Aberrant kinase activity contributes to the pathogenesis of brain cancers, neurodegeneration, and neuropsychiatric diseases, but identifying kinase inhibitors that function in the brain is challenging. Drug levels in blood do not predict efficacy in the brain because the blood-brain barrier prevents entry of most compounds. Rather, assessing kinase inhibition in the brain requires tissue dissection and biochemical analysis, a time-consuming and resource-intensive process. Here, we report kinase-modulated bioluminescent indicators (KiMBIs) for non-invasive longitudinal imaging of drug activity in the brain based on a recently optimized luciferase-luciferin system. We develop an ERK KiMBI to report inhibitors of the Ras-Raf-MEK-ERK pathway, for which no bioluminescent indicators previously existed. ERK KiMBI discriminates between brain-penetrant and non-penetrant MEK inhibitors, reveals blood-tumor barrier leakiness in xenograft models, and reports MEK inhibitor pharmacodynamics in native brain tissues and intracranial xenografts. Finally, we use ERK KiMBI to screen ERK inhibitors for brain efficacy, identifying temuterkib as a promising brain-active ERK inhibitor, a result not predicted from chemical characteristics alone. Thus, KiMBIs enable the rapid identification and pharmacodynamic characterization of kinase inhibitors suitable for treating brain diseases.

Aberrant kinase activity drives pathogenesis of multiple diseases of the central nervous system, including primary brain neoplasms and metastatic cancers in the brain[1–4], neurodegenerative disorders such as Alzheimer's and Parkinson's diseases[5,6], and psychiatric disorders such as bipolar disease and schizophrenia[7]. However, most kinase pathway inhibitors previously developed to treat disorders outside the brain do not efficiently cross the blood-brain barrier (BBB)[1,3,6]. As a result, there is intense interest in developing new drugs to effectively inhibit specific kinase pathways in the brain[1,3,6].

Brain-permeant inhibitors of the Ras-Raf-MEK-ERK pathway would have an especially wide range of potential applications. This pathway (hereafter the Ras-ERK pathway) is hyperactivated in a large fraction of solid tumors, many of which metastasize to the brain[3,4]. For instance, mutations are commonly observed in the upstream receptor tyrosine kinases EGFR and HER2 in brain metastases of lung and breast cancer, and in B-Raf in melanoma[4]. No inhibitors of Ras-ERK pathway components have been specifically approved for brain tumors, although numerous ones are under clinical investigation[1–4,8]. Inhibitors approved for extracranial cancers can be administered to patients with brain metastases of the primary tumors, but results are typically mixed, and only recently have clinical trials specifically for brain metastases been performed[4]. Thus, rapid assessment of the intracranial activity of Ras-ERK pathway inhibitors in vivo would be useful for identifying which approved or experimental compounds may be most successful.

In typical drug discovery efforts, candidate molecules with appropriate in vitro potency and selectivity are screened for suitable pharmacokinetics prior to commencing expensive in vivo efficacy studies. For indications outside of the brain, pharmacokinetics is typically assessed by measuring drug concentrations in blood at different times after administration. However, drug concentrations in blood differ from concentrations in the brain due to the BBB[9]. Thus, in the case of brain targets, pharmacokinetics requires obtaining brain tissue at various times after drug administration, which is a terminal low-throughput procedure. An alternative way to determine drug concentrations

in the brain would be to label candidate drugs with a radioactive element for imaging by PET or SPECT[10], but this requires a synthetic pathway to incorporate the isotope, plus specialized expertise and equipment.

Another fundamental challenge is that pharmacokinetics can differ from pharmacodynamics, i.e., how the drug target responds over time. Cell type-specific drug export or metabolism may limit drug efficacy even with high drug levels in the surrounding tissue[11,12]. Accurate assessment of kinase inhibition can be especially problematic for brain cancers, where cancer cells can be dispersed amongst a larger number of normal cells. One solution is to perform immunocytochemistry with phosphorylation-specific antibodies to specific kinase substrates and with cancer-specific markers, allowing some determination of phosphorylation levels specifically in cancer cells[13]. However, this approach is highly time-consuming, resource-intensive, and requires high-quality phosphorylation-specific antibodies that may not exist for every drug target. Given these limitations of current methods to assess pharmacodynamics in the brain, a fast and inexpensive approach to evaluating kinase inhibitor activity within target cells in the brain would be highly desirable.

Noninvasive imaging of kinase activity with genetically encoded biosensors could be one way to assess kinase inhibitor pharmacodynamics within target tissues in small animal models. To provide a near-real-time report of target engagement, the indicator kinetics with similar timescales as drug pharmacokinetics are needed, making transcription-based reporters unsuitable. Fluorescent protein-based reporters of kinase activity respond rapidly[14], but fluorescence is poorly suited for non-invasive quantitative imaging through tissue. A more suitable approach is to engineer a bioluminescent enzyme whose activity can be directly modulated by kinase activity, as bioluminescence can be detected from essentially any location in the mouse brain with high signal-to-background ratios. However, past bioluminescent reporters[15,16] of kinase activity were based on firefly luciferase (FLuc), which produces an order of magnitude less light from the brain compared to modern luciferases[17]. In addition, surprisingly, no bioluminescent indicator of the Ras-ERK pathway of any type has been reported in the literature.

Here, we report the development of kinase-modulated bioluminescent indicators (KiMBIs) for real-time visualization of kinase inhibition in living animals, including in the brain, through molecular engineering of the luciferase NanoLuc, for which a substrate with improved performance in the brain was recently developed (Su et al., in press). Given the importance of the Ras-ERK pathway in brain malignancies, we developed and extensively optimized an ERK KiMBI to achieve a 10-fold response to ERK pathway inhibition. ERK KiMBI expressed in the mouse brain differentiated between brain permeant and impermeant inhibitors of the ERK activator mitogen-activated protein kinase kinase (MAPKK or MEK). ERK KiMBI also revealed that the BBB is disrupted in common xenograft models of glioma. In addition, KiMBI could track the pharmacodynamics of kinase inhibition over time in the same mouse, whereas pharmacodynamics using traditional tissue sampling methods would require a large number of animals. Finally, we used KiMBI to characterize the in-brain efficacy of ERK inhibitors in clinical trials. We identify LY3214996 (temuterkib) as a brain-active ERK inhibitor and discover that theoretically predicted BBB permeability and empirically determined in-brain efficacy are uncorrelated.

Results
Design and development of KiMBIs. To develop reporters that produce light upon kinase inhibition, we hypothesized that the catalytic activity of NanoLuc luciferase could be modulated through interactions between phosphorylated substrates (pSub) and phosphopeptide-binding domains (PBDs). The NanoBiT version of NanoLuc can be split after amino acid 156 in the loop before the last beta-strand, producing complementing fragments LgBiT and SmBiT, with SmBiT available as different affinity variants[18]. We postulated that inserting a PBD (or kinase substrate) between LgBiT and SmBiT, and fusing the cognate substrate (or PBD) elsewhere in the protein, could confer dephosphorylation-dependence on the enzymatic activity of NanoBiT. Specifically, when a phosphorylating kinase is highly active, the PBD-pSub interaction could tether the SmBiT in a conformation incompatible with binding to LgBiT, effectively competing with the weaker LgBiT-SmBiT interaction. In contrast, if the kinase or an upstream kinase is inhibited by a kinase inhibitor, then ongoing dephosphorylation could shift the equilibrium of conformational states toward LgBiT-SmBiT interaction, resulting in light production (**Fig. 1a**).

We first tested our design concept using a PKA substrate and a cognate FHA domain[19]. We generated proteins with the topology LgBiT-FHA-linker-substrate-SmBiT, screening various linker lengths to allow the phosphorylated substrate to reach its binding site on FHA. Proteins were expressed in mammalian cells, which were then treated with forskolin and IBMX to activate endogenous PKA. All constructs showed lower bioluminescence with PKA activation, with the longest linker (44 amino acids) producing the largest induction (**Fig. 1b**).

Given the importance of the Ras-ERK pathway in human disease, we next aimed to develop a bioluminescent indicator for ERK inhibition. We created and tested fusion proteins of various topologies (**Supplementary Fig. 1a**) comprising the NanoBiT fragments, an ERK substrate peptide from Cdc25C[20], and a proline-directed WW phospho-binding domain (WW)[21] from Pin1. We screened the KiMBI candidates by co-transfection with a constitutively active MEK (caMEK) followed by treatment with the ERK inhibitor Vx-11e. One topology produced an increase in luminescence ($\Delta L/L$) of ~65% when treated with 1 μM Vx-11e (**Supplementary Fig. 1a**). In this top responder (LgBiT-WW-SmBiT-substrate), binding of pSub to WW is expected to force the SmBiT fragment to adopt an unfavorable conformation for its complementation with the LgBiT, while substrate dephosphorylation should allow LgBiT-SmBiT complementation and luciferase activity restoration (**Fig. 1c**). These results demonstrate that bioluminescent indicators of kinase inhibition can be engineered on the general concept of PBD-pSub binding competing with LgBiT-SmBiT binding.

Optimization and characterization of the ERK KiMBI prototype. We next explored optimizing the performance of ERK KiMBI. Based on the proposed mechanism of action, we reasoned that disfavoring LgBiT-SmBiT complementation or enhancing WW-phosphosubstrate binding could lower the background signals when ERK is active, thus improving the signal fold change upon inhibitor treatment. By screening truncated or mutated SmBiT variants, we found truncation of 3 amino acids (aa) from the SmBiT C-terminus (CT) improved the response to ~3-fold (ΔC3, **Supplementary Fig. 1b**). We then further improved ΔC3 by introducing a second ERK phosphorylation site at position –3 within the Cdc25C substrate sequence to increase WW-pSub avidity. This change improved the induction to 8.8-fold (ΔC3 V–3S, **Supplementary Fig. 1c**). Substitution of either the additional (serine, position –3) or original (threonine, position 0, **Supplementary Fig. 1c**) phosphorylation site with alanine notably decreased the drug response, suggesting that both sites are phosphorylated by ERK and recognized by the WW domain (**Supplementary Fig. 1d**). Finally, we further strengthened WW-phosphosubstrate binding by introducing an F25A mutation in the WW domain[22] (**Supplementary Fig. 1e**). The resulting construct showed a >10-fold response by Vx-11e, and was named ERK blue KiMBI (bKiMBI, **Supplementary Fig. 1e).**

We validated bKiMBI function in cancer cell lines with hyperactive ERK, choosing U87 (human glioma), U87-EGFRvIII (U87 expressing epidermal growth factor receptor variant III, which further activates ERK), and SK-OV-3 (human ovarian cancer). As expected, bKiMBI showed significant signal increases after ERK inhibition in all tested cell lines. U87-EGFRvIII exhibited a lower basal KiMBI signal than U87, consistent with its higher basal ERK activity due to the upstream constitutive activator EGFRvIII (**Fig. 1d**). Endogenous ERK activity in these cell lines appeared to be only partially activated, as co-expressing caMEK further suppressed basal KiMBI signal. Also, we found that ERK bKiMBI was activated by various MEK or ERK inhibitors, but not by any JNK or p38 inhibitors (**Fig. 1e**). This provides additional evidence that KiMBI responds positively to ERK inhibition, and argues against inhibitors directly binding KiMBIs to enhance NanoLuc assembly or catalysis. As a control, we also tested the effects of kinase inhibitors on a phosphosite mutant of ERK bKiMBI (bKiMBImut, A-A in **Supplementary Fig. 1e**); this revealed no response to kinase inhibition.

Next, to red-shift KiMBI emission for better tissue penetration *in vivo*, we explored fusing fluorescent proteins to bKiMBI to allow resonance energy transfer (RET). Although constructs in the early rounds of engineering included a CyOFP1[23] at their N-terminus, there was no detectable RET between the reconstituted NanoBiT and CyOFP1 (**Supplementary Fig. 1f,g**). Following the example of Antares luciferase[23], we tried fusing a second CyOFP1 domain to the C-terminus of the ΔC3 V–3S KiMBI precursor. Only the additional fusion of a C-terminal CyOFP1 with a 2-aa linker improved RET efficiency, but it also increased background luminescence and diminished the response to ERK inhibition (C6, **Supplementary Fig. 1f,g**). To rescue the response, we weakened the ability of SmBiT to bind LgBiT by performing alanine scanning followed by further mutagenesis, resulting in an optimized L163E mutation (**Supplementary Fig. 1h, Table S1** and **Table S2**). The resulting construct, named orange KiMBI (oKiMBI), maintained high RET while restoring most of the inducibility of bKiMBI (**Fig. 1f**).

We also tested other potential RET acceptors fused to the N-terminus of LgBiT in place of CyOFP in bKiMBI (**Table S3**). Fusion with tdTomato allowed a high amount of RET and even better inducibility by the inhibitor (**Fig. 1f** and **Table S3**), and was named tomato KiMBI (tKiMBI). Interestingly, the F25A mutation that had improved bKiMBI responses did not improve oKiMBI or tKiMBI responses, so Phe-25 was retained in these variants (**Supplementary Fig. 1i**). oKiMBI and tKiMBI were activated by all MEK or ERK inhibitors tested, but not by JNK or p38 inhibitors (**Supplementary Fig. 1j,k**), reconfirming specificity for ERK inhibitors.

We finally attempted to further improve tKiMBI responsivity by duplicating the WW domain and substrate peptide to add avidity and reduce signal in the kinase-active state (**Supplementary Fig. 2a,b**). Relative responses did indeed improve (**Supplementary Fig. 2c**), but maximal brightness and induction kinetics of the sensor were impaired (**Supplementary Fig. 2c,d**). Thus, we chose the original design of tKiMBI for further application in vivo.

Molecular imaging of ERK inhibition in a subcutaneous tumor xenograft model. To report ERK kinase inhibition in human tumor xenografts in mice, we first generated U87-EGFRvIII stable cell lines expressing tKiMBI. U87-EGFRvIII cells were transduced with lentiviruses expressing tKiMBI-T2A-AkaLuc, where AkaLuc allows kinase-independent tracking of tumor location and size (**Fig. 2a** and **Supplementary Fig. 3a**). Transduced cells were sorted by fluorescence-activated cell sorting (FACS) and selected by antibiotics to generate polyclonal stable cell lines. A control reporter cell line expressing the phosphosite mutant of tKiMBI (tKiMBImut) was generated in parallel, and the expression of the indicators was confirmed by fluorescence microscopy (**Supplementary Fig. 3b**).

These U87-EGFRvIII cells stably expressing tKiMBI exhibited ~4-fold bioluminescence increases upon treatment with mirdametinib (MEK inhibitor, previously PD0325901), trametinib (MEK inhibitor, GSK1120212), or SCH772984 (ERK inhibitor) (**Supplementary Fig. 3c**). In contrast, the tKiMBImut-expressing cells did not show induction of bioluminescence by these inhibitors. Thus, stably expressed tKiMBI responded to MEK or ERK inhibitors similarly to transiently expressed tKiMBI.

Fig. 2. Molecular imaging of Ras-ERK pathway inhibition in a subcutaneous tumor model. a, *Scheme of the experimental design. U87-EGFRvIII reporter cells expressing tKiMBI (right) and tKiMBImut (left) were implanted subcutaneously to establish tumors in J:NU mice. AkaLuc imaging with AkaLumine injection was used to monitor tumor growth. To visualize ERK inhibition, the indicators were imaged with FFz injection, 2 h before and 2 h after treatment with MEK-ERK inhibitors. All injections were performed intraperitoneally (i.p.).* **b,** *Scheme of ERK signaling pathway and MEK inhibition.* **c-d,** *U87-EGFRvIII tumor-bearing mice were sequentially treated (two days apart) with MEK inhibitors mirdametinib (**c**) and trametinib (**d**) and were imaged with FFz injection 2 h after inhibitor injection. Left, representative bioluminescent images collected before and after inhibitor treatment. Right, the percentage change of bioluminescence signals collected before and after inhibitor treatment. Each line represents an individual mouse. P values, paired two-tailed Student's t-test. L, luminescence.*

We then assessed the ability of tKiMBI to report ERK pathway inhibition in tumors in vivo by the clinically approved MEK inhibitors mirdametinib and trametinib (**Fig. 2b**, **Supplementary Fig. 4a**). Mice were injected subcutaneously with 10^6 tKiMBI-expressing cells on one side and, to control for differences in substrate delivery between injections, tKiMBI$_{mut}$-expressing reporter cells on the other side (**Fig. 2a**). One week after tumor cells implantation, sizes of the engrafted tumors were quantified by measuring peak AkaLuc bioluminescence after injecting AkaLumine (**Supplementary Fig. 4b**). We then imaged tKiMBI bioluminescence before or 2 h after injection of mirdametinib by administering the NanoLuc substrate fluorofurimazine (FFz)[17]. We saw a clear signal increase after mirdametinib treatment in the tKiMBI-expressing tumor, but not in the tKiMBI$_{mut}$-expressing tumor (**Fig. 2c, Supplementary Fig. 4c,d**). On average, tKiMBI responded to mirdametinib with a 120% increase in brightness, significantly different from the –20% signal change of tKiMBI$_{mut}$ (**Fig. 2c**). This result illustrates the ability of tKiMBI to report ERK inhibition within tumor cells in vivo.

An advantage of non-invasive tKiMBI imaging is that multiple kinase inhibitor candidates can be tested in one mouse by repeating the imaging procedure. For example, after waiting 2 days for injected mirdametinib to clear, a second test on the same group of mice with trametinib also revealed successful ERK pathway inhibition (**Fig. 2d, Supplementary Fig. 4e,f**). Thus, tKiMBI allows multiple kinase inhibitors to be tested and compared in a single mouse.

Reporting BBB permeability of kinase inhibitors by expressing KiMBI in the brain. For kinase inhibitors to effectively treat brain tumors, BBB permeability is crucial. Gliomas in the central nervous system can be either diffusively infiltrating without BBB breakdown, or can create large masses with central regions of BBB remodeling, forming a blood-tumor-barrier (BTB) that is typically more permeable[24]. However, even in gliomas with permeable BTBs, cancer cells migrate centrifugally into regions of brain parenchyma with intact BBB[25]. Indeed, most gliomas recur after the removal of the visible tumor due to the difficulty of completely removing these infiltrative tumor cells. Kinase inhibitors that can penetrate the BBB thus are more likely to be effective for diffusing tumors and for preventing the recurrence of gliomas after surgery.

Having validated tKiMBI's ability to respond to MEK inhibitors in vivo, we next asked whether tKiMBI expressed in the brain could provide a rapid method for assessing BBB permeability of kinase inhibitors. To report the BBB permeability of Ras-ERK pathway inhibitors, we used AAV to co-express tKiMBI and caMEK in mouse brains, where caMEK serves to raise the baseline level of ERK activity (**Fig. 3a**). Since the stoichiometric ratio between caMEK and tKiMBI may affect the performance of the sensor, we compared bicistronic reporter genes with opposite arrangements, caMEK-T2A-tKiMBI (A1) and tKiMBI-T2A-caMEK (A2) in cell-based bioluminescence assays (**Supplementary Fig. 5a**). When transiently transfected in HEK293A cells, both A1 and A2 reporter genes produced an approximately 4-fold increase in tKiMBI signals upon mirdametinib treatment (**Supplementary Fig. 5b**). A2 was chosen for further characterization using more MEK/ERK inhibitors, and demonstrated satisfactory responsivity (**Supplementary Fig. 5c**). After being packaged into AAV vectors, the reporter (tKiMBI-T2A-caMEK) or its negative control (tKiMBI$_{mut}$-T2A-caMEK) was expressed in mouse striatum by AAV transduction (**Fig. 3a**).

We then tested whether tKiMBI could report the efficacy of MEK inhibitors in the brain, using mirdametinib and trametinib as reference compounds. Mirdametinib accumulates in brain tissue and blocks ERK phosphorylation in the brain after peripheral administration[26,27]. In contrast, pharmacokinetic and pharmacodynamic analyses did not detect trametinib presence or ERK inhibition in the brain after peripheral injection[26–29]. We then measured tKiMBI responses upon treatment with mirdametinib or trametinib at doses effective against extracranial tumors[28,30], using recently reported brain-optimized NanoLuc substrates (Su et al., in press). The negative control tKiMBI$_{mut}$ did not respond to either drug (**Fig. 3b, Supplementary Fig. 5d-g**), confirming that the drugs do not directly inhibit NanoLuc or alter substrate levels in the brain. As expected, mirdametinib robustly induced a significant increase in tKiMBI signal, confirming its ability to inhibit the Ras-ERK pathway in mouse brain (**Fig. 3b, Supplementary Fig. 5d,e**). In contrast, trametinib produced no response from tKiMBI (**Fig. 3b, Supplementary Fig. 5f,g**), consistent with its previously characterized BBB impermeability. By using the same mice to assess mirdametinib and trametinib, we could conclude trametinib was less BBB-permeable with high confidence (**Fig. 3c**). These results demonstrate that tKiMBI expressed by AAV in mouse brains reliably reports BBB permeability of inhibitors targeting the Ras-ERK pathway.

We next tested whether KiMBI can report ERK inhibition in an orthopic xenograft model of brain cancer (**Fig. 3d**). Specifically, we implanted 3×10^4 tKiMBI- or tKiMBI$_{mut}$-expressing U87-EGFRvIII cells into the striatum and assessed the response of tKiMBI to peripherally injected mirdametinib or tramertinib. As U87-EGFRvIII brain xenografts are known to produce a permeable BTB in mice[24], we hypothesized that both mirdametinib and tramertinib would be able to enter the KiMBI-expressing tumor cells in the brain. Indeed, we observed ~180% and ~130% increases in tKiMBI signal after mirdametinib and trametinib administration, respectively (**Fig. 3e,f, Supplementary Fig. 6**).

As the provenance of U87 cells distributed by North American repositories is unknown[31], we also assessed KiMBI responses in a second widely used human glioblastoma line, LN-229. Cultured LN-229 cells stably expressing tKiMBI exhibited a roughly 1.6-fold increase in bioluminescence after treatment of Ras-ERK pathway inhibitors (**Supplementary Fig. 7a–c**), demonstrating some baseline ERK activity, albeit at lower levels than in U87-EGFRvIII cells. We implanted 3×10^4 LN-229 cells expressing tKiMBI or tKiMBI$_{mut}$ into the mouse striatum, and then performed bioluminescent imaging one week later. Treatment with either mirdametinib or trametinib resulted in >3-fold signal increases from tKiMBI, suggesting that LN-229 xenografts also produce a leaky BTB (**Supplementary Fig. 7d-g**). Taken together, these results demonstrate that the BTB is leaky in commonly used orthotopic xenograft mouse models of glioma.

Non-invasive characterization of drug pharmacodynamics in the body and brain. Noninvasive evaluation of kinase inhibition over time in target tissues, i.e. pharmacodynamics, would be extremely desirable for assessing

the optimal concentration and dosing intervals of drug candidates. For cancer indications in the brain, comparing pharmacodynamics in the presence of an intact BBB versus a leaky BTB could help rule out any efficacy differences between bulk tumor and tumor margin[25]. The brain-optimized NanoLuc substrate demonstrates rapid signal decay with a half-life of ~8 min, allowing repeated imaging with ≥1-h intervals (Su et al., in press). We thus performed repeated bioluminescence imaging of ERK KiMBI to track pharmacodynamics of the BBB-permeable MEK inhibitor mirdametinib. Specfiically, we tested pharmacodynamics in tumor xenograft models outside and inside the brain, as well as intact brain parenchyma (**Fig. 4a**).

Fig. 4. Molecular imaging of pharmacodynamics of ERK inhibition by mirdametinib in multiple disease models. a, *Design of experiments for measuring ERK inhibitor pharmacodynamics. Treatment with mirdametinib could conceivably alter tumor bloodflow or reporter expression at extended timepoints which could affect tKiMBI brightness, but these indirect mechanisms should affect tKiMBImut as well. Thus for intramuscular or subcutaneous tumors, we implanted tKiMBI-expressing and tKiMBImut-expressing cells on opposite sides in the same mice (**Supplementary Fig. 8a**) and normalized the fold change in tKiMBI intensity at each time with the tKiMBImut measurement from the contralateral tumor. For cranial tumors and AAV-transduced brain, we implanted tKiMBImut-expressing cells or injected tKiMBImut-expressing AAV in a parallel control cohort (**Supplementary Fig. 8b**) and normalized the fold change in tKiMBI intensity at each time with the mean tKiMBImut measurement from the simultaneously imaged control cohort (**Supplementary Fig. 8c**).

In intramuscular or subcutaneous tumors, tKiMBI signals reached a peak response 2 h after peripheral administration of 25 mg/kg mirdametinib, then decayed with a half-life of approximately 6 h (**Fig. 4b**). Peak response amplitudes were ~200% after correction by the tKiMBImut signal. Similar results were observed for tKiMBI in intracranial tumors (**Fig. 4c,d**). In tKiMBI-transduced brain tissue, kinetics were not discernably different in either time to peak or rate of decay (**Fig. 4c,d**). These results suggest that clearance rates were not slower in the brain than in plasma for mirdametinib; i.e. there was no discernable depot effect in the brain. Taken together, these results demonstrate that longitudinal tKiMBI imaging can reveal kinase inhibitor pharmacodynamics in bulk tumors or in normal tissue noninvasively.

Identification of an ERK inhibitor with activity in the brain. Given the success of AAV-transduced tKiMBI in reporting the BBB permeability of well-characterized MEK inhibitors, we finally asked if tKiMBI can identify ERK inhibitors with high efficacy in the brain. We found that no ERK inhibitors have been unambiguously identified as BBB-penetrant, and reports on brain concentrations have not been published for most of them. We selected KO-947, ulixertinib, and temuterkib (LY3214996) for testing with ERK tKIMBI due to their promising performance in pre-clinical trials for treating extracranial tumors (**Supplementary Fig. 9a**)[32–34].

Fig. 5. Molecular imaging of ERK inhibitors in AAV-infected mouse brain. a, *Pathway schematic with position of ERK inhibitors.* **b-d**, *After AAV infection in the striatum, tKiMBI- or tKiMBImut-expressing J:NU mice were imaged 2 h after ERK inhibitor treatment. Above, representative bioluminescence images collected before and after each ERK inhibitor treatment. Below, percentage change of bioluminescence signals collected before and after inhibitor treatment. P values, unpaired two-tailed Student's t-test.*

We first confirmed the in vivo efficacy of KO-947, ulixertinib, and temuterkib using a tKiMBI-expressing intramuscular xenograft mouse model (**Supplementary Fig. 9a**). As expected, all three ERK inhibitors induced a signal increase in tKiMBI-expressing tumors (**Supplementary Fig. 9b-d**). Next, using the tKiMBI brain AAV model where caMEK and tKiMBI are coexpressed (**Fig. 5a**), we examined the efficacy of the ERK inhibitors in mouse brains. Despite promising efficacy in intramuscular models, treatment with KO-947 and ulixertinib did not induce any significant response of tKiMBI (**Fig. 5b-c, Supplementary Fig. 10a-b**). These results demonstrated that KO-947 and ulixertinib cannot efficiently penetrate the BBB and inhibit the ERK activity in brain tissues. However, we found temuterkib to be efficacious in the AAV-transduced brain model (**Fig. 5d, Supplementary Fig. 10c**), demonstrating the BBB permeability of temuterkib. Our findings suggest that temuterkib is a more promising candidate ERK inhibitor than KO-947 and ulixertinib for brain indications.

Finally, we asked whether our findings could be reliably predicted in silico. Algorithms have been developed to predict BBB permeability of drugs based on their physicochemical properties, among which the "BBB score" is the most recent, outperforming earlier approaches[35]. Using the "BBB score calculator" on KO-947, ulixertinib, and temuterkib, we found KO-947 to have the highest BBB score and temuterkib the lowest (**Table S4**). This is contrary to our empirical findings that temuterkib but not KO-947 is effective in the brain. Thus, while the physiochemical properties of candidate drugs certainly affect BBB penetration, the ability of compounds to accumulate in the brain is apparently still difficult to predict, underscoring the utility of empirical approaches such as KiMBI imaging.

Discussion

In this study, we addressed the need for non-invasive imaging of kinase inhibition in the brain by creating kinase-modulated bioluminescent indicators (KiMBIs) that use optimized luciferase substrates. We find that an ERK KiMBI reports Ras-ERK pathway inhibition in tumors in mice, and can differentiate between BBB-permeable and BBB-impermeable inhibitors. We used ERK KiMBI to demonstrate BTB disruption in xenografts and track MEK inhibitor pharmacodynamics in an orthotopic glioma model and in normal brain tissue. Finally, we used ERK KiMBI to evaluate the intracranial activity of ERK inhibitors, identifying temuterkib to be suitable for use in the brain, despite algorithmic predictions of poor BBB permeability. The KiMBI technology described here provides a rapid and inexpensive method to empirically assess kinase inhibition in target tissues in living mice.

Our study demonstrates the advantages of non-invasive imaging over earlier methods for empirical evaluation of kinase inhibitors in the brain. Traditional methods for characterizing drugs in animal models require tissue collection and biochemical analysis, which are time-, labor-, and resource-consuming. In particular, such experiments require large numbers of animals, due to experimental variation between animals coupled with the inability of each animal to contribute more than one time point. In contrast, bioluminescence imaging is rapid and inexpensive, involving only injection of the luciferase substrate, anesthesia, and imaging. More importantly, by being noninvasive, KiMBI imaging allows a single experimental subject to be reused multiple times.

For example, a small set of KiMBI-expressing mice can be used to report on multiple drugs (**Fig. 2**), or to test different doses for a drug. Likewise, a small set of animals can report drug efficacy over time, as exemplified by our pharmacodynamic study on mirdametinib (**Fig. 4**). There, genetic encoding and the time-lapse nature of observation minimizes experimental noise from different tumor sizes. In traditional pharmacodynamics experiments, different tumor sizes would be expected to introduce variability in kinase activity measurements, as tumor size could influence pathway activity, protein concentration, or the degree of contamination of tumor sample by non-cancerous stroma. However, in xenograft models, KiMBI would only be expressed in the tumor cells, and its response to drug can be normalized to its pretreatment intensity. Thus, our mirdametinib experiment required only 4 mice to obtain 7 time points in the extracranial xenograft models, whereas traditional pharmacodynamic measurements would have required at least 28 mice, and likely more to compensate for variability from using different mice to construct a time course. Indeed, we were unable to find examples in the literature of time-lapse phamacodynamic profiling of mirdametinib; the sole example of pharmacodynamics actually only investigated the effects of two doses at a single timepoint[36]. KiMBI pharmacodynamic reporting can be useful for avoiding underdosing in mouse efficacy testing or for screening candidate inhibitors for prolonged pharmacodynamics.

Finally, while we used caMEK and ERK KiMBI to assess the efficacy of MEK and ERK inhibitors in the brain, it should also be possible to use Ras-ERK pathway activators that are further upstream. This would allow comparison in the same mice of the pharmacodynamic effects on pathway output (ERK activity) by inhibitors targeting the various levels of the pathway, which could have different effects due to feedback regulation. By

increasing the pharmacodynamic information obtainable from each animal subject by an order of magnitude, KiMBI reporters should facilitate new kinase inhibitor discovery and dose optimization.

Interestingly, to our knowledge, no bioluminescent reporter for the Ras-Raf-MEK-ERK pathway of any design has been reported. This is remarkable considering that proteins in this pathway are major drug targets in cancer, and that FLuc-based reporters have been reported for Akt, c-Met, EGFR, and ATM[15,16,37,38]. The development of ERK KiMBI thus also fills a previously unmet need for non-invasive reporting of Ras-ERK pathway activity in mammals.

Another conclusion of this study is that xenografts in the mouse brain may falsely report kinase inhibitor efficacy due to BBB leakiness. Specifically, we observed the BBB-impermeable trametinib still activating ERK KiMBI in U87-EGFRvIII and LN-229 xenografts in the brain. However, drugs with good BBB permeability are still required for maximally effective treatment of glioblastoma patients, as low-grade gliomas and a portion of progressive glioblastomas exhibit an intact BBB[39]. In addition, human xenografts in the mouse brain may exhibit more BBB disruption than the human tumors they are intended to model[40]. Evaluating candidate kinase inhibitors by only brain tumor shrinkage in mice may thus produce false-positive results, in addition to requiring large sample sizes for each compound and dosing regimen due to high variability in growth rates between individual xenografts. In contrast, comparing drug responses of KiMBI transduced into cells inside and outside the brain should provide a reliable non-invasive measure of BBB permeability.

A common question regarding bioluminescent indicators is how their use case differs from fluorescent indicators. Kinase indicators based on fluorescent proteins are widely used for live-cell experiments, where their high photon flux enables visualization of kinase activity with spatial and temporal resolutions on the micron and millisecond scales respectively[1]. However, the excitation light required for fluorescence imaging is difficult to deliver uniformly through tissue. Thus, fluorescent indicators can only be used in living mammals by inserting lenses of fibers to access specific sites of interest[41]. This is invasive, severely restricts the field of view, and adds to experimental variability between animals. In contrast to fluorescence, bioluminescence from luciferase proteins is suitable for non-invasive imaging at millimeter and second scales. The absence of excitation light and autofluorescence essentially eliminate background signal, allowing the relatively low photonic output of luciferase reporters to be detected from even deep locations in the body without the surgical implantation of optical elements, with sensitivity limited by camera dark current and read noise[42,43].

NanoLuc-based KiMBIs differ from earlier kinase reporters based on FLuc in two important ways. First, Nanoluc-RFP fusions with the substrate cephalofurimazine produce an order of magnitude more light in the brain than FLuc with either D-luciferin or CycLuc1 (Su et al., in press). The higher achievable brightness of NanoLuc-based reporters should allow drug effects to be detected at lower levels of reporter expression or with fewer cells than FLuc-based reporters, which is less likely to interfere with normal biological processes. Second, because FLuc is ATP-dependent, it has the potential to generate spurious signals if kinase inhibition, or off-target drug activity, alters cellular energy states. Indeed, FLuc alone serves as a reporter of ATP levels in cells[44]. In contrast, as NanoLuc is ATP-independent, KiMBIs can report kinase inhibition independently of ATP.

The modular design of KiMBIs should facilitate generalization to other kinases of therapeutic interest. The engineering of PKA and ERK KiMBIs demonstrated here shows that constructing a reporter to respond positively to kinase inhibition may require different ordering of elements (LgBiT, SmBiT, substrate, and PBP) for different kinases. Presumably, this is due to the distinct orientations that phosphosubstrates can interact with different PBPs relative to PBP termini (FHA for PKA, WW for ERK). We expect other PBPs such as 14-3-3 or SH2 domains could replace the WW domain in ERK KiMBI to develop indicators for a broader range of kinases. As a simple screen of possible topologies with PBP and/or substrate sequences linking LgBiT and SmBiT fragments was sufficient to obtain KiMBIs for PKA and ERK, we expect KiMBIs incorporating other PBPs can also be obtained in this manner.

In summary, we have developed a kinase-modulated bioluminescent indicator (KiMBI) to visualize ERK inhibition by small-molecule drugs in tissues of living mice. Our results demonstrate that non-invasive KiMBI imaging can provide valuable information on target engagement by kinase inhibitors in living subjects, including BBB penetration and pharmacodynamics of drug activity. ERK KiMBI thus provides an rapid method to assess inhibition of the Ras-ERK pathway in the body or the brain, and suggests a general strategy to greatly accelerate the discovery of effective small-molecule inhibitors for other kinases as well.

Methods

Chemicals. Drugs used in the paper include ERK inhibitor Vx-11e (Selleck Chemicals), SCH772984 (Selleck Chemicals), KO-947 (MedChem Express), Ulixertinib (Selleck Chemicals) and LY3214996 (Selleck Chemicals); MEK inhibitors U0126 (Tocris), PD0325901 (Selleck Chemicals, ApexBio) and GSK1120212 (Selleck Chemicals; ApexBio), JNK inhibitor SP600125 (Selleck Chemicals), and p38 inhibitor PD169316 (ApexBio). Antibiotics used in cell culture include Blasticidin (Invivogen), Geneticin (Invitrogen), penicillin/streptomycin (Gemini Bio), ciprofloxacin (Sigma-Aldrich), piperacillin (Sigma-Aldrich).

Molecular Cloning. DNA primers for molecular cloning were synthesized by Intergrated DNA Technologies. WW domain was PCR amplified from pcDNA3-ERK-SPARK, a gift from Xiaokun Shu (Addgene plasmid # 106921). PCR amplification was typically conducted with ~20 overlapping DNA base primers and the PrimeSTAR HS DNA Polymerase (Clontech) or the Phusion Flash High-Fidelity PCR Master Mix (Thermo Scientific). DNA fragments were spliced by overlap-extension PCR with ~20 overlapping DNA sequences by Phusion Flash High-Fidelity PCR Master Mix. Molecular cloning was typically carried out using infusion HD cloning kit (Takara Bio) with a plasmid vector linearized by restriction enzymes and an assembled DNA insert with ~20 overlapping DNA sequences. Constructed plasmids were verified using Sanger sequencing by Elim Biopharm. The KiMBI constructs were assembled in pcDNA3.1 vector (Addgene) behind the CAG promoter. The best KiMBI sensors (bKiMBI, oKiMBI, and tKiMBI) were then cloned into the lentiviral vector pLL3.7m[45] or the AAV packaging vector pAAV under the CMV promoter.

Cell lines. HEK293A cells (Invitrogen) were cultured at 37 °C with 5% CO_2 in Dulbecco's Modified Eagle's Medium (DMEM) supplemented with 10% fetal bovine serum (FBS), 2 mM L-glutamate, 100 U/mL penicillin and 100 µg/mL streptomycin. U87 (ATCC, No. HTB-14) and U87-EGFRvIII (previously developed in Lin lab by pcDNA3-EGFRvIII transfection and Geneticin selection) cells were cultured at 37 °C with 5% CO_2 in DMEM supplemented with 10% bovine calf serum (BCS), 2 mM L-glutamate, 100 U/mL penicillin, 100 µg/mL streptomycin, 0.8 mg/mL Geneticin, 10 µg/mL Ciprofloxacin, 10 µg/mL Piperacillin. SK-OV-3 cells (ATCC, No. HTB-77) were cultured at 37 °C with 5% CO_2 in Roswell Park Memorial Institute (RPMI) 1640 medium supplemented with 10% FBS, 2 mM L-glutamate, 100 U/mL penicillin and 100 µg/mL streptomycin. LN-229 cells (ATCC, No. CRL-2611) were cultured at 37 °C with 5% CO_2 in DMEM supplemented with 5% FBS, 2 mM L-glutamate, 100 U/mL penicillin and 100 µg/mL streptomycin.

Virus packaging. For lentivirus packaging, pLL3.7m-based plasmids were purified by PureLink Expi Endotoxin-free Maxi plasmid Purification kit (Invitrogen), and then HEK293T (ATCC, No. CRL-3216) cells at ~70% confluency were transfected with psPAX2, pMD2.G, and pLL3.7m plasmids using CalPhos mammalian transfection kit (Takara Bio). Two days following transfection, viral supernatant was filtered with a 0.45 µm PES filter before using to infect target cells. For AAV packaging, pAAV-CMV-tKiMBI-T2A-caMEK-bGH_pA plasmids were purified by PureLink Expi Endotoxin-free Maxi plasmid Purification kit (Invitrogen), and then were sent to Stanford Gene Vector and Virus Core to produce and titer AAV.DJ vectors.

Generation of KiMBI-expressing stable tumor cell lines. U87-EGFRvIII and LN229 cells were lentiviral transduced with pLL3.7m-CMV-KiMBI-T2A-AkaLuc-P2A-Blasticidin. Then, 72 h after transfection, cells were dissociated with trypsin and resuspended in DMEM and then changed to PBS. Suspended cells were sorted for the population with medium fluorescence level (20-40%) on a fluorescence-activated cell sorter (FACS), the FACSJazz (BD Biosciences) at Stanford Shared FACS Facility. After cell sorting, the KiMBI-expressing cells were maintained and passaged in corresponding culture medium supplemented with blasticidin (6 µg/mL for both cell lines) to select for stable polyclonal cell lines. Flow cytometry data were analyzed on FlowJo software. The stable KiMBI expression was validated by examination of tdTomato fluorescence in tKiMBI (and its variants) using an EVOS FL Autoimaging system (Thermo Scientific).

In vitro cell-based bioluminescent assay. Cells were seeded into 96-well Lumitrac plate (Greiner Bio-One) at a density of 1.5×10^4 to 2×10^4 cells per well. After 24h, cells were transiently transfected with KiMBI-expressing plasmids (5 - 10 ng per well) with or without caMEK-expressing plasmids (50 ng per well, empty pcDNA3.1 as negative control to keep total transfected DNA amount consistent) using lipofectamine 3000 (Invitrogen) following manufacturer's instructions. For the stable polyclonal KiMBI-expressing cell liens, this lipofection step was skipped. At 24h after transfection, the cells were treated with drugs at desired concentration in opti-MEM reduced-serum medium (Thermo Fisher) for 1–1.5 h. Then, for assaying luminescence, Nano-Glo live cell assay system (Promega)

was used following manufacturer's instructions. Time-lapse live luminescence was recorded on Safire-2 microplate reader (Tecan) with 100 ms integration and one read per min for 20 min. Luminescence spectrum was measured on a Varioskan LUX multimode microplate reader (Thermo Scientific) using the spectral scanning protocol with 1 s of integration for each wavelength at 400–680 nm (1 nm per data point).

General procedures of kinase inhibitor injection and in vivo bioluminescence imaging. All animal procedures were performed compliance with USDA and NIH ethical regulations and approved by the Stanford Institutional Animal Care and Use Committee and according to protocols approved by the Administrative Panel on Laboratory Animal Care (APLAC) of Stanford University. For i.p. drug administration in mice, kinase inhibitors (PD0325901, GSK1120212, KO-947, and Ulixertinib) were dissolved in an injectable formulation containing 5% DMSO, 40% PEG-300, 5% Tween-80 (v/v) in water, with each dose consisting of 25 mg/kg PD0325901, 1 or 3 mg/kg GSK11230212, 50 mg/kg KO-947, or 50 or 100 mg/kg Ulixertinib, in a volume of 150–250 μL. For oral (p.o.) administration, KO-947 and LY3214996 were suspended in a vehicle of 0.5% Methylcellulose and 2% Tween-80 in water, with each dose consisting of 300 mg/kg KO-947 or 100 mg/kg LY3214996. To measure KiMBI intensity, mice were injected i.p. with a solution of 1.3 μmol (0.56 mg) of NanoLuc substrate and 6 mg poloxamer-407 (P-407) in 150 μL of Dulbecco Phosphate Buffered Saline (DPBS, without Ca^{2+} or Mg^{2+}, no. 21-031-CV, Corning). Substrate was either fluorofurimazine (FFz) or cephalofurimazine (CFz) or compound 6, a fluorinated analogue of CFz (Su et al., in press). Immediately after substrate administration, mice were anesthetized using isoflurane, and images were acquired in an Ami HT optical imaging system (Spectral Instruments) every 1 min for 10 min, with 1–2% isoflurane in air for anesthesia. Unless otherwise stated in the specific procedures, imaging settings were open emission filter, 25-cm field of view, f/1.2 aperture, 2×2 binning, and 30-s exposure time. Images were analyzed in Aura 4.0 software (Spectral Instruments). The above conditions and settings were for most in vivo studies.

Molecular imaging of ERK inhibition in subcutaneously or intramuscularly implanted cells. For imaging ERK inhibition in subcutaneously (s.c.) or intramuscularly (i.m.) implanted cells, U87-EGFRvIII cells stably expressing KiMBIs were dissociated with trypsin and resuspended in DMEM and then changed to PBS with a density of 1×10^7 to 2×10^7 cells per mL. For s.c. implantation, 4×10^5 or 1×10^6 cells were resuspended in 100 μL FBS-free Opti-MEM containing 50% Matrigel matrix (Corning). For i.m. implantation, 8×10^5 cells were directly injected in DMEM suspension. First, under sterile conditions, 8- to 10-week-old male nude mice (strain J:NU No.007850, Jackson Laboratories) were anesthetized using isoflurane. Cells were subcutaneously injected into the flanks of nude mice. Mice were recovered on heat pads for 30 min while cells were allowed to settle. One week after cell implantation, for visualizing tumor growth, mice were i.p. injected with 1.5 μmol (0.5 mg) of AkaLumine-HCl (Sigma-Aldrich) in 100 μL 0.9% NaCl for imaging (1×1 binning, 10-s exposure time). To visualize ERK inhibition, tumor-bearing mice were i.p. injected with FFz (0.9 μmol, with 6 mg P-407) for imaging. Two hours after the first imaging, kinase inhibitors in the injectable formulation were injected i.p., and a second imaging was carried out 2 h post drug administration following the same procedures as the first imaging.

Molecular imaging of ERK inhibition in KiMBI-encoded AAV infected mouse brain. Under sterile conditions, the 9-week-old male J:NU mice were anesthetized with isofluorane and secured in a stereotaxic frame (RWD Life Science, Shenzhen, China), and a hole of the size of the needle was drilled through the skull. A Hamilton syringe with a 33-gauge needle was inserted at 0.5 mm dorsal and 2.0 mm lateral to the bregma to a depth of 3.1 mm, and after a 2-min wait the needle was pulled back 0.3 mm to allow space for the virus solution. 1.5 μL of AAV vector solution (2×10^{12} viral genomes per mL) was injected at a speed of 0.15 μL/min using a syringe pump (KD Scientific, Holliston, MA). The needle was left in place for 3 min after each injection to minimize the upward flow of viral solution after raising the needle. To visualize ERK inhibition, four weeks after AAV infection, mice were i.p. injected with CFz (1.2 μmol, with 6 mg P-407) for imaging (4×4 binning, 60-s exposure time). Two hours after the first imaging, kinase inhibitors in the injectable formulation were injected i.p., and a second imaging was carried out 2 hours post-drug administration following the same procedures as the first imaging.

Molecular imaging of ERK inhibition in intracranially implanted cells. The stereotaxic injection on the 7- to 9-week-old male J:NU mice were similar to the afore-mentioned AAV infection surgery. A Hamilton syringe with a 26-gauge needle was inserted 0.62 mm dorsal and 1.75 mm lateral to the bregma to a depth of 3.5 mm, and after a 2-min wait the needle was pulled back 0.5 mm to allow space for the cell suspension. Following this, 3×10^4 KiMBI-expressing U87-EGFRvIII or LN-229 stable cells in 1.5 μL of PBS were injected at an injection speed of 0.3 μL/min using the syringe pump. To visualize ERK inhibition in U87-EGFRvIII cell implants, 5 days after cell implantation, tumor-bearing mice were injected i.p. with CFz (0.4 μmol, with 1.8 mg P-407) for imaging. Two hours

after the first imaging, kinase inhibitors in the injectable formulation were i.p. injected, and a second imaging was carried out 2 hours post drug administration following the same procedures as the first imaging. To visualize ERK inhibition in LN-229 cell implants, imaging was done 7 days after cell implantation, and 1.05 or 0.7 μmol CFz with 5 or 3.3 mg P-407 was i.p. injected to each mouse for imaging (4×4binning, 30-s exposure time).

Time-lapse imaging of ERK inhibition in intracranially implanted cells. One week after tumor cell implantation or two weeks after AAV injection, the tumor-bearing or AAV-infected mice were i.p. injected with FFz or CFz (0.2 μmol, with 0.8 mg P-407) for the initial imaging to establish the signal baseline before drug administration. Two hours after the first imaging, PD0325901 (25 mg/kg) in the injectable formulation was i.p. injected, and the subsequent imaging was carried out at 1, 2, 4, 8, 24 hours or 1, 2, 4, 6.5, 10, 24 hours post drug administration following the same procedures as the initial imaging.

Statistics. Student's t-test, one-way analysis of variance (ANOVA) with Tukey's or Holm-Sidak's posthoc test were performed in GraphPad Prism version 9.0.0 (Dotmatics).

Data availability. The main data supporting the findings of this study are available within the Article and its Supplementary Information. The raw data generated in this study are available from the corresponding author upon request.

Supporting Information. Tables S1 (Alanine scanning on SmBiT), S2 (Mutations on SmBiT sites 161 and 163), S3 (Screening of N-terminal fusions of fluorescent proteins) and S4 (Predicted BBB scores of select ERK inhibitors) (PDF).
