genomes. Faster 86 implementations based on k-mer counting have been recently described to alleviate this bottleneck such as FastANI and MASH^{14, 15}, but these methods still do not scale with an 87 88 increasing number of database (or query) genomes, especially based on an all vs. all search strategy. Further, defining genetic distance (or relatedness) based on kmer 89 90 profiles can be problematic for incomplete genomes, which are commonly recovered from 91 metagenomic surveys, and/or genomes with lots of repeats. Kmer-weighted approaches

92 are advantageous in the latter cases because repeated genomic fragments can be 93 considered when hashing but they have not been widely adopted yet ^{16, 17}. Recently, a 94 phylogeny-based approach using a handful of universal genes (n = -100) was developed 95 to accelerate genome classification ¹⁸. However, phylogenetic replacement based on 96 concatenated universal gene tree can be memory demanding (300+ GB) and slow. 97 especially for a large number of or a few deep-branching (novel) query genomes, and this 98 approach cannot be applied to viral genomes, which lack universal genes. Further, 99 universal genes due to their essentiality, are typically under stronger (purifying) selection 100 and thus, evolve slower than the genome average. This property makes universal genes 101 appropriate for comparisons among distantly related genomes, e.g., to classify genomes 102 belong to new class or new phylum, but not the species and genus levels ^{18, 19}.

103 One of the most generally used approaches for finding closely related information 104 to a query, while circumventing an all vs. all search, is the K-Nearest Neighbor Search 105 (K-NNS). The K-NNS approach has been used for 16S rRNA gene-based classification 106 followed by a vote strategy ^{20, 21} and, more recently, for whole genome and metagenome 107 comparisons based on shared kmers ¹⁴. Approximate nearest neighbor search (ANN) algorithms, such as locality-sensitive hashing (LSH) ^{22, 23}, k-dimension tree ²⁴, random 108 projection trees ²⁵, k-graph ²⁶ and proximity graph ^{27, 28} have been recently used to 109 110 accelerate ANN search process. Proximity graph, as implemented for example in the 111 hierarchical navigable small world graph (HNSW)²⁹, has been shown to be one of the 112 fastest ANN search algorithms ³⁰. HNSW incrementally builds a multi-layer structure 113 consisting of a hierarchical set of proximity graphs (layers) for nested subsets of the 114 stored elements. Then, through smart neighbor selection heuristics, inserting and

searching the query elements in the proximity graphs can be very fast while preserving
high accuracy, even for highly clustered data ^{27, 29}. Therefore, finding the closest genomes
in a database can be substantially accelerated by using HNSW.

118 Here, we describe GSearch (for Genome Search), a tool that combines the most 119 efficient nearest neighbor search approaches (HNSW) with a universal approach to 120 measure genetic relatedness among any microbial genome, including viral genomes, 121 Probminhash ³¹, implemented in the Rust language for higher speed. Probminhash is 122 based on shared kmers, weighted by their abundance and normalized by total kmer size, 123 which can account for genome incompleteness of prokaryotic genomes and repeats 124 commonly found in eukaryotic and sometimes in prokaryotic genomes. Essentially, 125 Probminhash computes the normalized weighted Jaccard distance between each pair of 126 genomes and subsequently, the normalized (by total kmer size) weighted Jaccard 127 distance is used as input to build HNSW to create the graph of the database genomes. 128 Accordingly, the search of the query genome(s) against the graph to find the nearest 129 neighbors for classification purposes becomes an ultra-fast step using GSearch and can 130 be universally applied to all microbial genomes. The novelty of GSearch also includes a 131 hierarchical pipeline that involves both nucleotide-level (when guery genomes have close 132 relatives at the species level) and amino-acid-level searching (when guery genomes are 133 somehow novel), which provides robust classification for query genomes regardless of 134 their degree of novelty, as well as a database-splitting strategy that allows GSearch to 135 scale up well to millions of database genome sequences.

136

137 **Results**

138 Probminhash as a robust metric for genome relatedness of prokaryotes

139 Correlations between Probminhash distance (or we called it ProbMASH after 140 transformation) and ANI (determined by FastANI) or MASH distance showed that 141 Probminhash is robust and slightly better than MASH for determining distances among 142 bacterial genomes related at ~80% ANI, or higher, i.e., closely related genomes of the 143 same or closely-related species (Spearman rho=0.9643 and 0.9640 respectively, 144 P<0.001, Figure S1 (a) and (b), note that for finding best hits compare to ANI, Spearman 145 rank correlation is more relevant than Pearson correlation). For moderately related 146 genomes, for which nucleotide-level ANI or distances are known to lose accuracy, Probminhash was still robust compared to MASH for bacterial genomes (amino acid 147 148 distance or AAI), especially among genomes showing between ~52% and 95% AAI 149 (Spearman rho=0.90, P<0.01, Supplementary Figure S2 (a) and (b)). Below ~50% AAI, 150 both Probminhash and MASH distance lose accuracy compared to AAI. However, AAI of 151 just universal genes provides a robust measurement of genetic relatedness at this level 152 of distantly related genomes ¹⁹, and we show here that Probminhash distance for the 153 same set of universal genes is also robust (Spearman rho=0.9390, P<0.001, 154 Supplementary Figure S3). Thus, for distantly related (i.e., deep-branching) query 155 genomes, e.g., their closest genome in the database is related at the order level or higher, 156 restricting the search to the universal genes can provide robust classifications.

157

158 Graph building and search against reference prokaryotic genomes is faster than 159 alternative methods

160 To build the database graph for the entire GTDB v207 database (65,703 unique, non-161 redundant prokaryotic species) at the nucleotide level, the tohnsw module of GSearch 162 took 2.3 h on a 24-thread computing node and scaled well with increasing number of 163 threads (Figure 2 (a)). Maximum memory required for the building step was 28.3 GB. The 164 total size of written database files on disk was ~3.0 GB. There are 3 layers for the dumped 165 graph, 65180, 519 and 4 genomes for layer 0,1 and 2 respectively. The searching of query 166 genomes against this database graph, requesting best 50 neighbors for 1000 query 167 genomes, which represented different previously known as well as novel species of eight 168 bacterial phyla (see Methods for details on query genome selection), took 2.3 min 169 (database loading 6 seconds) on a 24 thread machine and also scaled well with 170 increasing number of threads (Figure 3 (a)). The memory requirement for the request 171 (search) step was only 3.0 GB for storing the entire database file in memory. To evaluate 172 the accuracy of these results, we compared the best neighbors found by GSearch with 173 brute-force FastANI and GTDB-tk. All best neighbors found by brute-force FastANI and 174 GTDB-tk for query genomes with close relatives in the database (e.g., showing >80%) 175 ANI) were found by GSearch (Supplemental File 1). Top 5 neighbors were 99.4% 176 overlapping and top 10 were 96.3% overlapping between GSearch and the other two 177 methods for the testing query genomes. We also compared the speed with MASH for the 178 same kmer and sketch size and MASH dist step took 7.51 min for comparing 1000 179 genomes with database using 24 threads. The speedup compared to MASH was even 180 larger for ~8,000 query genomes. Specifically, it took 12.5 min for GSearch to find the top 181 50 best hits (Supplementary Figure S4 (a)) while MASH took 80.8 minutes on the same 182 24 thread machine. However, for a given number database genomes, speedup is

183 saturated to log(N) as the number of query genome increases, where N is the number of 184 database genomes. GSearch will be orders of magnitude faster than MASH for larger 185 species database with millions of genomic species (see also phage section). GSearch 186 query time for a given number of genomes is related to the number of database genomes 187 in a O(log(N)) manner while brute-force methods are O(N), and our empirical analysis is 188 consistent with the theoretical log(N) prediction (Supplementary Figure S4 (b)).

189

190 For building the amino-acid level graph for moderately related guery genomes, all GTDB 191 v207 genomes are used for gene calling by FragGeneScanRs and subsequently, the 192 predicted amino acid sequences for each genome are used for the tohnsw module. The 193 graph building step took 1.4 h (Figure 2 (b)) with maximum memory required for the 194 building step to be 37.7 GB. The total size of written database files on disk by GSearch 195 was 5.9 GB. There were 65158, 543 and 2 genomes for layer 0,1 and 2 respectively. 196 Requesting 50 neighbors for 1000 genomes at this amino-acid level took 1.52 minutes 197 with memory requirement ~6.0 GB (database loading 9 seconds; Figure 3(b)). Top 5 198 neighbors were 98.9% recall with those of the brute-force MASH or blast-based AAI 199 approaches, with 97.1% overlap for the 10 top neighbors. In comparison, MASH dist took 200 5.96 min using 24 threads; for 8000 guery genomes, MASH dist took 47.2 min while 201 GSearch took 5.6 min.

202

Finally, for most distantly related query genomes, the graph building for the universal gene set follows the same logic with the amino-acid level graph mentioned above except for using a smaller kmer size (k=5) due to the smaller kmer space of 120 universal genes

vs. the whole-genome level (e.g., a few thousand genes). It took 7.76 min to build the
database (Figure 2(c)) and 32 seconds to request 50 neighbors for 1000 queries on a 24
threads node (Figure 3(c)) with similar high recall to the amino-acid level search (with top
5 and top 10 recall, 98.2% and 97.1%, respectively).

210

We also evaluated the effect of genome completeness on search and classification accuracy given that bacterial genomes recovered from environmental metagenomes are frequently incomplete. GSearch was robust to genome incompleteness down to 50% completeness level, e.g., 80% of top 10 best matches are found, while accuracy decreased considerably below this level (Supplementary table S6).

216

217 Graph database building and searching for phage and fungal genomes

218 Graph building and requesting for phage genomes is not effective at the nucleotide level 219 because many phage genera are too diverse and do not have close relatives in the public 220 genomic database; that is, the database is too sparse. Accordingly, kmer-based methods 221 (e.g., MASH and probminhash) will often lead to imperfect graph structure for viral 222 genomes. Therefore, we build only an amino-acid level graph for viral genomes, using all 223 genes in the genome due to the lack of universal genes for viral genomes. Database 224 building took 23.895 h on a 24-thread node (Supplementary Figure S6 (a)). Request 1000 225 neighbors scales well with increasing number of threads and took about 4.4 min 226 (database load takes additional 1.9 min) using 24 threads (Supplementary Figure S6 (b)). Top 10 neighbors for 1000 query phage genomes were still highly overlapping (98.32%) 227 228 recall; Supplemental Table S1) with the brute-force MASH-based approach. For such

229 large database, GSearch is about 20X faster than the brute-force MASH (Supplementary 230 Tables S1). We also compare GSearch with a new database build method called 231 PhageCloud, which relies on manually curated genome labels (e.g., environmental 232 source) for graph database building in Neo4j database software and Dashing software 233 for distance/relatedness computation. Since PhageCloud provides only a website and 234 allows only one genome query at a time, we searched only one phage genome at a time 235 with GSearch and MASH against the same database (Gut Phage Database ³²). It took 37 236 seconds for finding the two best matches with PhageCloud while GSearch took 15 237 seconds (database loading 14 seconds, search 1 second) for the same search. MASH 238 on the other hand took 4 minutes to find the same 2 best matches. It should be noted, 239 however, that, because the database is already available (loaded) on PhageCloud's 240 website, 37 seconds is only for search and website responses (average value for 5 runs 241 on 5 different days) whereas GSearch took only 1.5 second for the same step.

242

243 Graph building for fungal genomes is slower compared to prokaryotic genomes, despite 244 the smaller number of available fungal genomes (n=9700) because the average fungal 245 genome size is much larger and kmer and sketch size are accordingly much larger (k=21, 246 s=48000). It took 2.3 h on a 24 thread node to build the nucleotide-level graph for these 247 fungal genomes. Searching step was also slower due to the larger kmer space. 248 Accordingly, it took 3.13 min for identifying 50 neighbors for 50 query fungal genomes 249 while MASH tool 4.4 min. Nonetheless, recall was still very high (~99.4%) against MASH 250 and MUMMER-based ANI for the same datasets. For the amino-acid level graph, the time 251 for graph building was only 0.61 h, shorter than the corresponding prokaryotic graph due

to the lower coding density of fungal genomes relative to the prokaryotic genomes.
Identifying 50 neighbors for 50 query fungal genomes at the amino-acid level took 1.24
min (MASH took 2.59 min) with similar high top 5 recall (~99.7%) against brute-force
MASH (-a) and blastp-based AAI. Note that the difference in run time will be much larger
between MASH and GSearch as the number of fungal database genome increases,
which is similar to that of bacterial genomes

258

Combining the three graphs/levels together and comparison with GTDB-tk for prokaryotic genome classification

A three-step pipeline was developed to allow the identification and classification of a 261 262 query genome, depending on its level of novelty compared to the database genomes 263 (Figure 4). Specifically, when the query genome does not find a match in the database 264 better than ANI > 78%, corresponding to probminhash distance 0.9850, the nucleotide-265 level graph is abandoned, and the amino-acid level is used instead. If no match against 266 the latter graph is found above 52% AAI, corresponding to 0.9375 probminhash distance, 267 the amino-acid level is abandoned, and the universal gene graph is used instead (uAAI 268 based on universal gene below 80% indicates new order or higher taxonomic rank)(Figure 269 4). The overall running time for classifying 1000 prokaryotic genomes of varied levels of 270 taxonomic novelty on different computing platforms is showed in Table 1. On a 24 thread 271 Linux node, it took a total of 5.85 minutes while it took 19.49 minutes on an intel Core i7 272 laptop (2017 release) CPU personal laptop (6.02 minutes on the most recent ARM64 CPU laptop). Classifying 1000 genomes using GTDB-tk took 244.7 min on the same Linux 273

node with 24 threads (Figure 3 (d), memory requirement is ~328G) while MASH takes
53.7 min for 1000 genomes using 24 threads for the 3 steps.

276

277 In terms of the accuracy of the nearest neighbors found, query genomes (699 out of the 278 total 1000) that had a best match higher than 78% ANI against the GTDB database 279 genomes (i.e., a match at the same or closely related species), GSearch classified them 280 exactly the same with GTDB-tk and FastANI (Supplementary File 1, only 100/699 are 281 shown for simplicity). For the remaining 301 genomes that did not have same or closely 282 related species-level matches, for 266 of them (or 87.1%), GSearch also provided the 283 same classification with GTDB-tk but several inconsistencies were observed for 39/301 284 genomes (Supplementary Figure S5). Specifically, we noticed that for GTDB-tk, which 285 relies on RED values and tree topology, several genomes (n=14) were still classified at 286 the genus level even though AAI value against the best database genomes found was 287 below 60%, and some genomes (n=16) were still classified at the family level but not the 288 genus level even though their best AAI value was above 65%. Several genomes (n=9) 289 were classified at the order level but not family level even though their best AAI value was 290 above 52%. Therefore, high consistency was overall observed between GSearch and 291 GTDB-tk assignments, and the few differences noted were probably associated with 292 contaminated (low quality) MAGs or taxonomic inconsistencies, which was challenging to 293 assess further, and/or the peculiarities of each method. Since Probminhash distance 294 correlated well with AAI in the range of AAI values between 52% and 95%, the 295 classification results were always consistent with AAI-based classification, e.g., best 296 matches of 65% AAI or higher were classified at the same genus by GSearch and blast-

based AAI and best matches of 52% < AAI < 65% were typically classified at the same family ³³.

299

300 Database split for large genomic species database

301 For large databases (for example, >1 million bacterial genomes), the graph building and 302 requesting step could require a large amount of memory (due to the larger kmer space) 303 that is typically not available in a single computer node. We therefore provide a database 304 split solution for such large databases. The average database building time on each node 305 (for each piece of the database after the splitting step) scales linearly with increasing nodes/processors and requires much less memory (1/n total memory compared to when 306 307 building in one node) (Supplementary Figure S7(a)). The searching time scales sub-308 linearly with increasing number of nodes (Supplementary Figure S7(b)). The top 10 best 309 neighbor by splitting the database were exactly the same as the non-splitting strategy 310 (Supplementary file 2). Note that without multi-node support (e.g., run database build 311 sequentially), database build time is nearly the same with non-split strategy but memory 312 requirement is only 1/n, where n is the number of database pieces, despite the fact that 313 total request time will be larger (time*n in Supplementary Figure S7(b)). However, since 314 the request step is very fast, even for a decent number of pieces, overall runtime is still 315 short with the database split approach. The database split strategy is especially useful 316 when memory requirement is not satisfied on host machine for larger genomic species 317 database (e.g., millions of genomes).

- 318
- 319 **Discussion**

320 A popular way to assess genetic relatedness among genomes is ANI, which 321 corresponds well to both 16S/18S rRNA gene identity and DNA-DNA hybridization values, 322 the golden standards of fungal and prokaryotic taxonomies ¹¹. As the number of available 323 microbial genomes has grown at an unprecedented speed recently (e.g., there are 30% 324 more (new) species in GTDB v202 (2020) vs. v207 (2022), and the number of bacterial 325 species genomes alone is expected to surpass 1 million in the near future), the traditional 326 way that blast-based ANI or faster kmer-based implementations (e.g., FastANI or MASH) 327 are applied as an all vs. all search strategy (brute-force) does not scale because the 328 running time grows linearly with increasing number of query genomes and/or genomes in 329 the database. Phylogenetic approaches based on quick (approximate) maximum 330 likelihood algorithms and a handful of universal genes as implemented -for example- in 331 GTDB-Tk could be faster than brute-force approaches but are often not precise and 332 require a large amount of memory for querying step ^{18, 34} while the database building step 333 could take several weeks of run time because the underlying multiple sequence alignment 334 of the database genomes is computationally intensive. Further, approaches that reply on 335 k-medoid clustering to avoid all vs. all comparisons could be sometimes trapped into local 336 minima because of arbitrary partitioning of database genomes into clusters, a known 337 limitation of these methods ¹⁹. Our GSearch software effectively circumvents these 338 limitations by combining a new kmer hashing-based (Probminhash) algorithm for fast 339 computation of genetic relatedness among genomes with a graph based nearest neighbor 340 search algorithm. Accordingly, GSearch is at least an order of magnitude faster than 341 alternative approaches for the same purposes. Note that GSearch could also be applied 342 to whole metagenome comparisons and identification of the most similar metagenomes

in a series because ProbMinhash can estimate metagenomic distance in a similar way togenomes.

345 To the best of our knowledge, no current tool can efficiently search very large 346 genome databases. GSearch is able to handle a million microbial genomes on a small-347 to-average computer cluster since the dumped database file size is proportional to the 348 total number of genomes in database for fixed sketch size and graph parameters. 349 Specifically, with a million genome species, dumped file size (amino acid) will be 350 5.9G*20=118 GB, a modest computational requirement for current computer clusters. 351 Further, due to the nature of graph based NNS algorithm, there is no need to build the 352 entire database at once, but the database can split it into smaller pieces and thus, a 353 separate graph database be built for each piece as exemplified above and depending on 354 the computational resources available. For a modern laptop with 16 GB memory, a 355 database on one million species can be split into 10 pieces, so dumped file for each piece 356 will be only 11.8 GB, which can be loaded into memory, and then collect the results from 357 each piece within an approximate total running time of 30 minutes (assume each part will 358 be 3 minutes) (Supplementary table S7). With this logic, a computing node with 24 threads 359 and 256 GB of memory available can easily deal with 20 million bacterial genomes. This 360 represents a major improvement compared to existing tools for the same purposes.

361 It is also important to note that we could seemingly replace Probminhash with 362 another relatedness algorithm should such an algorithm become available and has 363 advantages in terms of speed and/or precision. Related to this, ANI as currently 364 implemented -for instance- in FastANI is not appropriate for this function because it is not 365 metric (that is, for the FastANI distances calculated among three genomes A, B, and C,

366 (A,B) + (B, C) is not necessary larger than (A,C), especially for genomes related at the 367 phylum level). To solve this "metric" problem, a norm adjusted proximity graph (NAPG) 368 was proposed based on inner product and it shows improvements in terms of both speed 369 and recall ³⁵. This could be another direction for further improving the speed and recall of 370 GSearch and/or the use of other metrics in place of Prominhash distances. In the 371 meanwhile, Probminhash was used in GSearch because it is metric, which ensures 372 neighbor diversity when building the graph, but also equally applicable to any microbial 373 genome, including viral genomes, in addition to its advantages for kmer weighting and 374 normalization mentioned above.

375 Another distinguishing aspect of GSearch (tohnsw module) is the speed and 376 flexibility in building reference databases. Indeed, users could build reference databases 377 (graphs) for any number and type (e.g., prokaryotic vs. viral) of genomes, up to several 378 millions of genomes. The high efficiency in building graphs allows users to also test and 379 optimize the key parameters of the graph, the M and ef_construct parameters. For any 380 given database size, M and ef_construct determine the quality of the graph and graph 381 build speed. Small M and ef construct may lead to frequent traps in local minima and 382 thus, low recall while large M and ef_construct may lead to slow speed without 383 proportional improvement in recall (Supplemental Table S2). Therefore, there is a tradeoff 384 between accuracy and speed that should be evaluated first. However, for most users this 385 task would not be necessary because they will work with pre-built databases such as 386 those provided here. Further, the search step against these pre-build databases with 387 guery genomes of known taxonomy for evaluating recall and tradeoffs can be performed, 388 within minutes, on any modern laptop with 5-6 GB of memory (Table 1).

389 Kmer-based methods for genetic relatedness estimation such as Probminhash 390 have lower accuracy between moderately-to-distantly related genomes compare to 391 alignment-based tools (see supplement Note 4 for further discussion). Our empirical 392 evaluation showed that this relatedness level, for nucleotide searches, is around 78% ANI 393 and 52% AAI for the amino-acid searches (e.g., probminhash distances do not correlate 394 well with blast-based ANI and AAI at these levels). To circumvent this limitation, we 395 designed a 3-step framework as part of GSearch to classify bacterial genomes that show 396 different levels of novelty compared to the database genomes, with high accuracy. This 397 framework included a search at the universal gene level for deep-branching genomes 398 that are novel at the phylum level (e.g., showing <52% AAI), for which searching at the 399 entire proteome level is less accurate. Recently, methods that employ kmers that allow 400 mismatches, that is, spaced kmers ³⁶, have shown promise in accurately estimating 401 genomic relatedness even among distantly related genomes with gains in speed and has 402 already been applied in classification. To apply spaced kmer to entire genomes, the 403 recently developed "tensor sketch" approaches could be explored in the future to simplify 404 the pipeline for bacterial and viral genomes ³⁷. In the meanwhile, the probminhash 405 approach, essentially a Jaccard distance estimation via MinHash-based analysis of kmers, is 406 highly efficiently, and, importantly, can effectively deal with incomplete genomes or 407 genomes of (drastically) different length, an known limitation of MASH-based methods ³⁸. 408 Comparing genomes of different length is not uncommon, e.g., bacterial genome size can 409 differ by more than two-fold, as can be the case between MAGs of different level of 410 completeness or when searching a short sequence (e.g., a bacteriophage genome) 411 against a large genome collection (e.g., whole viral genome database). Probminhash is

412 more robust with genomes of unknown completeness by weighting completed genomes 413 more due to the kmer normalization step, and our own analysis showed that it is robust 414 down to 50% completeness level (Supplemental Table S6), which is also the most 415 commonly used standard for selecting MAGs of sufficient/high quality ³⁹.

416 In general, the genome relatedness estimated, or best database matching genome 417 identified by GSearch were highly consistent with Blast-based AAI results or phylogenetic 418 placement of the genome using GTDB-tk, particularly for guery genomes with close 419 relatives in the database related at the species or genus level (Supplementary File 1, 420 Supplementary Figure S5). For more distantly related query genomes relative to database 421 genomes, classification results of GSearch showed some differences with GTDB-tk. 422 These differences were not always possible to assess further for the most correct genome 423 placement but could be due, at least partly, to the incompleteness and/or contamination 424 of query or/and database genomes, which renders the resulting concatenated alignment of a few universal genes used by GTDB-tk unreliable ⁴⁰ (and it is a few amino-acid 425 426 positions per gene that are used in the final alignment). In contrast, the AAI and 427 Probminhash approaches should be more robust to changes of a small number of genes 428 because the entire proteome is considered ¹⁵.

Graph-based NNS methods achieve good performance compared to tree based and locality-sensitive hashing (LSH) methods. Building a HNSW graph relies on proximity of database element; so, if the distances among database elements, in our case genomes, cannot be effectively estimated via hashing algorithms, the navigation in graph will be less efficient (e.g., get trapped in local minima) because the edges to choose from will not be accurate estimations of the targeted genomes they represent. This is especially

435 true for highly sparse/distantly related and diverse dataset, like the viral genome 436 database, e.g., two phage genomes could often share very little genomic information 437 (kmers) in the current dataset. This is confirmed by our own results when using 438 nucleotide-level search to build the viral graph. Hence, the amino acid level will be much 439 more robust for viral genomes and is the recommended level to use. Finally, the HNSW 440 graph, and graph-based K-NNS in general, can be further improved by adding shortcut 441 edges and maintaining a dynamic list of candidates, compared to a fixed list of candidates 442 by default ⁴¹. Graph reordering, a cache optimization that works by placing neighboring 443 nodes in consecutive (or near-consecutive) memory locations, can also be applied to 444 improve the speed of HNSW⁴². Another new direction for graph based NNS will be using 445 Graphics Processing Unit (GPU) instead of CPU because GPUs are more efficient in 446 handling matrix computations and machine learning tasks ⁴³. We will explore these 447 options in future version of GSearch.

448

To summarize, GSearch, based on Probminhash and HNSW, solves a major current challenge in classification of microbial genomes, especially given the exponential increase in the number of newly sequenced genomes due to its efficiency and scalability. GSearch will serve the entire microbial sciences for several years to come since it can be applied to fungal, bacterial and viral genomes and will accelerate the process to find new biological knowledge.

455

456 Data availability

457 All the mentioned pre-built database for bacteria, fungi and phage genomes can be found

588 Briefly, GSearch is composed of the following steps. Initially, the genetic relatedness 589 among a collection of database genomes is determined based on the probability MinHash 590 algorithm (or Probminhash), which computes the normalized weighted Jaccard distance 591 using the probminhash3a algorithm implemented in the probminhash¹. The normalized 592 weighted Jaccard distances are then used as input for building HNSW graphs (note that 593 a distance computation is required only when that genome pair is required for graph 594 building, thus GSearch avoids all vs. all distance computations). Genomes are 595 subsequently recursively added as the nearest neighbors of each node in the built graph 596 file with the same distance computation procedure. The built graph database file is stored 597 on disk. Query genomes are then searched against graph database and subsequently, 598 best neighbors are returned for classification. In this process, the best neighbor (or 599 neighbors) is also identified based on the smallest normalized weighted Jaccard distance 600 obtained.

601

602 Probminhash

MASH is a hashing-based algorithm based on MinHash², which is very efficient for 603 604 comparing genome/metagenome overall similarity ³. MASH distances represent a kmer-605 based overall overlap between sequences according to a minimal evolutionary model. 606 Essentially, MASH distance is the Jaccard similarity value of kmer shared between 607 sequence sets A and B. However, MASH, and similar MinHash-based tools, have several 608 limitations; most notably, the loss of k-mer frequency information (only presence/absence) 609 of kmer is counted) and the impact of relative set size (e.g., completeness level of a 610 genome) on the Jaccard similarity estimates ^{3, 4} Although some recent MinHash

611 implementations address these limitations (e.g., the over-sketching and track-abundance 612 methods of the MinHash-based tools finch , sourmash' or FracMinHash and HyperLogLog) ⁵⁻⁸, they do not utilize the frequencies of all observed k-mers in generating 613 614 the kmer-profile (sketch) for a given sequence set. More recently, in the HULK software, 615 consistent weighted sampling (D^2 histosketch, P-MinHash algorithm was proposed for J_p) 616 ⁹ was utilized to incorporate k-mer frequency information when estimating weighted and 617 standard Jaccard similarity, which effectively addresses these limitations mentioned 618 above ¹⁰. Notably, the hash algorithm (P-MinHash) used in D²histosketch could be further 619 optimized to achieve a time complexity below O(nm) (where m denotes the signature size 620 and n is the number of elements with nonzero weight in two sequence sets), further 621 improving the performance of applications such as HULK. Motivated by the 622 SuperMinHash for conventional Jaccard similarity estimation ¹¹ and BagMinHash algorithm for weighted Jaccard similarity estimation ¹², probminhash (probminhash 3(a) 623 624 and 4 algorithm) is orders of magnitude faster than the original algorithm P-MinHash proposed in D²histosketch¹. Probminhash estimates the Jaccard probability J_p index, and 625 626 1- Jp is indeed a metric on probability distributions and is Pareto optimal (Supplementary 627 Note 1)^{1,13}. Therefore, we reimplemented the Probminhash algorithm in Rust to estimate 628 genetic relatedness between any two genomes based on normalized (weighted) Jaccard 629 distances according to the original ProbMinHash paper¹ (Supplementary Note 1). The 630 Rust reimplementation of Probminhash can be found at: https://github.com/jean-631 pierreBoth/probminhash. Two important parameters of Probminhash are the sketch size 632 and kmer size. Similar to MinHash sketches, Probminhash sketches are also shared hashes from hashed kmer set by taking into account of kmer weights (See Figure 1 of
MASH paper). Time complexity analysis for ProbMinHash is in Supplementary Note 3.

To benchmark probminhash against MASH, we use the same sketch size (s=12000) and kmer size (k=16) for bacterial genomes at the nucleotide level and kmer size (k=7) at the amino acid level for both database building and searching. For fungal genomes a larger sketch size (48000) was used due to much larger gennome size Details of kmer choosing logic can be found in Supplementary Note 2. For graph search results, we also perform the same transformation of MASH distance from normalized weighted Jaccard distance to probMASH distance for convenience to compare with ANI based

$$probMASH = -\frac{1}{k}ln\frac{2*J_p}{J_p+1}$$

642 methods.

643

644 Hierarchical Navigable Small World Graphs (HNSW)

645 Generally, the framework of graph-based ANN search algorithm (here HNSW) can be 646 summarized as the following two steps: 1) build a proximity graph (HNSW) where each 647 node represents a database vector. Each database vector will connect with a few of its 648 neighbors while maintaining small world property in each layer of HNSW. 2) Given a query 649 vector (or sequence, kmer profile in our case), perform a greedy search on the proximity 650 graph by comparing the query vector with database vectors under the searching 651 measures (e.g., cosine similarity or L2 similarity, in our case probminhash distance). 652 Then, the most similar candidates are returned as outputs. The key point for these two-653 step methods is step 1, to construct a high-guality index graph, which provides a proper 654 balance between the searching efficiency and effectiveness. To guarantee the searching

655 efficiency, the degree (number of maximum allowed neighbors, denoted as M) of each 656 node is usually restricted to a small number (normally 20~200) while width of search for 657 neighbor during inserting (denoted as ef construct) is usually a larger number (above 658 1000) to increase the chance to find best M neighbors by increasing the diversity of 659 neighbors due to the larger number of them. Building graph and searching guery against 660 the graph follow very similar greedy search procedures except that there is an extra 661 reverse updating of neighbors list for each vector when inserting database vector 662 (building), one by one, into the existing graph (Figure 1 (a)). The first phase of the 663 insertion/building process starts from the top layer by greedily traversing the graph in 664 order to find maximum M closest neighbors to the inserted element P in the layer by doing 665 ef construct times search (Figure 1 (a)). After that, the algorithm continues the search 666 from the next layer using the closest neighbor found from the previous layer as entry 667 point, and the process repeats until to the bottom layer. Closest neighbors at each layer 668 are found by a greedy and heuristic search algorithm (Figure 1 (b) and (c)). For building, 669 after searches are finished at the bottom layer for each inserted element, a reverse update 670 step will be performed to update the neighbor list of each node in the existing graph while 671 for searching this is not needed. The overall database building time complexity is 672 $O(N^*\log(N))$, where N is the number of nodes in the graph. For searching, since there is 673 no need to reverse update best neighbor list for each node in the graph, time complexity 674 is (only) O(log(N)) (See Supplementary Note 3). Theoretical guarantee of graph-based 675 algorithm can be found in Supplementary Note 5.

676

677 Program implementation details in Rust

678 We reimplemented the original hnswlib library written in C++ using the Rust programming 679 language for its memory safety and thread use efficiency ¹¹. To benchmark our 680 reimplementation of hnswlib, we followed standard ANN benchmark procedures using two popular testing datasets (MINST and SIFT1M) based on their Euclidean distance¹⁴. 681 682 Our results showed that, for the MINST fashion dataset (784 dimensions, 60,000 vectors), 683 recall for top 100 neighbors of 10,000 guery vectors is greater than 98% for a smaller 684 number of M and ef construct, and even higher recall rate (99.86%) for a medium M and 685 ef construct while query speed is not compromised (Supplemental Table S2). For the 686 SIFT1M dataset (128 dimensions, 1,000,000 vectors), recall for top 100 neighbors of 687 10,000 query vectors was 99.77% for a medium M and ef_construct (Supplemental Table 688 S3 and S4). The Rust package hnswlib-rs can be found at: https://github.com/jean-689 pierreBoth/hnswlib-rs. For each genomic database, we chose M and ef construct 690 experimentally, by gradually increasing M and ef construct while monitoring query speed 691 and recall, similar to what is shown in Supplementary Table S2 for MNIST dataset. We 692 stopped the assessment when there was only a marginal increase in accuracy but decent 693 decrease in speed. To leverage between recall and speed, we use M=128 and 694 ef_search=1600 for graph building for GTDB database fungal database while M=128, 695 ef search=3200 for phage database. There are 2 modules in total: tohnsw and request. 696 Tohnsw is to build graph by gradually inserting genomes into graph while request is to 697 query new genomes against the graph database built in the tohnsw step. Tohnsw starts 698 from reading database genomes and generating kmer profile and sketches for distance 699 calculation. By selecting a random genome as the first genome to insert to the graph, 700 tohnsw module gradually add genomes to existing graph file following HNSW constructing

701 rules mentioned above by computing Probminhash distance between genomes. 702 Whenever a genome is going to be inserted into the existing graph, each genome in the 703 graph will hold a list that store the M closest neighbors/genomes that are linked to itself 704 and the distance to these neighbors. Then the distances of this genome with the nearest neighbors (M) of entry genome in this layer will be computed/searched (ef construct 705 706 times) using Probminhash3a algorithm and the smallest distance of the neighbor 707 genomes will be the new entry genome. This process will be repeated until the nearest 708 genomes (<= M) in the layer are found and subsequently, the program will go to the layer 709 below it using the genome that was represented by the nearest genome in the above 710 layer as new entry genome in the new layer. The search layer algorithm is repeated until 711 to the bottom layer is reached/analyzed. In contrast to the default settings in the original 712 hnswlib, we allow the two parameters of neighbor selecting heuristics, extendCandidates 713 to be true and *keepPrunedConnections* to be false because our genomic data is 714 extremely clustered and there is no need to fix the number of connections per element 715 considering the maximum connection allowed. Request module will load the graph 716 database and then search query genomes against it to return best neighbors of each 717 query following exact the same procedure with building step without updating the 718 database. Both tohnsw and request module are paralleled for high performance (see 719 Supplementary Note 6). The GSearch software can be found here: 720 https://github.com/jean-pierreBoth/archaea or here: 721 https://gitlab.com/Jianshu Zhao/archaea. GSearch relies on Kmerutils 722 (https://github.com/jean-pierreBoth/kmerutils), which is a Rust package to manipulate

genomic fasta files including kmer string compression, kmer counting, filtering usingcuckoo filter et.al.

Installation guide, manual and pre-built binaries can also be found. We provide static
binaries on the release page for major platforms such as Linux and MacOS, with support
for different CPU structures, e.g. Intel x86_64 or ARM64. GSearch program can be run
like this : 1) Build a graph database, which can be done running the following command:
tohnsw -d ./GTDB_r207 -k 16 -s 12000 -n 128 --ef 1600; 2) Request neighbors of query
genomes: request -b . -r ../query_folder -n 50 (--aa).

731

732 Prokaryotic classification pipeline

733 The amino-acid level graph showed that closest neighbors were found, with high 734 recall, when the query shared at least 52% AAI to its best neighbor. For more divergent 735 genomes, showing lower than 52% AAI equivalent, whole-genome amino-acid level graph 736 loses accuracy and we had to switch to universal, single-copy protein-coding genes. For 737 the nucleotide-level graph, we used kmer=16 for bacteria and archaea to have high 738 specificity for closely related database genomes (95% ANI to each other in GTDB 739 database). For building the whole-genome amino-acid graph, we used k=7 to have the 740 best specificity without *compromising* sensitivity, which is also consistent with previous 741 research on amino acid sequences classification based on kmers ¹⁵. For building graph 742 based on universal gene set, we use k=5 because of much smaller total amino acid size. 743 For details on the range of kmer that could be used for bacteria genome and proteome, 744 bacteriophage genome and proteome, see Supplemental Notes 2.

745 The proteome of each genome was predicted by FragGeneScanRs for 746 performance purpose compare to Prodigal despite small loss in precision (Supplementary Table S5) ¹⁶. Hmmsearch in the hmmer software ¹⁶ was used to extract universal gene 747 748 collection for bacteria and archaea genome for the universal gene graph. Note that for 749 phage genomes, this last step was not used because there is no universal single copy 750 genes for viral genomes. Evaluation of the speed and memory requiremetns for all steps 751 mentioned above were performed on a RHEL (Red Hat Enterprise Linux) v7.9 with 2.70 752 GHz Intel(R) Xeon(R) Gold 6226 CPU. Unless noted otherwise, all 24 threads of the CPU 753 are available by default.

754

755 Distributed implementation and database splitting

756 To accommodate the increasing number of genomes that become available at an 757 unprecedented speed in recent years and will soon reach 1 million or more, we provide 758 an option to randomly split the database into a given number of pieces and build graph 759 database separately for each piece. In the end, all best neighbors returned from each 760 piece will be pooled and sorted by distance to have a new best K neighbor collection 761 returned to the user for each query genome. We hereby prove that in terms of requesting 762 top K best neighbors, the database split strategy is equivalent to non-split database 763 strategy as long as the requested best neighbors for each database piece is larger than 764 or equals to requested best neighbors in the non-split strategy. The underlying reason is that the best neighbors globally are also the best locally ¹⁷. The database split and request 765 766 will be done sequentially, on one node, without multi-node support. For now, we split 767 GTDB database in to 5 pieces for testing purposes. In theory, a large database can be

split into any pieces as long as each piece can be used to build HNSW. In practice, a reasonable way is to split so that memory requirement for each piece is equal or smaller than the total memory of host machine. The. database split idea has been used in several graph-based larger scale (e.g., billions) nearest neighbor search tasks in industry ^{17, 18}.

773 Species database and testing genomes for benchmarking and recall

774 GTDB version 207 was used to build database for bacteria and archaea genome species 775 ¹⁹. It appears that virtually all metagenome-assembled dsDNA viral populations form discrete genotypic clusters/species and can be appropriately delineated using a \geq 95% 776 777 genome-wide ANI cut-off ²⁰. The IMGVR database version 3, with species representatives 778 at a \geq 95% genome-wide ANI were used for database building ²¹. For fungal genomes, 779 all genomes downloaded from the MycoCosm project (on 24th Jan., 2022) were used ²². 780 The amino acid sequences of predicted gene on the genomes were obtained using 781 FragGeneScanRs. The Universal Single Copy Gene (USCG) gene set for GTDB 782 genomes were also extracted via hmmer software.

To test the performance of our pipeline, we specifically chose genomes that are not included in the GTDB database (the database was used for graph building). In particular, the bacterial/archaeal genomes, mostly MAGs, reported by Ye and colleagues ²³ and Tara Ocean MAGs (total 8,466 MAGs) ²⁴ were used. We randomly selected 1000 genomes/MAGs from Ye's collection and use them as query genomes to test the performance and accuracy of GSearch. To compare with other database search tools for large database e.g. phage database, we compare GSearch with PhageCloud ²⁵, which

builds a graph database based on the labels of each phage genome (e.g., environment
source) and its search algorithm is Dashing2 (not published).

792

793 Recall of AAI-, ANI- and MinHash-based nearest neighbor searching for 794 bacteria/archaea, fungi and bacteriophage genomes.

795 To benchmark how GSearch performs compared to ANI/AAI- and MinHash-based tools, 796 we ran FastANI, Diamond blastp-based AAI and Mash to find the best neighbors for the 797 same query dataset and evaluate whether or not the best neighbors found by GSearch 798 were the same. FastANI parameters for the bacterial dataset were the following: fastANI 799 --ql query_path.txt --rl gtdb_path.txt -k 16 -p 24 --minFrac 3000 -o ANI.txt. GTDB 800 database was split into 50 subsets and run each subset parallelly on a multi-node 801 supercomputer to reduce memory requirement. MASH parameters were: mash sketch -a 802 (for AA only) -k 21 (7 for AA) -s 12000 -p 24 GTDB/*.fna > gtdb.msh; mash dist -p 24 803 gtdb.msh query.msh. For AAI calculation, the corresponding script in the enveomics 804 package ²⁶ was used: aai.rb -1 query.faa -2 db.faa -p diamond -t 24. Hmmer was used to 805 search for universal single copy gene against pre-built hmm profiles (120 for archaea and 806 122 for bacteria respectively); the profiles were obtained from the GTDB-tk software. For 807 bacteriophage genome, FastANI fragment size 1000 was used instead of 3000 while 808 aai.rb fragment size is 500 instead of 1000 with minimal number of matches of 5. MASH 809 kmer size 11 and 7 was used for nucleotides and amino acid, respectively, for 810 bacteriophage. For fungal genome ANI calculation, we use MUMMER v4.0.0 with default 811 parameters ²⁷. Gene prediction for fungal genomes was performed using GeneMark-ES 812 v2 (--fungus --ES) ²⁸. Kmer size 21 and 11 was used for fungal genomes in MASH for

nucleotides and amino acid, respectively. Detailed description of kmer size for each type
of genome can be found in Supplemental Note 2.

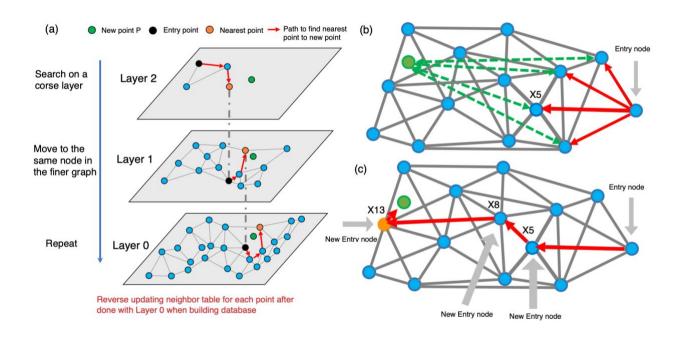

815 We calculated recall for our tool compare to standard ANI/AAI and MASH in the 816 following way: since biological species database are generally sparse because we are far 817 away from sequencing all species in the environment and likely the existence of natural 818 gaps in diversity, a larger top K by HNSW (e.g., 100) compared to the value used in 819 standard benchmark dataset will offer little, if any advantage, especially when the query 820 are relatively new, e.g. a new family compare to database genomes. Therefore, we use 821 top 5 and 10. Top 5 and top 10 recall are calculated based on top 5 and 10 neighbors 822 found by our tool and the available tools, and if all top 5 or 10 found by the latter tools 823 were also in top 5 or 10 of our tool, then recall was 100%. Similarly, if only 4 or 9 are 824 found by our tools, then recall was 80% and 90% respectively. However, if the distance 825 of query to some of the top 10 or top 5 neighbors found by our tool at the nucleotide level 826 was larger than 0.9850 for bacterial genomes, these matches will be filtered out and only 827 those neighbors below 0.9850 will be used (e.g. 8 out of 10 are kept, so only top 8 is 828 compared) because we have shown that above this threshold, Minhash-based methods 829 will lose accuracy and this is not specific to HNSW. Similar rules were applied for the 830 amino acid level searches with the threshold 0.9720 for filtering out bacterial genomes.

Figures 923

924 Figure 1. Schematic overview of GSearch building graph and searching graph steps. 925 (a) Graph was clasped into hierarchical layers following exponential decay probability. 926 In this graph, ef and M, represent the number of searches when finding nearest 927 neighbors and maximum allowed number of neighbors for each node, respectively. In 928 each layer, starting from an entry node (random or inherit from layer above it, 929 depending on whether it is the top layer or not), GSearch finds the closest connected 930 neighbor of the entry node and assigns it as the new entry point P (b), and then 931 traverses in a greedy manner (i.e., update the entry point using the newly found closest 932 connected neighbor (c)) until the nearest neighbor in the layer is found, and then goes 933 to next layer. This process is repeated until required number of nearest neighbors are 934 all found for the given new querying/inserting point. For building graph, after the 935 required number of nearest neighbors are found, a reverse update step will be 936 performed to update neighbor list of all nodes in the graph. 937

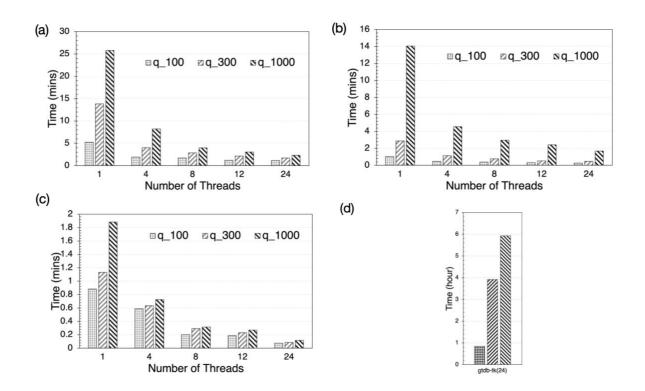

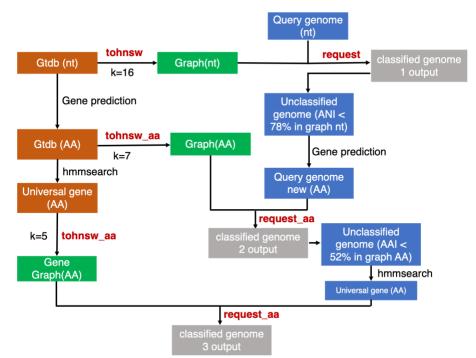

Figure 3. Total request time (wall time) for searching query genomes against the pre-built database of all GTDB genome (v207) at the whole-genome nucleotide (a), whole-genome proteome (b) and universal gene set proteome (c) levels. 100, 300 and 1000 query genomes (figure key) were used on a 24-thread Intel (R) Xeon (R) Gold 6226 processor. On average, database loading time ranged from 5-10 seconds. (d) is time needed to classify the same genomes using GTDB-Tk on the same 24-thread node.

Figure 4. Overview of the GSearch pipeline for classifying prokaryotic genomes. Orange boxes

1015 denote steps that aim to prepare genome files, in different formats, for graph building while

1016 green boxes denote building steps of the graph database (in nucleotide or amino acid format).

- 1017 Blue boxes indicate input/query genomes to search against the database while grey boxes
- 1018 indicate classification output for each input. Gene prediction was done using FragGeneScanRs
- and hmmsearch as part of the hmmer software for homology search. Two key steps of
 GSearch: tohnsw (aa) and request (aa) are used to build graph database and request new
- 1020 genomes, respectively. Two thresholds are used in the pipeline to decide between whole
- 1022 nucleotide vs. whole-genome amino acid search and whole-genome amino acid vs. universal
- 1023 gene amino acid, 78% ANI and 52% AAI, corresponding to Probminhash distance 0.9850 and
- 1024 0.9375, respectively (see main text).

 a RHEL v7.9, Linux v3.10.0-1160, all threads used. $^{b}MacOS$ v12.3, Darwin 21.4.0, all threads used.

Parallel package was used to run multiprocess at the same time. FGSrs stands for FragGeneScanRs. Note that in practice only those genomes failed in the Request for nt step (best found is less than 78% ANI) will be used in this step.

^dOnly 100 genomes are used for testing hmmsearch because this step is for very new genomes at order level or above and we often do not have that many new genomes in a real-world dataset. Parallel Packages was used to run multiple processes of hmmsearch, one thread per process for hmmsearch.
