Higher social tolerance is associated with more complex facial

behavior in macaques

Abstract

The social complexity hypothesis for communicative complexity posits that animal societies with more complex social systems require more complex communication systems. We tested the social complexity hypothesis on three macaque species that vary in their degree of social tolerance and complexity. We coded facial behavior in >3000 social interactions across three social contexts (aggressive, submissive, affiliative) in 389 animals, using the Facial Action Coding System for 23 macaques (MaqFACS). We quantified communicative complexity using three measures of uncertainty: entropy, specificity, and prediction error. We found that the relative entropy of facial be-25 havior was higher for the more tolerant crested macaques as compared to the less tolerant Barbary and rhesus macaques across all social contexts, indicating that crested macaques more frequently use a higher diversity of facial behavior. The context specificity of facial behavior was higher in rhesus as compared to Barbary and crested macaques, demonstrating that Barbary and crested macagues used facial behavior more flexibly across different social contexts. Finally, a random forest classifier predicted social context from facial behavior with highest accuracy for rhesus and 31 lowest for crested, indicating there is higher uncertainty and complexity in the facial behavior of crested macaques. Overall, our results support the social complexity hypothesis.

Introduction

Animals must overcome a range of environmental and ecological challenges to survive and reproduce, with group-living species having to overcome additional social challenges to maximize fitness. Communicative signals can be used to navigate a number of different social situations and may need to become more elaborate as social complexity increases. The social complexity hypothesis for communicative complexity encapsulates this idea, proposing that animal societies with more complex social systems require more complex communication systems [1]. The social complexity hypothesis has become a topical issue in recent years, with questions regarding the definitions, measurement, and selective pressures driving both social and communicative complexity [2,3]. Social complexity as experienced by group members can be affected by the level of differentiation of social relationships, where complexity increases as social relationships become more differentiated [4,5]. In a socially complex society individuals interact frequently with each other in diverse ways and in many different contexts [1]. If the types of interactions that individuals have is constrained, for example, by dominance or kinship, then social complexity decreases [1]. Social complexity is also affected by the predictability or consistency of social interactions [5,6]. When the behavior of social partners is unpredictable, such as when the dominance hierarchy is unstable, individuals likely perceive the social environment as more complex [6]. These operational definitions of social complexity are valuable to advance the study of social complexity but are not easy to quantify with a single measure [7]. Similarly, communicative complexity is also difficult to quantify. Many studies have used the number of signalling units as a measure of communicative complexity [2]. While a useful measure, it is not always apparent what a signaling unit is. For example, calls are sometimes graded on a continuous scale without a clear separation between different call types [8]. Fewer studies have investigated the complexity of non-vocal communication [1,2], but similar issues exist. One previous study quantified the repertoire of facial behavior in macaques by the number of discrete facial expressions that a species displays and found that it was positively correlated with conciliatory

tendency and counter-aggression across species [9]. However, classifying facial expressions into discrete categories (e.g., bared-teeth display) does not capture the full range of expressiveness and meanings that the face can convey. For example, subtle morphological variations in bared-teeth displays are associated with different outcomes of social interactions (e.g., affiliation versus submission) in crested macaques (Macaca nigra) [10]. A better approach is to quantify facial behavior at the level of individual facial muscle movements [11], which can be done using the Facial Action Coding System (FACS) [12]. In FACS, visible muscle contractions in the face are called Action Units and allow for a detailed and objective description of facial behavior [11,12]. Indeed, facial 67 mobility, as defined by the number of Action Units that a species has, is positively correlated with group size across non-human primates [13]. However, isolated muscle movements still do not account for the full diversity of facial behavior because facial muscles often contract simultaneously to produce a large variety of distinct facial expressions. 71 One promising avenue to approximate complexity in living organisms is to quantify the uncertainty or predictability of a system [14,15], which are general properties of complex systems [16,17]. Shannon's information entropy [18] is a measure of uncertainty that can be applied to animal communication. Conceptually, entropy measures the potential amount of information that a communication system holds, rather than what is actually communicated [18,19]. Entropy increases along two dimensions: (i) with increasing diversity of signals, and (ii) as the relative frequency of signal use becomes more balanced. For example, a system with three calls can hold more information than a system with one call and thus would have higher entropy. Likewise, a system with three calls used with equal frequency will have a higher entropy than another system that expresses one call more frequently than the two others. Uncertainty increases with entropy because each com-81 municative event has the potential to derive from a greater number of units. The relative entropy, or uncertainty, of different systems can be compared by calculating the ratio between the observed 83 and maximum entropy of each system.

The predictability and uncertainty of a communication system is also affected by how flexibly signals are used across different social contexts [5]. For instance, if signal A is always used in an

aggressive context and signal B is always used in an affiliative context, then it is easy to predict
the context from the signal. Conversely, if signals A and B are used in both contexts, then predictability is lower, and complexity is higher. Extremely rare signals do not substantially affect
the predictability of a system regardless of whether they have high or low specificity since they are
seldom observed in the majority of social interactions. Therefore, predictability is highest when
signals are both highly context-specific and occur in that context often. Additionally, predictability can be measured directly by training a machine learning classifier to predict the social context
that a given signal was used in. Differences in prediction error would approximate the relative
uncertainty and complexity, with accuracy being lower in more complex systems. However, as
complexity lies somewhere between order and randomness [15,19], we should still be able to predict the social contexts better than chance, even in a complex system.

Studying closely related species offers a robust means of testing the social complexity hypothesis due to their homologous communication systems. For this reason, macaques (genus *Macaca*) are excellent taxa to test the social complexity hypothesis. All species have a similar social organiza-100 tion consisting of multi-male, multi-female groups, but vary in social style in ways that are highly relevant to predictions of the social complexity hypothesis. The social styles of macaques consist of several covarying traits that can be ordered along a social tolerance scale ranging from the least 103 (grade 1) to most tolerant (grade 4) [20,21]. Social interactions for the least tolerant species, such 104 as rhesus (M. mulatta) and Japanese (M. fuscata) macaques, are generally more constrained by a 105 steep linear dominance hierarchy [22] and kinship [23–25]. Additionally, severe agonistic inter-106 actions are more frequent [25], instances of counter-aggression and reconciliation after conflicts 107 are rare [22,25], and formal signals of submission are commonly used [26,27]. Combined, these 108 behavioral traits indicate that agonistic interactions of the least tolerant species are more stereo-109 typed and formalized. Thus, the outcome of such interactions is more certain, whereas the opposite 110 is true for the most tolerant species, such as crested and Tonkean (M. tonkeana) macaques. The 111 unpredictability in the outcome of agonistic interactions of tolerant macaques likely results in a 112 social environment that is perceived as more complex by individuals [6], where more subtle means 113

of negotiation during conflicts may be necessary.

In this study we compared the facial behavior of three macaque species that vary in their degree 115 of social tolerance and, therefore, social complexity: rhesus (least tolerant), Barbary (M. sylvanus, 116 mid-tolerant), and crested macaques (most tolerant). For macaques (and primates in general), the 117 face is central to communication and is a key tool in allowing individuals to achieve their social 118 goals by communicating motivations, emotions and/or intentions [28,29]. We coded facial behav-110 ior at the level of individual visible muscle movements using FACS and recorded all observed 120 unique combinations, rather than classifying facial expressions into discrete categories. Based on 121 the social complexity hypothesis [1], we expected that tolerant species would have higher com-122 municative complexity, given that their social relationships are less constrained by dominance and 123 have higher overall uncertainty in the outcome of agonistic interactions. Specifically, we predicted the following: (1) relative entropy of facial behavior will be lowest in the rhesus and highest in crested macaques, (2) context specificity of facial behavior will be highest in rhesus and lowest in crested macagues, and (3) social context can be predicted from facial behavior most accurately in rhesus and least accurately in crested macaques. For all three metrics, we expected Barbary macaques to lie somewhere in between the rhesus and crested macaques.

Results

Entropy of facial behavior

To compare the relative uncertainty in the facial behavior of macaques, we defined facial behavior
by the unique combination of Action Units (facial muscle movements) that occurred at the same
time. We calculated the entropy ratio for each species and social context, defined as the ratio
between the observed entropy and the expected entropy if Action Units were used randomly. Values
closer to 0 indicate that there is low uncertainty (e.g., when only a few facial movements are used
frequently) and values closer to 1 indicate high uncertainty (e.g., when many facial movements are

used frequently). To determine whether the entropy ratios for each species differed within social context, we calculated the entropy ratio on 100 bootstrapped samples of the data, resulting in a distribution of possible values. The bootstrapped entropy ratio of facial behavior differed across species and within social contexts (Figure 1). In an affiliative context, the entropy ratio was highest for crested, then Barbary, and lowest for rhesus macaques (crested: mean = 0.52, range = 0.50–0.53; Barbary: mean = 0.45, range = 0.45–0.46; rhesus: mean = 0.38, range = 0.37–0.39). In an aggressive context, the entropy ratio was highest for crested, then rhesus and lowest for Barbary macaques (crested: mean = 0.62, range = 0.60–0.65; Barbary: mean = 0.32, range = 0.32–0.33; rhesus: mean = 0.48, range = 0.47–0.49). In a submissive context, the entropy ratio was highest for crested, then Barbary, and lowest for rhesus macaques. (crested: mean = 0.67, range = 0.64–0.70; Barbary: mean = 0.49, range = 0.48–0.50; rhesus: mean = 0.38, range = 0.37–0.39). Overall, across all contexts, including when the context was unclear, the entropy ratio was highest for crested, and similar for Barbary and rhesus macaques (crested: mean = 0.57, range = 0.56–0.58; Barbary: mean = 0.51, range = 0.51–0.51; rhesus: mean = 0.52, range = 0.51–0.52; Figure 1).

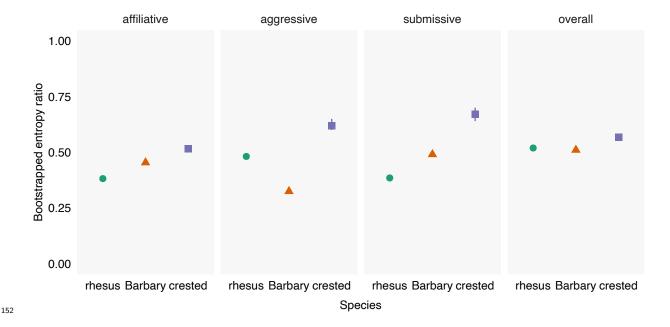

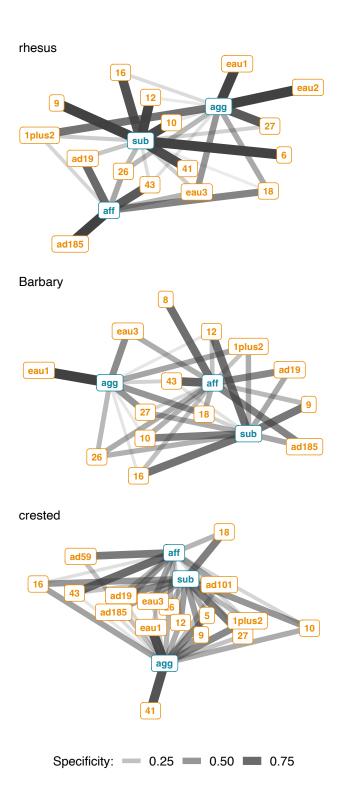

Figure 1: Bootstrapped entropy ratio of facial behavior across social contexts for three species of macaques. The entropy ratio was calculated on 100 bootstrapped samples of the data by dividing the observed entropy by the expected entropy if Action Units were used randomly for each social

context. The entropy ratio ranges from 0 to 1, with higher values indicating higher uncertainty.

Symbols and whiskers indicate mean and range of bootstrapped values.

SE Context specificity of facial behavior

We calculated the context specificity for all possible combinations of Action Units. Here we re-150 port specificity for combinations that were observed in at least 1% of observations per species and 160 social context because extremely rare signals do not affect the predictability of a system substan-161 tially, regardless of whether they have high or low specificity. Specificity for each Action Unit 162 combination was defined as the number of times it was observed in one context divided by the 163 total number of times it was observed across all contexts. When considering single Action Units, some were observed in only one context, but most were observed at least once in all three contexts for all three species (Figure 2). On average, single Action Units were observed in fewer contexts for rhesus (mean degree = 1.9), compared to Barbary (mean degree = 2.4), and crested macaques (mean degree = 2.6). The specificity of all Action Unit combinations used in an affiliative context 168 was highest for the rhesus macaques, then Barbary, and lowest for crested macaques (rhesus: mean 169 = 0.80, SD = 0.28, n = 69; Barbary: mean = 0.63, SD = 0.26, n = 450; crested: mean = 0.37, SD 170 = 0.26, n = 327; Figure 3a). The specificity of Action Unit combinations used in an aggressive 171 context was highest for rhesus, then crested, and lowest for Barbary macaques (rhesus: mean = 172 0.71, SD = 0.35, n = 83; Barbary: mean = 0.44, SD = 0.38, n = 64; crested: mean = 0.51, SD = 173 0.30, n = 281). The specificity of Action Unit combinations used in a submissive context was also 174 highest for rhesus, then crested, and lowest for Barbary macaques (rhesus: mean = 0.93, SD = 0.18, 175 n = 312; Barbary: mean = 0.61, SD = 0.18, n = 297; crested: mean = 0.70, SD = 0.21, n = 595). 176 The majority (>50%) of Action Unit combinations used by rhesus macaques had high specificity 177 (>0.8) in all three social contexts, whereas only a minority (<50%) of Action Unit combinations 178 used by Barbary and crested macaques had high specificity (Figure 3b).

180

Figure 2: Bipartite network of single Action Units (orange) and social context (blue) for three species of macaques. Edges are shown for Action Units that occurred in at least 1% of obser-

vations per context. Edge thickness and transparency are weighted by specificity, which ranges from 0 (indicating an Action Unit is never observed in a context) to 1 (indicating an Action Unit is only observed in one context). Context abbreviations: agg = aggressive, aff = affiliative, sub = submissive.

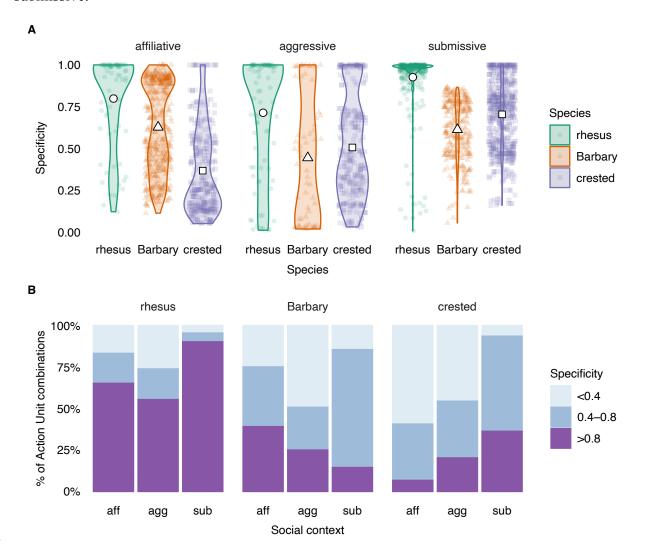

Figure 3: Specificity of Action Unit combinations that were used in at least 1% of observations per species per social context. Specificity ranges from 0 (indicating an Action Unit is never observed in a context) to 1 (indicating an Action Unit is only observed in one context). (**A**) Distribution of Action Unit combination specificity. Width of violin plots indicate the relative density of the data. Colored symbols indicate unique Action Unit combinations. White symbols indicate mean specificity. (**B**) Proportion of Action Unit combinations used with high (>0.8), moderate (0.4–

0.8) or low (<0.4) specificity. Context abbreviations: agg = aggressive, aff = affiliative, sub = submissive.

Predicting social context from facial behavior

A random forest classifier was able to predict social context (affiliative, aggressive or submissive)
from facial behavior with a better accuracy than expected by chance alone for all three species
of macaques. The classifier was most accurate for rhesus (kappa = 0.92), then Barbary (kappa =
0.68), and least accurate for crested macaques (kappa = 0.49). The confusion matrices for model
predictions are shown in table S1.

Discussion

We investigated the hypothesis that complex societies require more complex communication sys-203 tems [1] by comparing the complexity of facial behavior of three species of macaques that vary in their degree of social tolerance and complexity. We defined facial behavior by the unique combinations of muscle movements visible in the face. Doing so allows for a much more precise description of facial behavior and captures subtle differences that are lost if facial expressions are classified as discrete categories. We quantified communicative complexity using three measures of uncertainty 208 and predictability: entropy, context specificity, and prediction error. Collectively, our results sug-209 gest that the complexity of facial behavior is higher in species with a more tolerant—and therefore 210 more complex—social style; complexity was highest for crested, followed by Barbary, and low-211 est in rhesus macaques. In light of what we know about the differences between macaque social 212 systems, our results support the predictions of the social complexity hypothesis for communicative 213 complexity. 214

The entropy ratio of facial behavior was highest in crested compared to Barbary and rhesus macaques, both overall and within each social context (affiliative, aggressive, submissive). This

result suggests that crested macaques use a higher diversity of facial signals within each social context more frequently, resulting in the higher relative uncertainty in their use of facial behavior. 218 Information theory defines information as the reduction in uncertainty once an outcome is learned [18]. By this definition, our data suggest that the facial behavior of crested macaques has the 220 potential to communicate more information, compared to Barbary and rhesus macaques, although 221 this would need to be explicitly tested in future studies. Our findings are in line with predictions 222 of the social complexity hypothesis [1] given the differences in social styles between tolerant and 223 intolerant macaques. In tolerant macaque societies, social interactions are less constrained by 224 dominance [22] such that rates of counter aggression and reconciliation post-conflict are higher 225 Thus, there is a greater variability in the kind of interactions that individuals have, 226 potentially requiring the use of more diverse facial behavior to achieve social goals, particularly 227 during conflicts. Similarly, strongly bonded chimpanzee (*Pan troglodytes*) dyads exhibit a larger 228 repertoire of gestural communication than non-bonded dyads, presumably due to the former 229 having more varied types of social interactions [31]. 230

The overall entropy ratio of rhesus and Barbary macaques was similar, suggesting that they have similar communicative capacity using facial behavior. However, the entropy ratio differed when compared within social contexts; while relative entropy was higher for Barbary macaques in af-233 filiative and submissive contexts, it was higher for rhesus macaques in aggressive contexts. One 234 possible explanation may be due to the use of stereotyped signals of submission and dominance in 235 each species. For example, subordinate rhesus macaques regularly exhibit stereotyped signals of 236 submission (silent-bared-teeth), whereas dominant Barbary macaques regularly exhibit stereotyped 237 threats (round-open-mouth) [26,27]. Frequent use of a stereotyped signal within a context reduces 238 the overall diversity of signals, resulting in a lower entropy ratio for submission and aggression in 239 rhesus and Barbary macaques, respectively. It has been suggested that in societies with high power 240 asymmetries between individuals, such as in rhesus macaques, spontaneous signals of submission 241 serve to prevent conflicts from escalating as well as increasing the tolerance of dominant individuals 242 toward subordinates [27]. In societies with more moderate power asymmetries, such as in Barbary

macaques, subordinates may be less motivated to spontaneously submit and thus dominants may need to assert their dominance with formalized threats more frequently [27].

While the entropy ratio captures the uncertainty of facial behavior used within a social context, 246 context specificity captures the uncertainty generated when the same facial behavior is used flexi-247 bly across different social contexts. Overall, the context specificity of facial behavior was higher 248 for the intolerant rhesus macaques as compared to the more tolerant Barbary and crested macaques 240 across all three social contexts. This pattern occurred for both the mean specificity values and the 250 proportion of Action Unit combinations used that had high (>0.8) specificity. Similarly, a previous 251 study demonstrated that vocal calls of tolerant macaques are less context specific than in intoler-252 ant macaques [32]. There was not a clear difference in specificity between Barbary and crested 253 macaques; specificity was higher for Barbary macaques in affiliative contexts, similar for both 254 species in aggressive contexts, and higher for crested macaques in submissive contexts. These dif-255 ferences in context specificity of communicative signals across macaque species may be related to differences in power asymmetry in their respective societies, particularly as it relates to the risk of injury. For macaques, bites are far more likely to injure opponents than other types of contact aggression (e.g., grab, slap) and thus provide the best proxy for risk of injury [21]. The percentage of conflicts involving bites is much higher in the less tolerant rhesus macaque, compared to the 260 more tolerant Barbary and crested macaques who have similar low rates of aggression involving 261 bites [25,33]. Risky situations may promote the evolution of more conspicuous, stereotypical sig-262 nals to reduce ambiguity [34]. Indeed, intolerant macaques such as the rhesus more commonly use 263 formal signals of submission [26,27]. In our study, rhesus macaques used facial behavior with high 264 specificity across all contexts but particularly in submissive contexts. If the same facial behavior 265 (or signal in general) is used in multiple social contexts, its meaning may be uncertain and must 266 be deduced from additional contextual cues [35]. When facial behavior is highly context specific, 267 there is less uncertainty about the meaning of the signal and/or intention of the signaler. In a society 268 where the risk of injury from aggression is high, it may be adaptive for individuals to use signals that 260 are highly context specific or ritualized to reduce uncertainty about its meaning. By contrast, the

lower risk of injury in Barbary and crested macaques may allow room for more nuanced exchanges of information during conflicts as well as higher rates of reconciliation post conflict [25,30]. In all three species of macagues, at least some facial muscle movements had low specificity and 273 were therefore used across multiple social contexts that likely differed in valence. This finding is 274 in line with the idea that communicative signals in primates are better interpreted as the signaler 275 announcing its intentions and likely future behavior [36,37], and not necessarily as an expression 276 of emotional state [28,29,36,38]. 277 We found that a random forest classifier was least accurate at predicting social context from facial 278 behavior for crested, followed by Barbary, and then rhesus macaques. The behavior of complex systems is generally harder to predict than simpler ones [16,17]. Thus, the relatively poorer performance of the classifier in crested macaques suggests that they have the most complex facial behavior. Nevertheless, the classifier was able to predict social context from facial behavior with better 282 accuracy than expected by chance alone for all three species of macaque, including the crested. 283 This result confirms the assumption that facial behavior in macagues is not used randomly and 284 most likely has some communicative or predictive value [39]. Completely random systems are not 285 considered complex [19], but the communications systems of living organisms are unlikely to be 286 observed as random. Therefore, measuring uncertainty becomes a good proxy for complexity [14]. 287 In addition to social complexity, it is possible that other factors are related to the complexity of 288 facial behavior. For example, primates with a larger body size have greater facial mobility [13,40], 289 which could allow for greater complexity of facial behavior. However, differences in mean body mass across the three macaques species of this study are small (rhesus: 6.5 kg; Barbary: 11.5 kg; crested: 7.4 kg) [41] with substantial overlap in body weight across adult individuals of the different species [42], and so it is unlikely to explain the differences in the complexity of facial behavior that we report in this study. The degree of terrestriality could also influence the evolution of facial signals due to more limited visibility in the canopy. However, differences in facial mobility 295 across terrestrial and non-terrestrial primates are not significant once body size is controlled for

[13]. Furthermore, all three species included in this study have comparable levels of terrestriality, spending the majority (52-72%) of the time on the ground [43–45]. Spatial spread and predation pressure could potentially also influence the use of facial signals. For example, when group spread is higher, reliance on facial signals could be lower, or when predation pressure is higher, reliance on facial signals could be higher. There are currently no reliable data on predation pressure and spatial spread of the three species in their natural habitat but it could be a good avenue for future studies.

Our results on the complexity of facial behavior in macaques is mirrored by previous studies show-304 ing that the complexity of vocal calls is similarly higher in tolerant compared to intolerant macaques 305 [32,46]. Although not all macaque facial expressions have a vocal component, vocalizations are 306 fundamentally multisensory with both auditory and visual components, where different facial mus-307 cle contractions are partly responsible for different-sounding vocalizations [47]. Indeed, some areas of the brain in primates integrate visual and auditory information resulting in behavioral benefits [48]. For example, macaques detect vocalizations in a noisy environment faster when mouth move-310 ments are also visible, where faster reaction times are associated with a reduced latency in auditory cortical spiking activity [49]. Combined, these findings suggest that the evolution in the complexity of vocal and facial signals in macaques may be linked and the same may be true of primates in 313 general. For instance, humans not only have the most complex calls (language) and gestures, but 314 most likely use the most complex facial behavior as well, given that their general facial mobility 315 is highest among primates (most Action Units) [12,50]. In lemurs (Lemuriformes), the repertoire 316 size of vocal, visual, and olfactory signals positively correlate with group size and each other, sug-317 gesting that complexity in all three communicative modalities coevolved with social complexity 318 [51]. While the complexity of different communication modalities is likely interlinked and cor-319 related with each other, future studies would ideally integrate signals from all modalities into a 320 single communicative repertoire for each species. While collecting and analyzing data on multiple 321 modalities of communication has historically been a challenge, such endeavors would be an im-322 portant next step in the study of animal communication [52]. By breaking down signaling units to their smallest components, as we have done for facial behavior in this study, we may be able to define a "signal" by temporal co-activation of visual, auditory, and perhaps even olfactory cues, which would provide the most comprehensive picture of animal communication.

7 Methods

Study subjects and data collection

Behavioral data and video recordings were collected on one adult male and 31 adult female rhesus macaques (M. mulatta), on 18 adult male and 28 adult female Barbary macaques (M. sylvanus), and 17 adult male and 21 adult female crested macaques (M. nigra). See supplementary text for 331 further details. For all study groups and subjects, focal animal observations [53] lasting 15-30 minutes were con-333 ducted throughout the day in a pseudo-randomized order such that the number of days and time of 334 day that each individual was observed was balanced. Videos of social interactions were recorded 335 with a recording camera (Panasonic HDC-SD700, Bracknell, UK) during focal animal observations 336 as well as ad libitum. Social behavior, including grooming, body contact, and agonistic interactions 337 were recorded using a handheld smartphone or tablet with purpose-built software (rhesus: Animal 338 Behavior Pro [54]; Barbary: CyberTracker (http://cybertracker.org), crested: Microsoft Excel). 330

Facial behavior and social context coding

Facial behavior was coded at the level of observable individual muscle movements using the Facial Action Coding System (FACS) [12], adapted for each species of macaque (MaqFACS): rhesus [55], Barbary [56], crested [10]. In FACS, individual observable muscle contractions are coded as unique Action Units (AU; e.g., upper lip raiser AU10). Some common facial movements where the underlying muscle is unknown are coded as Action Descriptors (AD; e.g., jaw thrust AD29). In

MagFACS, the lip-pucker AU18 has two subtle variations normally denoted as AU18i and AU18ii [55,56]. However, it was often difficult to reliably distinguish between these two subtle variations when coding videos, and so the lip-pucker was simply coded as AU18. We added a new Action Descriptor 185 (AD185) called jaw-oscillation, to denote the stereotyped movement of the jaw up and 340 down. When combined with existing Action Units of lip movements, the jaw-oscillation AD185 350 allows for a more detailed and accurate coding of some facial behaviors that would otherwise be 351 labeled as lipsmack (AD181), teeth-chatter, or jaw-wobble [10,55]. A complete list of Action Units 352 and Action Descriptors coded in this study is given in table S2. 353 We coded facial behavior of adult individuals but included their interactions with any other group 354 member regardless of age or sex. Each social interaction was labeled with a context; aggressive, 355 submissive, affiliative, or unclear. We did not consider interactions in a sexual context because data 356 for the rhesus macaques were only collected during the non-mating season. Social context was la-357 beled from the point of view of the signaler based on their general behavior and body language (but not the facial behavior itself), during or immediately following the facial behavior. An aggressive 359 context was considered when the signaler lunged or leaned forward with the body or head, charged, chased, or physically hit the interaction partner. A submissive context was considered when the 361 signaler leaned back with the body or head, moved away, or fled from the interaction partner. An 362 affiliative context was considered when the signaler approached another individual without aggres-363 sion (as defined previously) and remained in proximity, in relaxed body contact, or groomed either 364 during or immediately after the facial behavior. In cases where the behavior of the signaler did not 365 match our context definitions, or displayed behaviors belonging to multiple contexts, we labeled 366 the social context as unclear. Social context was determined from the video itself and/or from the 367 matching focal behavioral data, if available. Videos were FACS coded frame-by-frame using the 368 software BORIS [57] by AVR, CP and PRC, who are certified FACS and MaqFACS coders. Table 360 1 shows the number of social interactions per species and context from which FACS codes were 370

made.

Table 1: Total number of social interactions per species and social context that were MaqFACS coded.

Species	Context	N interactions	N subjects
rhesus	affiliative	193	29
	aggressive	413	32
	submissive	318	31
	unclear	121	30
Barbary	affiliative	683	43
	aggressive	585	44
	submissive	529	34
	unclear	603	45
crested	affiliative	241	35
	aggressive	62	23
	submissive	25	18
	unclear	107	25

Statistical analyses

Prior to analyses, MaqFACS data were formatted as a binary matrix with Action Units and Action
Descriptors (hereafter simply Action Units) in the columns. Each row denoted an observation time
block of 500ms, where if an Action Unit was active during this time block, it was coded 1 and coded
0 if not. Thus, each row contained information on the combination of facial muscle movements
that were co-activated within a 500ms time window. All statistical analyses were conducted in R
(version 4.2.1) [58].

The observed entropy for each social context was calculated using Shannon's information entropy formula [18]:

$$H = -\sum_{i}^{n} p_{i} \log p_{i}$$

where n is the number of unique Action Unit combinations and p is the probability of observing each Action Unit combination in each social context. The expected maximum entropy was 384 calculated by randomizing the data matrix while keeping the number of active Action Units per 385 observation (row) the same. This process was repeated 100 times and the mean of the randomized 386 entropy values was used as the expected entropy. Therefore, the expected entropy indicated the 387 entropy of the system if facial muscle contractions occurred at random, while keeping the com-388 bination size of co-active muscle movements within the range observed in the data. The entropy 380 ratio was calculated by dividing the observed entropy by the expected (maximum) entropy. To determine whether the entropy ratios for each species differed within social context, the entropy ratio was calculated on 100 bootstrapped samples of the data, resulting in a distribution of possible entropy ratios. If the distribution of bootstrapped entropy ratios did not overlap, the differences between entropy ratios were considered to be meaningful.

We calculated the specificity with which Action Unit combinations are associated with a social con-395 text within each species using the function "specificity" from the R package "NetFACS" (version 396 0.5.0) [59]. Due to an imbalanced number of observations across social contexts, contexts with 397 fewer observations were randomly upsampled prior to the specificity calculation. During the up-398 sampling procedure all observations of the minority contexts were kept, and new observations were 390 randomly sampled to match the number of observations in the majority context. This procedure 400 corrects for any bias in the specificity results from an imbalanced dataset (see fig. S1). Specificity 401 is the conditional probability of a social context given that an Action Unit combination is observed, 402 and ranges from 0 (when an Action Unit combination is never observed in a context) to 1 (when 403 an Action Unit is only observed in one context). Low specificity values indicate that Action Units were used flexibly across multiple contexts whereas high values indicate that Action Units were 405 used primarily in a single context. Specificity was calculated for all Action Unit combination sizes

ranging from 1 to 11 (the maximum observed combination size) co-active Action Units. When reporting context specificity results, we excluded Action Unit combinations that occurred in less than 1% of observations within a social context because extremely rare signals do not impact the predictability of a communication system regardless of whether specificity is low or high. There-410 fore, excluding rare Action Unit combinations removes noise from the specificity results. We report 411 the mean specificity of Action Unit combinations per social context and the proportion of Action 412 Unit combinations that have high, moderate, or low specificity. For single Action Units we plotted 413 bipartite networks that show how Action Units are connected to social context weighted by their 414 specificity. 415 To predict social context from the combination of Action Units we fit a random forest classifier us-416 ing the "tidymodels" R package (version 1.0.0) [60] using the function "ran forest" with the engine 417 set to "ranger" [61], 500 trees, 4 predictor columns randomly sampled at each split, and 10 as the 418 minimum number of data points in a node required for splitting further. The data were randomly split into a training set (70%) and a test set (30%), while keeping the proportion of observations 420 per social context the same in the training and test sets. Due to an imbalanced number of observations across social contexts, contexts with fewer observations were over-sampled in the training set using the SMOTE algorithm [62] to improve the classifier predictions. To assess the classifier 423 performance, we report the kappa statistic, which denotes the observed accuracy corrected for the 424 expected accuracy [63]. Kappa is 0 when the classifier performs at chance level and 1 when it 425 shows perfect classification. Kappa values between 0 and 1 indicate how much better the classi-426 fier performed than chance (e.g., kappa of 0.5 indicates the classifier was 50% better than chance). 427 Kappa is a more reliable estimate of model performance than accuracy alone when the relative 428

sample size for each context is imbalanced, as was the case with our data.

Acknowledgments

We thank the German Primate Center (DPZ) for permission to collect data on the rhesus macaques,

Uwe Schönmann for logistical support, and Julia Ostner for being our host at the DPZ. We thank

Matt Lowatt and Ellen Merz for permission to collect data on the Barbary macaques at Trentham

434 Monkey Forest. We thank the Indonesian State Ministry of Research and Technology (RISTEK),

the Directorate General of Forest Protection and Nature Conservation (PHKA) and the Department

for the Conservation of Natural Resources (BKSDA), North Sulawesi, for permission to access

groups of crested macaques in the Tangkoko-Batuangus Nature Reserve. We thank Christof Neu-

mann for statistical advice. This work was funded by the Leverhulme Trust (RPG2018-334).

Ethics

This work adhered to the Guidelines for the treatment of animals in behavioral research and teach-

ing [64] and was approved by the Animal Welfare and Ethical Review Body of the University of

Portsmouth (AWERB, approval number: 919B). The AWERB uses UK Home Office guidelines

on the Animals (Scientific Procedures) Act 1986 when assessing proposals and adheres to the reg-

ulations of the European Directive 2010/63/EU. The German Primate Center also complies with

the European Directive 2010/63/EU, as well as with the provisions of the German Animal Welfare

446 Act.

Data availability

The data and R code used for all statistical analysis is available on GitHub, https://github.com/
