Abstract

No preclinical experimental approach enables the study of voluntary oral consumption of high-concentration Δ^9-tetrahydrocannabinol (**THC**) and its intoxicating effects, mainly owing to the aversive response of rodents to THC that limits intake. Here we developed a palatable THC formulation and an optimized access paradigm in mice to drive voluntary consumption. THC was formulated in chocolate gelatin (**THC-E-gel**). Adult male and female mice were allowed *ad libitum* access for 1 and 2 h. Cannabimimetic responses (hypolocomotion, analgesia, and hypothermia) were measured following access. Levels of THC and its metabolites were measured in blood and brain tissue. Acute acoustic startle responses were measured to investigate THC-induced psychotomimetic behavior.

When allowed access for 2 h to THC-E-gel on the second day of a three-day exposure paradigm, adult mice consumed up to ≈30 mg/kg over 2 h which resulted in robust cannabimimetic behavioral responses (hypolocomotion, analgesia and hypothermia). Consumption of the same gelatin decreased on the following 3rd day of exposure. Pharmacokinetic analysis show that THC-E-gel consumption led to parallel accumulation of THC and its psychoactive metabolite, 11-OH-THC, in brain, a profile that contrasts with the known rapid decline in brain 11-OH-THC levels following THC intraperitoneal (*i.p.*) injections. THC-E-gel consumption increased the acoustic startle response in males but not in females, demonstrating a sex-dependent effect of consumption. Thus, while voluntary consumption of THC-E-gel triggered equivalent cannabimimetic responses in male and female mice, it potentiated acoustic startle responses preferentially in males. We build a dose-prediction model that included cannabimimetic behavioral responses elicited by *i.p.* versus THC-E-gel to test the accuracy and generalizability of this experimental approach and found that it closely predicted the measured acoustic startle results in males and females. In summary, THC-E-gel offers a robust preclinical experimental approach to study cannabimimetic responses triggered by voluntary consumption in mice, including sex-dependent psychotomimetic responses.

Introduction

The use of *Cannabis* products containing high concentrations of THC is rapidly increasing despite our limited understanding of its potential impact on physical and mental health [1-3]. These products are typically inhaled as combusted plant matter, vaporized extracts, or consumed in edible formulations. THC acts as a partial agonist at cannabinoid 1 receptors (**CB$_1$R**) to trigger a myriad of responses such as physiological responses (e.g., increase heart rate), altered mood and time perception, inhibition of motor control, and impaired learning and memory [4-10]. Subsequently, a relationship between *Cannabis* and psychotic/affective symptoms and an observable increase in *Cannabis*-associated vehicle crashes has become apparent without an understanding of the neural effects of higher dose THC [6,11-14]. Many of these effects translate to preclinical models where in rodents, THC reduces spontaneous locomotion and locomotor control, induces hypersensitivity to tactile and auditory stimuli, ataxia, and sedation; all of which have been shown to be mediated through action at CB$_1$R [15-18]. Importantly, some cannabimimetic responses are sex-dependent, as exemplified by the finding that THC (5 mg/kg, *i.p.*) triggers a more pronounced reduction in spontaneous locomotion and anxiogenic response in females than in males [19,20]. In addition to these cannabimimetic responses, preclinical investigations have pursued psychosis-related behaviors through the acoustic startle response, finding that involuntary administration of THC impairs psychomotor/sensorimotor gaiting [21-24], emphasizing the translational value in understanding THC's bioactivity in humans.

Understanding the effects of increased THC use in humans through preclinical models of voluntary THC administration has proven difficult to establish due to the aversive behaviors to higher doses in rodent models [25,26]. In recent years, progress has been made in promoting

voluntary oral consumption of THC in rodents, but results have been limited to mild, acute CB$_1$R-dependent cannabimimetic responses [27-29]. This lack of experimental tools to translate higher-dose THC intake in humans to preclinical models emphasizes the urgent need to develop and fully characterize a novel experimental approach. To bridge this translational gap, we initially developed an approach where mice are given *ad libitum* access to consume a sugar-water gelatin (**CTR-gel**) containing fixed amounts of THC [28,30]. Matching previous rodent studies, we found that mice consumed more vehicle gelatin than THC gelatin, indicating that they detected and avoided THC [31]. To overcome this limitation, in the current study we developed and characterized a palatable oral gelatin formulation that increases voluntary consumption by formulating THC in a chocolate-flavored nutritional shake, Ensure™ (**E-gel**). Previous work has shown that mice have a preference for chocolate flavor, making it an ideal THC formulant to increase palatability [32,33]. We leveraged this approach to determine whether oral consumption of high concentration THC gelatin induces commonly studied cannabimimetic responses in mice (hypolocomotion, analgesia, and hypothermia) and then we examined the effects of THC E-gel consumption on acoustic startle response, a preclinical measure of reflexive response rate and psychomotor arousal [22,34]. The model developed here leverages acute voluntary consumption of a sweetened gelatin to investigate psychomotor and reflexive behaviors, pharmacokinetics, and triad responses following consumption of THC E-gel in mice.

Materials and Methods

Animal Studies

Animal studies followed the guidelines established by AAALAC and were approved by IACUC

of the University of Washington. Male and female C57BL/6J mice ranging from 8-14 weeks of

age were used. Animals were housed with sibling littermates and were provided with standard

chow and water, *ad libitum,* and without any additional environmental enrichment. Investigators

were not blinded to experimental exposure conditions throughout assays due to the noticeable

behavioral effects measured in response to THC. Animal procedures were approved by the

Institutional Animal Care and Use Committee of the University of Washington and conform to

the guidelines on the care and use of animals by the National Institutes of Health.

Pharmacological Agents

Animals received THC (0.1, 0.3, 1, 3, 5, 10, and 30 mg/kg) and SR141716 (**SR1**, 1 mg/kg) *i.p.*

or were exposed to THC suspended in gelatin. THC and SR141716 (SR1) were provided by

the National Institute of Drugs abuse Drug Supply Program (Bethesda, MD). THC in ethanol

(50 mg/ml) was either added to gelatin mixtures (CTR or Ensure®) or prepared for *i.p.*

injection. For *i.p.* injection, both THC (0.1, 0.3, 1, 3, 5, 10, and 30 mg/kg) and SR1 (1mg/kg)

were dissolved in 95% ethanol and then vortexed thoroughly with equal volume Cremophor

and finally dissolved in sterile saline to reach a final 1:1:18 solution consisting of

ethanol:cremophor:saline.

Gelatin formulation

Control gelatin (CTR-gel): Deionized water (100 mL) was warmed to 40°C and stirred at a

constant rate. 2.5 g of Polycal™ sugar and 3.85 g of Knox™ Gelatin were added and the

mixture was maintained at a temperature below 43°C. The mixture was removed from heat,

and THC (50 mg/ml in ethanol) was added to reach a concentration of 0.3, 1, 2, or 4 mg/15 ml.

An equal volume of ethanol was added to vehicle gelatin (<1% total volume). Gelatin was

poured into plastic cups ranging from 2-10 ml and set into a 4°C fridge to solidify overnight.

Ensure gelatin (E-gel): Chocolate-flavored Ensure™ (100 ml) was warmed to 40°C and stirred

at a constant rate. 3.85 g of Knox™ Gelatin were added and the mixture was maintained at a

temperature below 43°C. The mixture was removed from heat and THC (50 mg/15 ml ethanol)

was added to reach a concentration of 1, 2, 5, or 10 mg/15 ml. At the 10 mg/15 ml

concentration, ethanol was evaporated off to 50% volume before being added to the mixture to

reduce total alcohol concentration below 1%. An equal volume of ethanol was added to vehicle

gelatin (<1% total volume). Gelatin was poured into plastic cups ranging from 2-10 ml and set

into a 4°C fridge to solidify overnight. Mice were always exposed to more gelatin than they

could consume, smaller volumes were used to conserve THC.

Acute gelatin access: Animals were first habituated to gelatin by receiving an excess of gelatin

in their home cage the day before the first timed access. On the first day of access, mice were

placed into a home cage-like environment equipped with a vehicle gelatin cup that was

stabilized to the cage. Behavior was recorded during the consumption window via an overhead

camera. On the second day of access, animals were placed into the same gelatin access cage

with either a vehicle or THC gelatin cup. Animals experienced either a triad of behaviors (open

field, tail flick, and body temperature) measured immediately preceding and following the

consumption window or an acoustic startle trial immediately following consumption. On the

third and final day of access animals were placed into the same cage with a vehicle gelatin

cup. For all gelatin access days, gelatin cups and animals were weighed before and after the

consumption window. Access to gelatin during the consumption window was limited to either 1

or 2 h after which the animals were removed and returned to their home cage.

Triad of Cannabimimetic behaviors

Hypolocomotion, hypothermia, and analgesia were measured 1 h post-*i.p.* injection or immediately following gelatin exposure. Pre-tests were collected immediately prior to injection or gelatin exposure.

Open Field: A 50 cm x 50 cm chamber (25 LUX) was equipped with an overhead camera to record movement. Animals were placed in the chamber for 15 minutes and then returned to their home cage. Total distance traveled (cm) was measured using Noldus Ethovision behavioral tracking software. Locomotion behavior was measured immediately before and after gelatin access to calculate a gelatin dependent difference score (post-pre). Pre-test measurements for CTR-gel were not collected and pre-test values were instead normalized to vehicle post-tests to produce a difference score as Post-VEH.

Tail Flick Analgesia: A hot water bath was set to 52.5°C. Mice were securely held upright in the air with their tail hanging downward. A timer was started as 75% of their tail was submerged into the water. Time was measured once a painful response was presented, marked as a latency to flick their tail out of the hot water. Tail flick responses were measured immediately before and after gelatin access to calculate a gelatin-dependent difference score (post-pre).

Measuring body temperature: Animals were placed on a stable surface with their tails lifted. A rectal thermometer probe (RET-3 Kent Scientific) was inserted into the anus for 10-20 s until the temperature recording stabilized. This test was always performed prior to the Tail Flick test to reduce any potential temperature contamination effects. Body temperatures were measured immediately before and after gelatin access to calculate a gelatin dependent difference score (post-pre).

Blood and brain tissue collection and quantification

Animals underwent the same gelatin access paradigm for day 1 and 2 described in acute gelatin access. After 2 h of gelatin access, blood was collected by cardiac puncture with a 23-gauge needle and placed on ice. Immediately following, brain tissue was collected and flash frozen in liquid nitrogen. Blood samples were spun in a 4°C centrifuge at 1450 x g for 15 min. Plasma was transferred to another tube and stored alongside brain samples in -80°C until being shipped on dry ice to the Piomelli Lab at UCI for sample analysis. Samples were collected immediately following 1 and 2 h gelatin access and 30 min and 24 h after 2 h gelatin access. THC and its first-pass metabolites 11-OH-THC and 11-COOH-THC were quantified in plasma and brain tissue using a selective isotope-dilution liquid chromatography/tandem mass spectrometry assay (26). Concentration data after E-gel consumption were compared to blood and brain tissue concentrations after $i.p.$ administration from previous publications from the Piomelli Lab [35].

Acoustic startle

Acoustic Startle behaviors were measured after 1 or 2 h THC-E-gel exposure (10 mg/15 ml) and THC-$i.p.$ (0.1, 1, 5, 10 mg/kg) injection. Sound-buffered startle chambers (SR-Lab, San Diego Instruments) were used to measure acoustic startle responses, equipped with a holding tube and an accelerometer. Background sound was maintained at 65 dB from a high-frequency speaker producing white noise. Startle tests were conducted 1 h post-THC-$i.p.$ injection or immediately following THC-E-gel exposure. Animals were set in the holding tube for 5 min to habituate prior to a series of seven trials presenting escalating sound levels of null, 80, 90, 100, 105, 110, and 120 dB. Tones were presented for 40 ms with an inter-trial interval of 30 s. Animals were only ever exposed to the acoustic startle paradigm once, immediately after gelatin access, to avoid auditory habituation.

Data/Statistical analysis

All data were analyzed using GraphPad Prism 10-11. For all statistical analyses (unpaired *t* test, one- and two-way ANOVA, and post hoc analyses), alpha level was set to 0.05. For all ANOVA analyses, Sidak's post-test was performed for increased power and repeated measures analysis was performed for time-dependent consumption data. All behavioral locomotor tracking was analyzed using Noldus Ethovision software and statistical analyses performed through GraphPad Prism 10-11. Nonlinear regressions (Figure 4B-d and Supplemental Figure S3B-G) were performed with a 3-parameter nonlinear, least squares, regression.

Results

E-gel promotes heightened voluntary oral consumption of THC and induces cannabimimetic behaviors by adult mice.

To incentivize voluntary oral consumption of high concentration THC, we utilized an E-gel formulation and optimized an exposure paradigm based on previous studies [28,36]. Here, individual mice were exposed to a control (CTR-gel) during a 2 h consumption period (Habituation, Day 1); and the following day exposed to THC formulated in either CTR-gel or E-gel (X mg/15 ml) for 2 h (**Figure 1a**). Gelatin mass was measured before and after access to calculate grams consumed, and gelatin concentrations are expressed as *X* mg of THC (X = mg of THC/15 ml gelatin) (**Figure 1b**). As expected, higher concentrations of THC-CTR-gel reduced gelatin consumption, an effect significant at 1 mg THC (**Figure 1c**, One-way ANOVA $F_{4,108} = 9.126$, $p < 0.001$, Sidak's). Remarkably, 7/17 (41%) of mice exposed to 4 mg CTR-gel did not consume any gelatin while all mice consistently consumed 5 mg and 10 mg THC-E-gel

(**Figure 1d**). Thus, mice consumed 1.9 ± 0.05 g of VEH-E-gel and 1.0 ± 0.07 g of E-gel

containing THC (10 mg/15 ml) (**Figure 1d**, One-way ANOVA $F_{5,75}$ = 14.10, p < 0.001, Sidak's).

Note that mice consumed similar amounts of VEH-E-gel and VEH-CTR-gel (1.96 ± 0.15 g and

1.92 ± 0.17 g, respectively), indicating that chocolate flavor *per se* does not increase

consumption. When calculating the amount of THC consumed in mg/kg, we found that mice

consumed more THC when formulated in E-gel (**Figures 1e**). For example, mice consumed

10.5 ± 0.7 mg/kg/2 h when exposed to 2 mg E-gel compared to only 4.6 ± 0.5 mg/kg/2 h when

exposed to the same amount of THC formulated in CTR-gel. Using this experimental

approach, maximal consumption reached 29.2 ± 1.8 mg of THC per kg/2 h when exposed to E-

gel containing THC (10 mg/15 ml), compared to the few mice that consumed only 8.4 ± 1.2 mg

of THC per kg/2 h when exposed to CTR-gel containing THC (4 mg) (**Figures 1e**, Two-way

ANOVA $F_{7,94}$ = 73.14, p < 0.001, Sidak's). As previously shown, we found no statistically

significant sex-dependent effects in consumption between male and female mice across all

treatments (Two-way ANOVA $F_{1,60}$= 3.64, p<0.06) but did see an individual significance

between males and females at 1 mg THC-E-gel (**Supplementary Figure S1**, Two-way

ANOVA, p<0.05) [28,30]. These data show that mice consistently consume significant

quantities of E-gel despite high THC concentrations. Based on these results, we next focused

our study on quantifying the pharmacological effects of THC formulated in E-gel.

Considering that THC-CTR-gel triggers mild cannabimimetic responses due to limited

consumption [28,30], we determined whether consumption of THC-E-gel could induce

cannabimimetic responses measured immediately following the 2 h access period (**Figure 1f**).

Thus, we selected three well-described behavioral effects of THC in mice: hypolocomotion,

analgesia, and hypothermia (**Figure 1g-i**) [17]. THC was formulated and administered either

by *i.p.* injection (grey), CTR-gel (green), or E-gel (purple) and behavioral responses to gelatin

consumption were plotted from the average dose consumed, calculated in **Figure 1e**. **Figure**

1g shows that *i.p.* administration of THC reduced locomotion starting at 3 mg/kg, as previously

reported [17], and that this response was significant after access to 4 mg THC-CTR-gel (avg:

8.4 mg/kg) and 2 mg THC-E-gel (avg: 10.5 mg/kg) (**Supplementary Figure 2b, e**, One-way

ANOVA $F_{5,68}$ = 14.54, p<0.001, Sidak's for CTR-gel and $F_{4,56}$ = 3.24, p=0.02 for E-gel, Sidak's).

Figure 1h shows the greatest THC-induced analgesia was reached at 30 mg/kg *i.p.* and after

access to 2 mg THC-E-gel (**Figure 1h** and **Supplementary Figure S2d, g**, One-way ANOVA

$F_{4,104}$ = 9.4, p<0.001, Sidak's for CTR-gel and $F_{7,77}$ = 8.7, p<0.001 for E-gel, Sidak's). THC

injection (*i.p.*) reduced core body temperature starting at 3 mg/kg, and that this response

reached significance at 4 mg THC-CTR-gel (avg: 8.4 mg/kg) and at 5 mg THC-E-gel (avg: 17.2

mg/kg). **Figure 1i** also shows that reduced core body temperature induced by THC reached a

significant effect of -5.84°C at 30 mg/kg *i.p.*, -1.5°C after 4 mg THC-CTR-gel (avg: 8.4mg/kg)

and -1.8°C after 10 mg THC-E-gel (avg: 29.2 mg/kg) (**Supplementary Figure S2d, g**, One-

way ANOVA $F_{5,61}$ = 11.16, p<0.001, Sidak's for CTR-gel and $F_{4,114}$ = 6.36, p<0.001 for E-gel,

Sidak's). Analgesia and hypothermia did not plateau, matching prior studies which have also

shown that 30 mg/kg THC-*i.p.* does not produce a maximal response for these cannabimimetic

behaviors [37,38]. Sexual dimorphic responses were measured after THC administration

through either *i.p.* injection or E-gel, although VEH-E-gel did show a significant difference in

hypolocomotion between males and females (Supplementary Figure S3b-g, THC: Two-way

ANOVA, Sidak's post-test, VEH-E-gel locomotion: Unpaired T-test, t=2.721, df=16, p = 0.02)

Thus, **Figures 1g-i** show that: 1) THC reduces locomotion when administered using these

three experimental paradigms, and to a greater extent at higher-dose *i.p.* THC and higher-

concentration THC-E-gel; 2) THC induced analgesia only when administered *i.p.* and using

THC-E-gel, though *i.p.* administration is more potent; and 3) THC reduces core body

temperature only when administered *i.p.* and using THC-E-gel, though *i.p.* administration is

more potent.

Next, we analyzed the cannabimimetic responses of individual mice following THC (10

mg/15 ml) E-gel access and how the CB_1R inverse agonist, SR1, administered 1 h into the

consumption window influences these responses (**Figure 1j**). SR1 was administered at 1 h to

reach peak circulating concentrations during the behavioral testing (1-2 h post-injection) and to

reduce any anorectic effects that would inhibit consumption of THC-E-gel [39,40].

Cannabimimetic responses increased as a function (linear regression) of increasing amount of

THC consumed, demonstrating a significant relationship between the amount of THC

consumed and the three cannabimimetic readouts: hypolocomotion (linear regression

$F_{1,46}=9.74$, p=0.003), Analgesia (linear regression, $F_{1,57}=15.73$, p<0.001), and hypothermia

(linear regression, $F_{1,46}=24.72$, p<0.001) (**Figure 1k-m**). Confirming the involvement of CB_1R,

SR1 blocked the three THC-induced cannabimimetic responses: hypolocomotion ($F_{1,6}=4.1$,

p=0.09), Analgesia ($F_{1,6}=0.66$, p=0.45), and hypothermia (SR1: $F_{1,6}=0.68$, p=0.44) (**Figure 1k-**

m). As expected, SR1-treated mice did not consume maximal THC-E-gel compared to some

animals exposed to 10 mg THC-E-gel, likely due in part to the SR1 injection 1 h into the

consumption window and the known anorectic effects of SR1 [39,40]. We additionally

compared the linear regression of all THC-E-gel consumption within the range of SR1-treated

animal consumption and found that THC-E-gel alone still produced a significant correlation to

all behaviors. These results indicate that consumption of THC-E-gel evokes robust CB_1R-

dependent cannabimimetic behavioral responses in adult mice that are comparable to *i.p.*-THC

administration when measuring hypolocomotion, and less potent when compared to *i.p.*-THC

administration when measuring analgesia and reduction in core body temperature.

THC-E-Gel reduces locomotion during the exposure period.

We found that mice consumed ~2 g of vehicle E-gel (VEH-E-gel) compared to ~1 g of THC-E-gel (10 mg/15 ml), indicating a 2-fold reduction in consumption (**Figure 2a**). To investigate the time course of this effect, we weighed gelatin every 10 min during the 2 h access period in a 3-day paradigm: access to VEH-E-gel on Day 1, access to either VEH-E-gel or THC-E-gel Day 2, and access to VEH-E-gel on Day 3 (**Figure 2a**). **Figure 2b** shows that consumption of VEH-E-gel on Day 1 started within 20 min of availability and was constant during the 2 h period. On Day 2, mice consumed comparable amounts of VEH-E-gel and THC-E-gel during the initial 40 min of access (16.3 and 13.0 mg/min, respectively) (**Figure 2c** and **Supplementary Figure S4a**). However, consumption of THC-E-gel plateaued after 40 min to a rate of 4.2 mg/min (67.7% reduction), while consumption of VEH-E-gel was sustained at 9.9 mg/min (39.3% reduction), producing a significant effect by THC to modify gelatin consumption (**Figure 2c**, Two-way ANOVA, repeated measures $F_{1,14}$ = 7.604, p = 0.015, Sidak's and **Supplementary Figure S4b**, Two-way ANOVA, $F_{1,14}$ = 6.05, p = 0.03, Sidak's). By sharp contrast, mice that had consumed THC-E-gel the day prior consumed VEH-E-gel on Day 3 at a significantly slower rate (6.2 mg/min) during the access period, suggesting an aversive memory to THC-E-gel (**Figure 2d**, Two-way ANOVA, repeated measures $F_{1,14}$ = 4.865, p = 0.045, Sidak's and **Supplementary Figure S4b**). Consequently, mice exposed to THC-E-gel on Day 2 significantly decreased their total VEH-E-gel consumption on Days 2 and 3 (**Figure 2e**, Two-way ANOVA, $F_{1,83}$ = 37.51, p < 0.001, Sidak's). These data suggest that, on Day 2, mice

consumed high enough quantities of THC to induce a typically *i.p.*-high-dose (5-10 mg/kg) cannabimimetic response resulting in an avoidance to gelatin on Day 3.

Reduced spontaneous locomotion is a hallmark response to THC in mice. To address whether THC-E-gel consumption impacts spontaneous locomotion, we video-recorded the travelling distance of mice during the gelatin access period (total distance in cm over 2 h) (**Figure 2f**). **Figure 2g-i** shows that locomotion during the consumption period initially reached (1,200 cm/ 5 min) and then steadily decreased over the 2 h session on Day 1, as expected in mice that are habituating to the environment. On Day 2, spontaneous locomotor activity between mice that consumed VEH-E-gel and THC-E-gel diverged after 40 min, showing a significant decrease in total locomotion in mice that consumed THC-E-gel (**Figure 2h**, Two-way ANOVA, repeated measures $F_{1,14}$ = 11.18, p = 0.005, Sidak's). Thus, this reduction in locomotion parallels a corresponding reduction in consumption in **Figure 2e** that is significantly different on day 2 (**Figure 2j**, Two-way ANOVA, $F_{1,42}$ = 0.3413, p = 0.562, Sidak's). Importantly, spontaneous locomotion of mice exposed to VEH-E-gel and THC-E-gel was similar on Day 3. Together, these results show that consumption of THC-E-gel induced hypolocomotion on Day 2 after 40 min of access. Additionally, the decreased consumption of VEH-E-gel on Day 3 is likely due to an aversive memory of the THC exposure period and not to hypolocomotion. Thus, E-gel incentivizes voluntary THC consumption to induce robust hypolocomotion, a hallmark cannabimimetic response, within 40 min of access.

Consumption of THC-E-gel results in concomitant increases in the levels of THC and its metabolites in brain tissue.

Several studies have shown that the PK profile of THC (5 mg/kg, *i.p.*) results in peak

circulating concentrations of THC (1000pmol/g), its bioactive metabolite 11-OH-THC

(300pmol/g), and its inactive metabolite 11-COOH-THC (100 pmol/g) in the brain after 2 h

[35,41]. To determine the PK profile of THC-E-gel consumption (10 mg/15 ml) and considering

the hypolocomotion behavior occurring during the consumption window, we collected plasma

and brain tissue samples after 1 h of consumption, at the end of the 2 h access period, as well

as 30 min (2.5 h) and 24 h (26 h) following the 2 h access period (**Figure 3a**). **Figure 3b**

shows THC levels in the brain reached 500-600 pmol/g tissue between 1 h and post 2.5 h

time-point and was below 50 pmol/g tissue after 24 h. Remarkably, 11-OH-THC and 11-

COOH-THC levels in brain increased concomitantly to THC levels, reaching 400-500 pmol/g

tissue and 200-350 pmol/g tissue, respectively, between 1 h and the post 2.5 h time-point, and

both were also below 50 pmol/g tissue after 24 h. Thus, levels of both CB_1R agonists, THC,

and 11-OH-THC, concomitantly peaked after 1 h of THC-E-gel consumption, a result that

matches the hypolocomotion response measured starting at 40 min during the 2 h

consumption period (**Figure 1**). Furthermore, THC and 11-OH-THC levels in brain tissue were

lower, near zero, 24 h after the 2 h exposure, as previously reported [42,43]. THC levels in

plasma reached approximately 400 pmol/g tissue at the 1 h time-point and decreased

thereafter (**Figure 3c**). Statistical comparisons between the 1 h and 2 h exposure periods were

limited due to different treatment paradigms, prompting the normalization of all PK values to

the 1 h exposure period samples (**Figure 3d-e**). Brain samples were all increased at 2 h

relative to 1 h exposure but significant differences to 1 h exposure was only found at the 26 h

collection time point (**Figure 3d**, One-way ANOVA, $F_{3,139}$ = 14.03, p < 0.001, Sidak's).

Alternatively, plasma samples were significantly decreased at 2 h for THC and COOH-THC

while all three compounds were significantly decreased at the 26 h collection time point (**Figure 3d**, One-way ANOVA, $F_{3,141}$ = 35.23, p < 0.001, Sidak's). Correlation of PK findings with cannabimimetic triad results did not reveal any significant relationships. Note that 11-OH-THC and 11-COOH-THC levels peaked after 2 h of consumption which contrasts with the early onset hypolocomotion response measured in **Figure 1** after 40 min of gelatin access. Thus, PK analysis of high concentration THC-E-gel consumption demonstrates parallel accumulation of THC and 11-OH-THC in the brain, a unique profile that differs compared to previously established PK profile resulting from THC-*i.p.* injection [35,41].

Correlating *i.p.* THC and THC-E-gel triad cannabimimetic responses predicts THC-E-gel-dependent behaviors.

To further establish the pharmacological relationship between *i.p.* THC injections and THC-E-gel consumption after 1 h and 2 h consumption along with the low variability in the cannabimimetic responses triggered by both routes of administrations, we calculated "predicted THC doses" by correlating their cannabimimetic responses across experiments (**Figure 4a**). Thus, we extrapolated the relative *i.p.* dose for each cannabimimetic response triggered by consumption by plotting the cannabimimetic response following consumption onto the dose-response curve of THC-*i.p.* as reference (**Figure 4b-d**). **Figure 4b-d** also shows that 1 h access to high concentration THC-E-gel triggered greater cannabimimetic responses compared to 2 h access. Consequently, this resulted in a higher "predicted *i.p.* dose" shown by dotted lines tracked to the *i.p.* dose-response curves. Of note, 1 h access to high dose THC-E-gel triggered stronger hypolocomotion and reduction in core body temperature corresponding to 10.3 and 11.6 mg/kg THC *i.p.*, respectively, and analgesia corresponding to 4.5 mg/kg THC

i.p. (**Figure 4b-d**). By contrast, 2 h access to high concentration THC-E-gel triggered a comparable response in the three cannabimimetic behaviors corresponding to 3-4 mg/kg THC *i.p.* (**Figure 4b-d**). **Figure 4e** illustrates the predictive value of these calculations, and the larger variability for the 1 h access predicted dose of 8.8 ± 2.2 mg/kg *i.p.* and 3.7 ± 0.3 mg/kg *i.p.* for 2 h access, a 2.4-fold higher predicted dose after 1 h access. The variability between the cannabimimetic response for the 1 h access results suggest that a difference in the PK profile of THC at 1 h compared to 2 h access (see **Figure 3**). Together, these results indicate that consumption of high dose THC-E-gel triggers strong cannabimimetic responses, comparable to *i.p.* injections of THC between 4-12 mg/kg, although this is not necessarily adaptable to all behavioral readouts.

THC-E-gel consumption and THC *i.p.* injections induce sex-dependent changes in acoustic startle responses.

Acoustic startle responses in mice represents a well-established preclinical approach to evaluate an unconditional reflex characterized by the rapid contraction of muscles to a sudden and intense startling stimulus. It is an especially useful measure in preclinical research as it is consistent across species and involves simple neural circuitry in sensorimotor gating [44]. It is known that *i.p.* injection of THC (6 and 10 mg/kg) reduces acoustic startle in male mice [22,34,45]. Thus, whether acute startle response is affected in a sex-dependent manner and by lower dose THC delivered *i.p.* or via oral consumption remains unknown. Here we compared the effect of THC-E-gel consumption and THC *i.p.* injections on acute acoustic startle in male and female mice. Acute startle responses were measured as the peak velocity of startles (Vmax) using an accelerometer and following audible tones of 80, 90, 100, 105, 110,

and 120 dB delivered either 1 h after *i.p.* administration of THC (from 0.1 to 10 mg/kg) or

immediately after access to THC-E-gel (10 mg/15 ml) (**Figure 5a**). THC administration via *i.p.*

injection induced a significantly increased startle response in males at 1 and 5 mg/kg with a

trend decrease at 10 mg/kg, and only a significantly decreased startle response in females at

10 mg/kg (**Figure 5b-c**, males: v. VEH Two-way ANOVA $F_{4,122}$ = 13.89, p < 0.001, Sidak's;

females: v. VEH Two-way ANOVA $F_{4,116}$ = 6.76, p < 0.001, Sidak's). **Figure 5d** shows the

male and female startle responses that occurred at the 120 dB tone exposures and follows an

inverted U shape characterized by: 1] increased acute startle response at 1 and 5 mg THC

(i.p.) in males, 2] absence of such response in females and 3] a comparable reduction in acute

startle response in both male and female at 10 mg THC (i.p.) in males and females (Two-way

ANOVA $F_{3,23}$ = 26.66, p <0.001, Sidak's).

THC-E-gel consumption by males and females also triggered a sex-dependent startle

response. **Figure 5e-f** show that only males that were allowed access for 2 h to THC-E-gel

exhibited an increase in acute startle response (2.2-fold increase) (males: Two-way ANOVA

$F_{2,70}$ = 26.85, p < 0.001, Sidak's). Further analysis of the relationship between THC-E-gel

consumption and modification of the acute startle response delivered at 120 dB resulted in a

significant correlation (**Figure 5g**, p = 0.05).

Finally, we sought to determine whether the predicted dose calculations from **Figure 4e**

could be applied to the *i.p.* THC acoustic startle response dataset to test the accuracy and

generalizability of the dose-prediction model. Specifically, we plotted the predicted doses of 3.7

and 8.8 mg/kg *i.p.* (from **Figure 4e**) on to **Figure 5d** depicting the acoustic startle response

measured at 120dB resulting from *i.p.* injections (**Supplemental Figure S5a,b**). This

produced predicted startle responses of: 310 cm/min for 1 h consumption and 688 cm/min for

h consumption for females, as well as 558 cm/min for 1 h consumption and 1733 cm/min for 2 h consumption for males. We then plotted the measured acute acoustic response (Vmax, 120 dB tone) following THC consumption in **Figure 5h-i**, as well as the predicted acute startle responses (dashed lines) from **Figure 5d** (**Supplemental Figure S5a-c** shows methodology). The predicted acute startle responses in males exposed to 10 mg/15 ml THC-E-gel for 1 and 2 h access was close to, or within, the standard error of the measured startle response following THC-E-gel for 1 and 2 h access (**Figure 5h-i**). This dose-prediction model demonstrates the reliability of voluntary THC-E-gel consumption as a behavioral paradigm to produce consistent cannabimimetic responses across different experimental modalities.

Discussion

Here we report a novel experimental approach that enables the behavioral impact of voluntary oral consumption of high dose THC by adult mice. Access to E-gel for 2 h over a two-day period incentivizes robust consumption, and at the highest dose tested here (10 mg/15 ml), mice of both sexes consumed ~30 mg/kg THC in 2 h on the second day. Acute consumption of THC triggers commonly established cannabimimetic responses, the potencies of which were right shifted compared to the responses measured with *i.p.* injections. Furthermore, we discovered that acute consumption of 10 mg/15 ml THC-E-gel increases the acoustic startle response in males and not in females; whereas *i.p.* injection of THC triggers a dose-dependent, inverse U-shaped, impairment of acoustic startle response that was also more pronounced in males than females. Our study provides important translational results at two levels: voluntary consumption of THC by rodents and its sex-dependent impact on acoustic startle response as a measure for psychomotor reflexive behavior.

Mice of both sexes consumed similar amounts of VEH-CTR-gel and VEH-E-gel, and none

consumed more than 20% of their daily caloric intake indicating comparable consumption

behaviors. However, consumption of high concentration THC-CTR-gel (4 mg) was

inconsistent, and 41% of the mice completely avoided consumption (as assessed by an

unbroken gelatin surface at the end of the 2 h access period) (**Figure 1c**). By contrast,

consumption of THC-E-gel (10 mg, i.e., 2.5X more concentrated) was more consistent with a

total consumption rate of 0.95 g/2 h (**Figure 1d**). This difference in consumption between THC-

CTR-gel (4 mg/15 ml) and THC-E-gel (10 mg/15 ml) is likely due to the chocolate flavoring in

Ensure™ that masks the strong odor and bitter taste of high-concentration THC and its

aversive properties. At higher doses of THC-E-gel exposure, we found more variability in dose

consumed (**Figure 1e**), a consumption behavior similar between sexes (**Supplemental Figure**

S1b). Future studies of such increased variability at even higher doses of THC may reveal

differences in absorption or metabolism for example. Significantly, mice that consumed the

higher dose THC-E-gel on Day 2 consumed remarkably less VEH-E-gel on Day 3

(**Supplementary Figure S2c**). This decrease in consumption is likely due to the development

of aversive conditioned associations to higher dose THC. Thus, the THC-E-gel experimental

approach reported here also enables the study of aversive memory to voluntary oral

consumption of high dose THC.

I.p. injection of THC induces hypolocomotion, analgesia, and hypothermia in mice with

different median effective doses (ED_{50}, 1.3, 3.9 and 14.4 mg/kg, respectively) (**Figure 2b-d**).

By comparison, 1 h access to 10 mg THC-E-gel produced cannabimimetic responses that

paralleled the ED_{50} of *i.p.* injections and are equivalent to an *i.p.* dose of ~9 mg/kg. Also, 1 h

access to 10 mg THC-E-gel evoked a more pronounced cannabimimetic response compared

to 2 h access, agreeing with prior studies which have shown that oral gavage increases brain peak concentration of THC 1-2 h after administration [46]. Oral consumption also increases 11-OH-THC levels in the brain with comparable kinetics and concentration as THC, and the levels of both cannabinoids decrease in parallel (**Figure 3b-c**). Considering that ~600 pmol/g of THC and 11-OH-THC is roughly equivalent to 3 nM of both compounds in the brain that persists over several hours, and both activate CB_1R with comparable potencies, our results suggest that the accumulation of both THC and 11-OH-THC in the brain might contribute to cannabimimetic responses [47]. Because of the experimental design implemented for this study, we did not determine if variation in the time course of distinct cannabimimetic response we different following consumption. Thus, future studies that prioritize behavioral responses at multiple time points following consumption of THC using E-gel results might reveal differences in the dynamics of onset and decay in cannabimimetic responses.

We found that oral consumption of THC-E-gel produced a higher brain concentration of the primary metabolite 11-OH-THC in the brain compared to previously published concentrations after *i.p.* administration [41]. This suggests oral administration may modify the accumulation of 11-OH-THC or its metabolism in the brain. Both males and females were studied for all pharmacokinetic timepoints, and we found no significant sexual differences (**Supplementary Tables S6,7**). Finally, considering that voluntary oral consumption of 10 mg/15 ml THC results in nanomolar concentrations of THC and 11-OH-THC for several hours, the time-dependent reduction in cannabimimetic response that follows their maximal response may also be due either to CB_1R desensitization/tolerance or to redistribution of the drug within brain parenchyma.

An *i.p.* injection of THC 6 and 10 mg/kg in male mice reduces acoustic startle behaviors [34,45]. We show here that THC-*i.p.* induces a dose-dependent biphasic behavioral response that is more pronounced in males than females, demonstrating sex-dependent sensorimotor behaviors, and confirming that THC impacts neurocognitive function in a sex-dependent manner (**Supplementary Figure S3**) [48-50]. THC-E-gel (10 mg/15 ml) consumption also increased the response to acoustic startle preferentially in males compared to females. Whether the dose of THC formulated in E-gel can be increased to levels that remain palatable to mice and might trigger the pronounced reduced acoustic startle measured with 10 mg THC injection *i.p.* remains an open question.

Analysis of the behavioral responses following *i.p.* injection and consumption of THC-E-gel enabled us to propose a model that correlates the doses of THC capable of producing comparable behavioral responses, emphasizing the robustness of this experimental approach. Thus, the flexibility of the THC-E-gel experimental approach may extend its utility as a substitute for traditional *i.p.* injections, better bridging the translational gap between preclinical investigations and human use. For example, the THC-E-gel experimental model can be easily modified and implemented to measure, in a less invasive manner, the impact of oral THC consumption on additional mouse behaviors, including self-administration and preference/aversion, paradigms that require multiple treatment regimens.

In conclusion, we report a new experimental approach that achieves robust voluntary oral consumption of THC in adult mice by formulating THC in a chocolate-flavored sweetened E-gel. Given the recent rise in use of *Cannabis* products that contain high doses of THC such as edibles [51], this voluntary consumption model allows the study of its effect on translational relevant behaviors, including sex-dependent psychomotor reflexes in mice.

Author Contributions: A.E., D.P., M.B., N.S., and B.L. conceived and designed the study. A.E., F.U., A.T., D.S., and A.S. acquired the data. A.E., F.U., A.T., D.S., and A.S. performed the analysis. All authors have edited and approved the final manuscript.

Figure 1: <u>E-gel promotes heightened voluntary oral consumption of THC and induces cannabimimetic behaviors by adult mice.</u>

a) Mice were given free access to vehicle (VEH), or THC formulated in either CTR-gel or E-gel for 2 h on Day 1 and Day 2. **b)** Consumption was determined by weighing gelatin at the end of each session. **c)** Consumption of CTR-gel on Day 2 is decreased after addition of THC. **d)** Consumption of E-gel on Day 2 is maintained after addition of THC. **e)** Dose of THC consumed, in mg/kg, when formulated in either CTR-gel or E-gel on Day 2. Results are mean ± S.E.M. Consumption compared ANOVA and Sidak's, *$p < 0.05$, **$p < 0.01$, and ***$p < 0.001$, N=8-40. **f)** Diagram of behavioral paradigm before and after *i.p.* or gelatin administration. **g-i)** Dose-dependent behavioral responses for hypolocomotion (**g**), analgesia (**h**), and hypothermia (**i**) after THC exposure. Administration by *i.p.* (grey) is plotted on x-axis by single bolus injection while CTR-gel (green) and E-gel (purple) are plotted based on average THC consumed after 2 h exposure window shown in **e**. **j)** Diagram of THC-E-gel exposure, behavioral measurements, and SR1 injection (by *i.p.*) at 1 h into exposure window. **k-m)** Individual behavioral responses for hypolocomotion (**k**), analgesia (**l**), and hypothermia (**m**) for each animal. Individual points are plotted based on individual THC consumption with a linear regression to show correlation between consumed THC and behavioral output (p-values: **k**=0.003, **l**<0.001, **m**<0.001). SR1 treated mice are plotted (red) based on consumed THC after exposure to 10 mg/15 ml THC-E-gel with a linear regression to show no correlation across three behaviors (p-values: **k**=0.09, **l**=0.44, **m**=0.45).

Figure 2: <u>THC-E-gel consumption triggers CB$_1$R-dependent behaviors</u>

a) Over a 3-day exposure paradigm, mice received 3 days of E-gel with either VEH or THC (10mg/15ml) E-gel on day 2. **b-d)** Cumulative gelatin consumption recorded every 10 minutes throughout the 2 h exposure window over the 3-day paradigm. VEH (black) and THC (purple) groups received access to VEH on day 1 (**b**), VEH or THC on day 2 (**c**), and VEH on day 3 (**d**). **e)** Total gelatin consumption after 2 h of access to gelatin was plotted comparing VEH and THC treatment groups. **f)** Animal consummatory and locomotor behavior was tracked during gelatin exposure window. **g-i)** Distance traveled recorded every 5 min over the 3-day paradigm, similar as to **b-d. j)** Total distance traveled (cm) after 2 h of gelatin access was

plotted comparing VEH and THC groups. Main effect over 2 h exposure period (**b-d, g-i**)
measured using Two-way ANOVA with repeated measures and Sidak's, main effect on total
response (**e, h**) measured by One-way ANOVA and Sidak's (*p<0.05, **p<0.01, ***p<0.001)
N=8-16.

Figure 3: <u>Consumption of THC-E-gel results in concomitant increases in the levels of</u>
<u>THC and its metabolites in brain tissue</u>

a) Diagram outlining gelatin exposure paradigm where blood and brain samples were collected
immediately following 1 h and at 2, 2.5, and 26 hours from the beginning of 2 h access to
10mg/15ml THC-E-gel. **b)** Brain concentration of THC, 11-OH-THC, and COOH-THC after E-
gel exposure, 1 h access is separated due to a reduced total access time to THC-E-gel
compared to the other time points. **c)** Plasma concentrations for the three compounds plotted
similarly to b. **d-e)** PK concentrations in brain **(d)** and plasma **(e)** normalized to the 1 h access
period. Statistical comparison to 1 h Two-way ANOVA, Sidak's, *p<0.05, **p<0.01, and
***p<0.001, N=8-15.

Figure 4: <u>Correlating *i.p.* THC and THC-E-gel triad cannabimimetic responses predicts</u>
<u>THC-E-gel-dependent behaviors.</u>

a) Diagram of 1 h and 2 h THC-E-gel exposure and *i.p.* administration with behavioral tests. **b-**
d) Cannabimimetic responses after THC administration by *i.p.* and subsequent dose-response
curve in grey. Responses after 1 h or 2 h exposure to 10 mg THC-E-gel are plotted with dotted
lines tracking to relative THC-*i.p.* dose response. **e**) Predicted *i.p.* dose after 1 h and 2 h THC-
E-gel exposure window from all three triad behaviors.

Figure 5: <u>Sex-dependent acoustic startle responses after *i.p.* injection of THC and high</u>
<u>concentration THC-E-gel consumption</u>

a) Diagram of THC-E-gel exposure or *i.p.* administration followed by acoustic startle response
behavioral testing. **b-c)** Male and female acoustic startle responses after *i.p.* administration of
THC in response to escalating tones (80, 90, 100, 105, 110, and 120dB) following *i.p.*
administration of THC in males (**b**) and females (**c**). **d)** Male and female acoustic startle dose-

responses to a 120dB tone after *i.p.* THC administration. Results are mean ± S.E.M. One-way

ANOVA, Sidak's comparing VEH and *i.p.* THC dose between males and females **p<0.01, and

***p<0.001, N=6-11. **e-f)** Male and female acoustic startle responses after 1 h or 2 h THC E-

gel exposure in response to escalating tones (80, 90, 100, 105, 110, and 120dB. **g)** THC dose

consumption based on grams consumed and individual body weight correlated with individual

acoustic startle response after 2 h exposure. **h-i)** Startle response to a 120dB tone for males

(**h**) and females (**i**) after 1 h or 2 h access to THC E-gel. Predicted doses calculated from a

second order polynomial of *i.p.* dose responses are plotted to show the consistency in

predicted dose response after E-gel exposure.
