GRAPHICAL ABSTRACT

HIGHLIGHTS

- Bs-ATLAS-seq profiles L1 position and methylation genome-wide
- L1 has a frequent but short-range (300 bp) influence on the DNA methylation status of the upstream sequence
- Hypomethylated L1s are bound by tissue-specific transcription factors which drive L1 and chimeric transcripts synthesis
- L1 hypomethylation alone is insufficient to enable its transcription at most loci

KEYWORDS

SUMMARY

1 Long interspersed element-1 (L1) retrotransposons play important roles in human disease and
2 evolution. Their global activity is repressed by DNA methylation, but studying the regulation of
3 individual copies has been difficult. Here, we combine short- and long-read sequencing to resolve the
4 DNA methylation profiles of these repeated sequences in a panel of normal and cancer cells genome-
5 wide at single-locus resolution. We unveil key principles underpinning L1 methylation heterogeneity
6 among cell-types, families and integration sites. First, intronic L1 methylation is intimately associated
7 with gene transcription. Conversely, L1s can influence the methylation status of the upstream region
8 over short distances (300 bp). This phenomenon is accompanied by the binding of specific transcription
9 factors, which drive the expression of L1 and chimeric transcripts. Finally, L1 hypomethylation alone is
10 generally insufficient to trigger L1 expression due to redundant silencing pathways. Our results
11 illuminate the epigenetic and transcriptional interplay between retrotransposons and their host
12 genome.

INTRODUCTION

1 Transposable elements represent a considerable fraction of mammalian genomes and contribute
2 substantially to their gene regulatory networks^{1,2}. In humans, the long interspersed element-1 (LINE-
3 1 or L1) retrotransposon accounts for at least 17% of the genome, and is the sole autonomously active
4 transposable element³. Its dramatic expansion to approximately half a million copies is driven by a
5 copy-and-paste mechanism named retrotransposition. This process is mediated by two L1-encoded
6 proteins, ORF1p and ORF2p, which associate with the L1 mRNA to form a ribonucleoprotein particle
7 (RNP), considered as the core of the retrotransposition machinery. The L1 RNP cleaves the host DNA
8 and directly synthesizes a new L1 copy at integration sites through target-primed reverse transcription
9⁴⁻⁷. Retrotransposition thus depends on L1 transcription, which initiates at an internal CpG-rich
10 bidirectional promoter located in its 5'-untranslated region (UTR) (**Figure 1A**). The sense promoter (SP)
11 drives the synthesis of the L1 mRNA, with a significant fraction of read-through into the downstream
12 genomic sequence⁸⁻¹². As for the antisense promoter (ASP), it can act as an alternative promoter for
13 neighboring genes, leading to spliced chimeric transcripts, or even to fusion proteins with an L1-
14 encoded antisense ORF, called ORF0¹³⁻²⁰.

15 The propagation of L1 elements throughout mammalian evolution occurred in successive waves of
16 expansion and extinction implicating a limited number of concurrent families. In anthropoid primates,
17 a single lineage, L1PA, has been active, leading to the sequential emergence of the L1PA8 to L1PA1
18 families (from the oldest to the youngest) in the last 40 million years²¹. L1PA1 - which is human-specific
19 and also known as L1HS - is the only autonomous transposable element remaining active in modern
20 humans^{22,23}, with an estimated rate of one new insertion every 60 births²⁴. Such additional insertions
21 not catalogued in the reference genome are referred to as non-reference elements and contribute to
22 our genetic diversity^{23,25-29}. As a result, two individual human genomes differ on average at ~300 sites
23 with respect to L1 presence or absence³⁰. Although all L1PA sequences are related, the 5' UTR and
24 ORF1 regions are subject to rapid adaptive evolution, likely resulting from an arms-race with the host
25 genome³¹⁻³³. Moreover, following their integration, L1 sequences accumulate alterations such as
26 mutations, indels, or nested transposable element insertions, and therefore diverge relative to their
27 original progenitor³⁴. Thus, although L1 elements are highly repeated sequences, they also exhibit a
28 significant level of heterogeneity, between and within families, particularly in their promoter region,
29 suggesting that they may be subject to distinct regulatory mechanisms. In support of this possibility, a
30 variety of Krüppel-associated box domain zinc finger proteins (KZFPs) can specifically bind L1PA8 to
31 L1PA3 elements in different cell types, leading to TRIM28-dependent silencing^{35,33,36}, whereas younger
32 L1PA2 and L1HS elements are presumably silenced through TRIM28-independent mechanisms, such
33 as DNA methylation^{35,37-42}. Similarly, the HUSH complex represses a subset of the youngest L1 families
34 in various cell types⁴³⁻⁴⁵.

35 Despite these repressive mechanisms, L1HS can mobilize in the germline and during early
36 embryonic development, creating heritable genetic variations and potentially causing genetic diseases
37⁴⁶. In addition, L1HS can also retrotranspose in a few somatic tissues such as the brain⁴⁶, as well as in
38 many epithelial tumors^{47,48}. Of note, even if L1 elements older than L1HS have lost the ability to
39 achieve a full cycle of retrotransposition, they can be transcribed, and their transcriptional reactivation
40 is not without consequence. By providing alternative promoters and forming chimeric transcripts, they
41 can be responsible for oncogene activation in some tumors⁴⁹⁻⁵¹ and lead to the formation of long non-
42 coding RNA (lncRNA) in many tissues⁵². Nuclear L1 transcripts and transcriptional activity have also

1 been implicated in regulating nuclear architecture, chromatin accessibility and totipotency in
2 mammals^{53–55}.

3 A prevailing idea is that the global loss of DNA methylation commonly seen in tumor cells is
4 responsible for the frequent and generalized reactivation of L1 elements in cancer⁵⁶. Consistently,
5 targeted analyses of selected progenitor L1 elements confirmed their hypomethylation in tumors
6 compared to normal tissues^{12,22,48,57,58}. A similar association between L1 hypomethylation and activity
7 was found in human pluripotent and neuronal progenitor cells^{39,59–64}. However, early studies also
8 suggested that DNA methylation can be heterogeneous between different L1 loci, particularly in tumor
9 cells^{37,42}. Such heterogeneity was also reported at the level of L1 expression, with only a restricted
10 subset of L1 loci, and among them a handful of L1HS, being robustly expressed in transformed cells
11^{9,22,65} and ultimately acting as source elements for new retrotransposition events in tumors^{12,22,28,48}.
12 Altogether, these observations suggest that DNA methylation must be lifted to permit L1 reactivation.
13 Yet the extent of L1 DNA hypomethylation in tumor cells, and whether DNA demethylation is sufficient
14 to promote L1 reactivation remains unclear. As L1s can efficiently insert into regions with a wide range
15 of chromatin states^{66,67}, it is conceivable that the locus of integration could influence the capacity of
16 a given L1 element to be reactivated upon demethylation. Addressing these questions in a systematic
17 way has been challenging so far, given the technical difficulties in assessing L1 DNA methylation
18 genome-wide at single locus resolution, particularly for the most recent L1HS family⁶⁸.

19 Here, we employed a novel genome-wide approach, termed bs-ATLAS-seq, as well as targeted
20 nanopore sequencing, to map the position of individual full-length L1 elements and reveal their
21 methylation levels in a panel of normal, embryonal and tumoral human cell lines. This strategy
22 uncovered the heterogeneity of L1 DNA methylation, which was previously masked by aggregate
23 analyses, and further revealed that L1 methylation patterns are in fact highly cell-type-, family- and
24 locus-specific. Yet, in most cell types, including cancer cells, the majority of L1HS remains
25 hypermethylated. We observed that gene body methylation of transcriptionally active genes is
26 associated with the methylation of intronic L1 elements in many cell types. Inversely, L1s can
27 frequently affect DNA methylation in the neighboring genomic region within 300 bp. This epivariation
28 is associated with unique transcription factors binding profiles controlling L1 expression and the
29 synthesis of L1 chimeric transcripts with neighboring genes. Finally, L1 hypomethylation or
30 pharmacological demethylation is not sufficient alone to trigger expression at most loci. Together, our
31 results highlight the interplay between L1 retrotransposons and their integration sites with respect to
32 DNA methylation and expression, and reveal the existence of redundant layers of epigenetic regulation
33 at individual loci.

RESULTS

34 *Genome-wide and locus-specific human L1 DNA methylation profiling*

35 The L1 bidirectional promoter is 910 bp long and possesses in its first half a CpG island which
36 coincides with its sense promoter activity (**Figure 1A**)^{69–71}. To individually measure the DNA
37 methylation levels of each full-length L1HS copy inserted in the genome, we adapted to bisulfite-
38 treated DNA the ATLAS-seq approach, a method originally developed to map L1HS elements in the
39 human genome^{9,72}. This strategy, termed bisulfite-ATLAS sequencing (bs-ATLAS-seq, **Figure 1A**),

1 provides both the location of L1HS insertions and the methylation state of the most distal region of
2 their promoter at single-locus, single-molecule and single-nucleotide resolutions (**Figure 1B** and **Figure**
3 **S1A**). Importantly, these data are obtained both for reference and non-reference insertions (**Figure 1C**
4 and **Figure S1B**). The amplified region within the L1 5'UTR covers the first 15 CpG dinucleotides -
5 including 7 being considered as critical for L1 regulation⁷³ - and its methylation level is representative
6 of the broader internal promoter (see below and **Figure S1I**). Therefore, for the sake of simplicity, and
7 unless otherwise specified, we will hereafter use the term "L1 methylation" to refer to the DNA
8 methylation of this distal region of the L1 promoter. Bs-ATLAS-seq only requires 10 million read pairs
9 to recover 97% of detectable L1HS elements and 20 million read pairs to recover 100% of them (**Figure**
10 **S1C**), and it is highly reproducible (**Figure S1D** and **Figure S1E**).

11 We applied bs-ATLAS-seq to a panel of 12 human cell lines, which includes normal primary
12 fibroblasts (BJ, IMR90 and MRC-5), artificially immortalized and transformed cells (HEK-293,
13 adenovirus-immortalized embryonal kidney cells; HEK-293T, a derivative of HEK-293 further
14 transformed by SV40 Large T antigen), cancer cell lines (HepG2, hepatoblastoma; K-562, chronic
15 myeloid leukemia; MCF-7, breast cancer; HeLa-S3, cervical cancer; HCT-116, colon cancer), as well as
16 cells of embryonal origins (H1, embryonic stem cells; 2102Ep, embryonal carcinoma cells) (**Figure S1F**,
17 **Table S1**). We compiled the results into a comprehensive database containing the position of each L1
18 copy in the 12 cell lines and their DNA methylation levels at single locus-, nucleotide-, and molecule-
19 resolutions (**Table S3** and **Data S1**). These data can be easily and interactively interrogated through a
20 dedicated web portal (<https://L1methdb.ircan.org>). On average, we identified 312 full-length L1HS in
21 each cell line, of which 42 are non-reference insertions and assumed to be full-length (**Figure 1D**). In
22 addition to these copies, we also detected an average of 81 L1HS reference elements with an
23 amplifiable 5' end but annotated as 3' truncated (**Table S3**). Among them, half contain Alu insertions
24 (AluY or AluS) or other forms of internal rearrangements, or represent chimeras with older L1PA
25 elements. We identified approximately 90% of all full-length reference L1HS copies (**Figure 1E**), the
26 undetected elements being likely absent from the assayed samples. All detected non-reference L1HS
27 were either identified in previous studies by distinct methods, or experimentally validated (see
28 Methods and **Figure S1G**), indicating that false-positive insertions are virtually absent (**Table S3**).
29 Although we designed bs-ATLAS-seq to profile the youngest and human-specific L1 family, L1HS, a
30 significant proportion of older primate-specific families (L1PA2 to L1PA8) are also amplified given the
31 high levels of sequence identity between them and the reduced sequence complexity associated with
32 bisulfite treatment (**Figure 1E**).

33 To further validate bs-ATLAS-seq, we compared the DNA methylation levels of select L1 copies
34 obtained by this approach with results obtained by methylated DNA immunoprecipitation (MeDIP)
35 followed by quantitative PCR (qPCR), or by direct nanopore sequencing of methylated CpGs (ONT-seq),
36 two orthogonal techniques that do not rely on bisulfite treatment. We found a good correlation
37 between bs-ATLAS-seq and MeDIP or ONT-seq, which independently verifies the accuracy of bs-ATLAS-
38 seq DNA methylation values (**Figure S1H**, **Table S2** and **Figure S1I**). Long-read nanopore sequencing
39 confirmed that methylation levels of the first 15 CpG reflect those of the entire L1 CpG island (**Figure**
40 **S1I**). At the genome-wide level, bs-ATLAS-seq data obtained in MCF-7 cells were also cross-validated
41 by a combination of Hi-C with methylated DNA immunoprecipitation (Hi-MeDIP)⁷⁴. Thus, bs-ATLAS-
42 seq is a cost-effective method to accurately profile L1 position and methylation genome-wide.

1 **L1 promoter DNA methylation is cell type- and family-specific**

2 At first sight, the profiles we obtained across the twelve cell types are globally consistent with the
3 prevalent view that L1 DNA methylation is relaxed in cancer cells^{37,75–77} (**Figure S2A**). However, a closer
4 examination of the L1 methylation landscape across cell types and L1 families offers a more refined
5 picture and reveals a heterogeneity not detectable by aggregate analyses (**Figure 2**). In most cell types,
6 even cancer cells, the youngest L1HS family appears hypermethylated as compared to the bulk of older
7 L1 families (**Figure 2** and **Figure S2B**). Within the L1HS family, reference and non-reference copies
8 (considered to include the youngest elements) show similar methylation levels (**Figure S2C**). CpG sites
9 are progressively mutated into TpG over time owing to spontaneous deamination⁷⁸, and thus older L1
10 families contain fewer CpG sites than younger ones^{27,79} (**Figure S2D**). However, the fraction of
11 methylated CpG measured by bs-ATLAS-seq for these fixed elements is unaffected by the actual
12 number of CpG in the L1 sequence as reads are mapped against the reference genome and not a
13 consensus sequence. Thus, our data suggest that L1 families with a lower CpG density could be more
14 prone to inter- and intra-locus heterogeneity, as previously observed for Alu elements⁸⁰.

15 In two cell lines, the embryonal carcinoma cells 2102Ep and the chronic myeloid leukemia cells K-
16 562, L1HS elements are exceptionally hypomethylated but with very distinct epigenetic contexts. In
17 2102Ep cells, hypomethylation is restricted to the young L1 families (L1HS, L1PA2, and to a lesser
18 extent L1PA3), while older L1 elements and the rest of the genome show high levels of methylation
19 (**Figure 2** and **Figure S2E**). In contrast, K-562 cells display a global hypomethylation phenotype that
20 affects all L1 families and reflects genome-wide hypomethylation, down to levels as low as those
21 observed in HCT-116 cells with *DNMT1* and *DNMT3B* inactivating mutations (**Figure 2** and **Figure S2E**).

22 Altogether, these data show that accessing L1 DNA methylation at individual loci reveals their
23 heterogeneity and demonstrates that L1 DNA methylation is cell type- and family-specific.

24 **L1 DNA methylation can be influenced by genic activity**

25 To test whether particular subsets of L1 elements are systematically hypo- or hyper-methylated,
26 we compared the methylation levels of the youngest L1 loci (L1HS and L1PA2) across the different cell
27 lines (**Figure 3A** and **Figure S3A**). Two hundred eighty-eight L1HS copies (including full-length and 3'
28 truncated elements) are shared by all cells. Consistent with the above results, the majority of them are
29 highly methylated in most cell types, including cancer cells (**Figure 2** and **Figure 3A**). Excluding 2102Ep
30 and K-562 cells, only a small subset of 59 L1HS loci shows variable methylation levels, and none is
31 invariably unmethylated. We obtain similar results if polymorphic insertions are included (**Figure S3B**).
32 Interestingly, in cells where L1HS elements are globally unmethylated (2102Ep and K-562), we still
33 observe methylated copies (n=54 and n=46, respectively) (**Figure 3A**).

34 To understand why individual loci adopt a methylation profile distinct from the bulk of L1HS, we
35 compared their genomic environment with that of unmethylated copies. In K-562 cells, methylated
36 L1HS elements are enriched in genes (**Figure 3A**). L1HS elements inserted in genes are more
37 methylated than in intergenic regions (**Figure 3B**), and those in expressed genes are more methylated
38 than in unexpressed genes (**Figure 3C**). Moreover, two thirds of L1HS are methylated in expressed
39 genes, but less than 10% are methylated in non-transcribed compartments (non-expressed genes or
40 intergenic regions, **Figure 3D**, top left). This contrasts with 2102Ep cells, which exhibit a similarly low

1 proportion of methylated L1HS loci as the K-562 cells (**Figure 3A**), but for which the relative proportion
2 of methylated and unmethylated copies remains similar regardless of the transcriptional state of the
3 integration locus (**Figure 3D**, top right). Similar results were obtained when also including L1PA2 to
4 L1PA8 families (**Figure 3D**, bottom). In absolute numbers, 33 out of 46 (72%) of hypermethylated L1HS
5 (mCG \geq 75%) are located in a transcribed genomic compartment in K-562 cells, but only 12 out of 54
6 (22%) in 2102Ep cells (**Figure 3E**).

7 In mammals, DNA methylation is widely targeted to gene bodies through transcription-coupled
8 deposition of H3K36me3 histone marks and the subsequent recruitment of the DNA methyltransferase
9 Dnmt3b⁸¹⁻⁸⁴. Our observation thus suggests that, in K-562 cells, most L1HS DNA methylation results
10 from their co-transcription with genes as previously described for intragenic CpG islands⁸⁵.
11 Consistently, methylated L1s are predominantly embedded in transcribed regions enriched in
12 H3K36me3 histone modification and DNA methylation (**Figure 3F**, **Figure 3G** and **Figure S3C**). Thus, at
13 the global level, L1HS elements are not directly targeted by DNA methylation in K-562 cells, but locally,
14 some are methylated due to their co-transcription with genes. We also observe a significant - yet
15 modest - association of genic transcription with L1HS DNA methylation in all other but embryonic cell
16 types (**Figure 3B** and **Figure 3C**), in agreement with the previous observation showing no correlation
17 between gene body methylation and expression in embryonic stem cells⁸². We note that high levels
18 of young L1 DNA methylation in the H1 embryonic stem cells, which were grown in medium containing
19 LIF and serum, are consistent with a primed state, as previously reported⁸⁶.

20 ***L1 elements drive local but short-range epivariation***

21 Transposable elements have been proposed to function as “methylation centers” from which
22 methylation can propagate into the flanking sequences in many species, including mammals (REF
23 Turker). However, this possibility has never been tested systematically for L1 elements, particularly in
24 human cells. Bs-ATLAS-seq provides not only the DNA methylation state of L1 promoters but also that
25 of proximal CpGs upstream of L1 elements, giving us the opportunity to assess the association between
26 L1 DNA methylation and that of its 5’ flanking genomic region. DNA methylation of L1 upstream
27 sequences is remarkably similar to the methylation of the L1 promoter itself (**Figure S4A**).
28 Unmethylated L1HS to L1PA4 are associated with a hypomethylated 5’ flank. Conversely, methylated
29 elements are associated with methylated upstream sequences. For L1HS and L1PA2, hypomethylation
30 of the flank progressively decreases as the distance from L1 increases and disappears around 300 bp,
31 a situation previously observed for transgenic CpG islands in reporter genes and termed “sloping
32 shores”⁸⁷.

33 To investigate whether L1 elements instruct the methylation state of their flanks, we compared
34 allelic epivariation in the region upstream of L1 at heterozygous loci (*i.e.* having one filled allele - with
35 L1 - and one empty allele - without L1 - in the same cell line). By design, bs-ATLAS-seq only probes the
36 filled alleles. Therefore, to gain access to the methylation states of both alleles at heterozygous loci,
37 and to extend the region analyzed around the L1 promoter, we performed long-read nanopore Cas9-
38 targeted sequencing⁸⁸, with direct calling of 5-methyl-cytosine (5mC) (**Figure 4A**). Sequencing starts
39 at the single guide RNA (sgRNA) binding site in the region downstream of L1 and common to both
40 alleles, and progresses towards the target L1 in the antisense direction⁸⁹. By applying this strategy to
41 a subset of 124 potentially polymorphic loci in 4 cell lines (2102Ep, MCF-7, K-562 and HCT116), we

1 genotyped and obtained the methylation profile of each allele, including the entirety of the L1 element
2 when present, and several kilobases upstream, with a mean coverage of 45x (**Figure 4A** and **Table S4**).
3 The target L1s were selected as present in less than half of the 12 cell lines of the panel and therefore
4 more likely to be heterozygous. On average, 40 loci are heterozygous (40 ± 4 ; mean \pm s.d.) and 21 are
5 homozygous and filled (21 ± 0.5) in each cell type, with a total of 162 heterozygous alleles and 83
6 homozygous filled alleles sequenced (**Figure 4C** and **Table S4**). In agreement with bs-ATLAS-seq results,
7 we observe that cell lines differ by their L1 methylation profiles and levels (**Figure S11**) and that L1 and
8 their proximal upstream sequence adopt a similar methylation state (**Figure S4B**). Moreover,
9 unmethylated L1 promoters surrounded by hypermethylated distant genomic flanks, such as those
10 frequently observed in 2102Ep cells, inform us on the extent of the non-methylated domain within L1
11 elements and on the width of sloping shores. Methylation starts decreasing approximately 300 bp
12 upstream of L1 to reach a minimum at the beginning of the L1 promoter. Methylation stays low over
13 the first 500 bp of L1 5' UTR, and increases again to reach a plateau around position +800 with high
14 levels of methylation over the entire L1 body (**Figure S4B** and **Figure 4A**).

15 Next, we systematically examined potential L1HS-driven allelic epivariation. We reasoned that the
16 influence of an L1 element on the flanking region could only be assessed if the methylation state of
17 the L1 promoter differs from that of its cognate empty allele (**Figure 4B**). Out of 78 heterozygous loci,
18 37 were found informative as they exhibit a significant difference of DNA methylation levels between
19 the L1 promoter and the empty allele ($> 30\%$) and possess at least one CpG site 300 bp upstream of
20 the insertion site (**Figure 4C**). Upon manual inspection, 4 loci were further excluded as they show high
21 variability and were inconclusive. Remarkably, more than two third of the remaining loci (23/33)
22 exhibit short-range L1-mediated epivariation. Fourteen hypomethylated L1 elements have sloping
23 shores (demethylation of the proximal upstream CpGs, **Figure 4D**), while 9 hypermethylated elements
24 propagate methylation in their upstream sequence (**Figure 4E**). Of note, methylation spreading was
25 detected at both extremities of methylated L1s (**Figure 4E**, left, and **Figure S4C**), while sloping shores
26 were only observed at the 5' junction of unmethylated L1s. In most cases, we can confidently conclude
27 that the presence of the L1 insertion directly causes the observed allelic epivariation, as epivariation
28 is not just associated with the filled locus, but also forms a gradient starting from the L1 element. For
29 one locus in K-562 cells, we observe broad allelic epivariation between the empty and filled alleles, but
30 it is unclear whether the methylation difference is due to the presence or absence of the L1HS
31 insertion, or simply reflects the inclusion of an L1 element in an already existing epiallele (**Figure S4D**
32 and **Figure S4E**). Finally, for 10 L1 elements, we did not detect variation of methylation between the
33 filled and the empty alleles (**Figure S4F**). Thus, L1HS elements exert a short-range but frequent
34 epigenetic influence on their genomic environment, which can create local epivariation.

35 ***Local epivariation at L1 loci is associated with distinct transcription factor landscapes***

36 To further understand what differentiates methylated from unmethylated L1 loci, we examined
37 whether these subsets could be associated with distinct transcription factor (TF) binding profiles. We
38 performed differential TF binding site enrichment analysis, comparing the 5' junction of unmethylated
39 versus methylated L1. The analyzed region spans the 300 bp of upstream sequence under L1 epigenetic
40 influence, as well as the first 500 bp of the L1 5' UTR which appears to be variably methylated (**Figure**
41 **S4B** and **Figure 5A**). For this purpose, we screened the entire Unibind database⁹⁰, a catalogue of high-
42 confidence TF binding sites (TFBS) predictions based on ~3500 publicly available chromatin-

1 immunoprecipitation and sequencing (ChIP-seq) experiments from various tissues and cell types,
2 including those from ENCODE (**Figure 5A**). The number of unmethylated L1HS being relatively small in
3 most cell types, we also included the L1PA2 family to increase the statistical power of this analysis, as
4 it is the most recent primate-specific family after the L1HS family (**Figure S3A**) and shows a similar
5 pattern of proximal upstream epivariation (**Figure S4A**). Note that for each cell line in our panel, we
6 compared the methylated and unmethylated L1 subsets to all ChIP-seq data stored in Unibind,
7 irrespective of the cell-type or conditions in which they were obtained. The rationale is that even if
8 datasets from our cell line of interest are not present in Unibind, a similar cell type or condition may
9 be represented. Indeed, the screen revealed several TFs specifically associated, in at least one
10 biological condition, with the subset of methylated or unmethylated L1s found in one of the cell lines
11 of the panel (**Figure 5B**). Closer examination of the motifs underneath the ChIP-seq peaks indicates
12 that some of the binding sites are internal to the L1 promoter (such as for YY1), and some are found in
13 both the upstream and internal sequences (such as for ESR1, FOXA1, or CTCF) (**Figure 5C**)^{91,92}.

14 Among the top hits, YY1 is strongly enriched at the unmethylated subset of L1s from 2102Ep cells
15 (**Figure 5B**). The YY1 binding site is internal to the L1 promoter, but close enough to the 5' end (position
16 $+10 \pm 2$ bp) that the ChIP-seq signal largely overlaps the flanking sequence. The strong YY1 enrichment
17 at unmethylated L1s from 2102Ep cells was detected in Unibind datasets obtained in different cell
18 types, including two embryo-related cell lines, the H1 embryonic stem cells and NTera2/D1 embryonal
19 carcinoma cells. To confirm this association in matched cell types, we performed YY1 ChIP-seq in
20 2102Ep cells (**Figure 5D**) and tested if it was also observed in other cell types of the panel for which
21 YY1 ChIP-seq data were publicly available (**Figure 5E**). Although YY1 is relatively ubiquitously expressed
22 (**Figure S5A**), its binding to L1HS elements mostly occurs in the embryonal cell types, H1 and 2102Ep,
23 where YY1-bound L1HS elements represent a large fraction of all L1HS elements (**Figure 5E**, 41% and
24 69%, respectively). In these cells, YY1-bound L1HS elements are significantly less methylated as
25 compared to their YY1-unbound counterparts (**Figure 5D** and **Figure 5E**). Among other cell types, only
26 the hepatoblastoma cell line HepG2 shows a significant difference of methylation between YY1-bound
27 and -unbound elements, but overall, the number of bound elements is extremely limited in these cells
28 (**Figure 5E**, 9% in K-562, and <3% in HCT-116 and HepG2, 0% in HEK-293). Interestingly, the binding of
29 YY1 is not restricted to L1HS elements. A large fraction of L1PA2 elements in H1, and the majority of
30 them in 2102Ep cells, are bound by YY1, and again bound elements are significantly less methylated
31 than unbound ones (**Figure S5B**). By tracking an L1 progenitor active in the brain and carrying a small
32 5' truncation spanning the YY1 motif (chr13Δ31_{L1}), a previous report suggested that the YY1 binding
33 site is involved in L1 silencing, and thus proposed that YY1, or another pathway acting on its binding
34 site, may drive L1 methylation⁶³. As YY1 was best known to activate the L1 promoter, helping to define
35 accurate L1 transcription start site⁹²⁻⁹⁶, this finding was unexpected. We confirmed that the same
36 locus, as well as a small set of other elements lacking the YY1 motif, are hypomethylated in the
37 embryonal cell types H1 and 2102Ep (**Figure 5E**, blue labeled data points, and **Figure S5C**). However, if
38 we consider L1HS elements that are actually bound by YY1, and not only those that contain the YY1
39 motif, we observe that YY1 binding is in fact strongly associated with L1 hypomethylation (**Figure 5D**
40 and **Figure 5E**). Finally, copies bound by YY1 are also marked by active chromatin marks (H3K4me3)
41 (**Figure 5D**) and are more expressed in 2102Ep as compared to unbound elements (**Figure S5D**).
42 Altogether, these results reinforce the idea that, genome-wide, YY1 binding is not associated with the
43 repression of L1s, but is instead associated with L1 hypomethylation and transcriptional activity, at
44 least in embryonic stem cells or embryonal carcinoma cells. Thus, our data are consistent with a

1 scenario whereby alterations of the YY1 motif may incidentally affect other pathways targeting the
2 same sequence and leading to L1 hypomethylation⁶³.

3 Another prominent hit in our TF search was the estrogen receptor ESR1, which is strongly enriched
4 at unmethylated loci in the MCF-7 breast cancer cell line (**Figure 5B**). Unlike YY1, ESR1 binds not only
5 to the internal L1 sequence, but also to the upstream region (**Figure 5C**, **Figure 5G** and **Figure S5G**).
6 Altogether, almost one fourth of the loci are bound by ESR1 (**Figure 5F**). The expression level of this
7 TFs is higher in MCF-7 as compared to other cell types (**Figure S5A**), and L1 elements associated with
8 ESR1 binding are less methylated (**Figure 5F**). Among the 327 L1 elements with ESR1 binding, we
9 detected 42 L1 chimeric transcripts with a neighboring gene (**Figure 5H-I** and **Table S5**). These chimeric
10 transcripts engage both protein-coding RNA and lncRNA species, many of them being associated with
11 cancer, either as biomarkers or as oncogenes, and can encode tumor-specific antigens such as L1-
12 GNGT1^{13,49,97,98}. As an example, the 5' UTR of an L1PA2 element located in the intron of the *BCAS3*
13 gene is unmethylated, and covered by active chromatin marks (H3K4me3 and H3K27ac), while its 5'
14 UTR and immediate upstream region (-189 bp) are bound by ESR1 (**Figure 5H** and **Figure 5I**, left).
15 Moreover, RNA-seq data in MCF-7 show a high proportion of spliced reads between the L1PA2
16 antisense promoter and the closest *BCAS3* intron, indicating that L1 demethylation and ESR1 binding
17 are associated with antisense promoter activity, which can act as an alternative promoter for *BCAS3*.
18 Of note, unit-length L1 transcripts are also detected at this locus, suggesting that the L1 sense
19 promoter is also active. Finally, when ESR1 expression is experimentally reduced by siRNA-mediated
20 knockdown⁹⁹, the expression of L1 elements themselves (**Figure S5F**) and their chimeric transcripts
21 (**Figure 5I**) decreases. Given the importance of estrogen receptor (ER) status in breast cancer prognosis
22 and management, we explored data from the Pan-Cancer Analysis of Whole Genomes (PCAWG)
23 project to test whether ER status might be associated with increased L1 mobilization in this cancer
24 type^{48,100}. We found that ER⁺ tumors more frequently exhibit somatic L1 retrotransposition than ER⁻
25 tumors (**Figure S5H**, left). Nevertheless, the number of events is not significantly different between
26 the two groups (**Figure S5H**, right). Consistent with the detection of L1 ORF1p in more than 90% of all
27 breast adenocarcinoma cases, irrespective of their ER status^{101,102}, our results suggest that L1 might be
28 activated through different sets of transcription factors in ER⁻ and ER⁺ tumors. Altogether we conclude
29 that ESR1 directly drives L1 sense and antisense promoter activities in MCF-7 cells, and more generally,
30 that TFs bound within or next to unmethylated L1s can drive cell-type-specific functional alterations of
31 neighboring genes.

32 Finally, other TFs significantly enriched at hypomethylated L1s were bound to 5% or less of the
33 whole set of L1HS and L1PA2 elements (**Figure 5F**). Among them, FOXA1 is highly expressed in MCF-7
34 cells (**Figure S5A**). As FOXA1 has pioneer activity and can drive distance-dependent local demethylation
35¹⁰³, we speculate that cell-type-specific FOXA1 expression and binding could lead to the
36 hypomethylation of a small subset of L1 loci.

37 ***L1HS promoter hypomethylation is not sufficient to promote expression at most loci***

38 It is broadly accepted that hypomethylation of L1 leads to their transcriptional reactivation, at least
39 at the global level^{39,73}. To test this assumption at individual loci, we performed poly(A)⁺ RNA-seq for
40 the cell lines of the panel since these cells show a broad range of L1 expression⁹. Of note, RNA samples
41 were prepared from cells collected from the same plate as for bs-ATLAS-seq to match methylation and

1 expression data, with the exception of the embryonic stem cell H1 for which we used publicly available
2 data (due to regulatory restrictions). Unambiguously measuring L1HS expression levels at individual
3 loci is extremely challenging due to: (i) the low mappability of these repeated sequences; (ii) L1HS
4 insertional polymorphisms; and (iii) pervasive transcription of L1 embedded in genes that greatly
5 exceeds the autonomous transcription of unit-length L1 elements³⁴. To recognize autonomous L1
6 expression driven by the L1 promoter, we applied a previously devised strategy which measures
7 readthrough transcription downstream of reference and non-reference L1HS elements, after removing
8 potential signal from gene transcription or pervasive transcription⁹ (**Table S6**). To exclude that some
9 expressed copies could escape detection due to a strong polyadenylation signal at – or close to – an
10 L1 3' end, we also assessed L1 expression by L1EM¹⁰⁴, a software relying on the expectation-
11 maximization algorithm to reassign multi-mapping reads (**Table S6**).

12 Irrespective of the strategy used to identify expressed loci, we found that only a limited number of
13 them are expressed in a given cell type, consistent with our previous findings⁹ (**Figure 6A**, **Figure 6B**
14 and **Table S6**). Of note, some show intact ORFs and published evidence of retrotransposition capability,
15 as measured by cell culture assays or through the identification of transduction events deriving from
16 the locus (**Figure 6C** and **Table S6**). As expected, we observe a weak but significant anti-correlation
17 between L1HS methylation and expression in most cell types expressing detectable levels of L1HS
18 (**Figure 6A** and **Table S6**). Hence, the top-expressed loci are unmethylated (**Figure 6A** and **Figure 6D**,
19 top left) while fully methylated loci are not expressed (**Figure 6A** and **Figure 6D**, top right). However,
20 most unmethylated loci show no evidence of expression, indicating that hypomethylation of L1HS
21 elements alone is insufficient to permit their expression (**Figures 6A**, **Figure 6B** and **Figure 6D**, bottom
22 left). K-562 cells represent an extreme case of this configuration as only one single element shows
23 detectable expression while most copies are hypomethylated. Inversely, some L1HS with relatively
24 high levels of methylation are expressed in MCF-7 and HepG2 cells (**Figure 6A** and **Figure 6D**, bottom
25 right). Methylated copies could escape silencing by using upstream alternative promoter^{63,105}.
26 Alternatively, epiallele heterogeneity in the cell population or even between alleles could account for
27 their expression. Indeed, even if these elements are in the upper range of methylation, they show a
28 significant proportion of unmethylated reads (**Figure 6D**, bottom right). Beside the activity of the L1
29 sense promoter, we also detect antisense transcription, and some unmethylated L1HS elements only
30 produce antisense transcripts (**Figure 6D**, bottom left). These observations suggest that the absence
31 of DNA methylation at L1HS elements may not always be sufficient to trigger their transcriptional
32 activation.

33 To experimentally test this hypothesis, we measured L1HS methylation and expression in HCT-116
34 cells treated by the DNA methyltransferase inhibitor 5-aza-2'-deoxycytidine (5-aza)¹⁰⁶ (**Figure 7**).
35 Under our experimental conditions, 5-aza homogenously decreases methylation by 50% for all L1HS
36 elements (**Figure 7A**), with completely unmethylated reads at most loci (**Figure 7B**), as a likely
37 consequence of passive loss of DNA methylation during replication. As expected, this acute and
38 massive reduction of DNA methylation allows the reactivation of several transposable element families
39 including L1HS to L1PA8 (**Figure 7C**). However, it appears that only a subset of L1HS copies (22%, 85
40 out of 379 loci) are detected as expressed (**Figure 7D**). 5-aza-induced demethylation acts not only on
41 promoter regions, but also on gene bodies, with opposing effects on gene expression¹⁰⁷ – and thus
42 possibly on the expression of intragenic L1 elements. To exclude unpredictable effects of gene body
43 demethylation on intragenic L1 expression, we analyzed separately L1 loci located outside genes,

1 within genes that are expressed, and within genes that are not expressed (**Figure 7E**). The result shows
2 that the proportion of derepressed L1 loci upon 5-aza treatment is slightly superior in the expressed
3 genes as compared to non-transcribed regions. However, overall, the majority of L1 elements stay
4 silent. We thus conclude that acute demethylation is not sufficient at most L1 loci to ensure their
5 transcriptional reactivation.

6 To understand what differentiates reactivable loci from those that remain repressed, we measured
7 the association of each group of loci with histone modifications and chromatin segmentation states
8 obtained from the ENCODE project^{108,109}. Non-activable L1HS loci are associated with H3K9me3-rich
9 regions (**Figure 7F**, left), as well as with heterochromatin (**Figure 7F**, middle). Consistently non-
10 reactivable elements are enriched in B-compartments as compared to reactivable ones (**Figure 7F**,
11 right). These observations suggest that multiple layers of epigenetic repression coexist in the same cell
12 type, on the same family, and even on the same locus, and may persist at the majority of loci after
13 acute DNA demethylation by 5-aza, at least in HCT-116 colon carcinoma cells. Interestingly, an L1HS
14 element inserted in the intron of *CASC21* (L1-CASC21) shows strong levels of expression after 5-aza
15 treatment in HCT-116 (**Figure 7G** and **Figure 7H**). In K-562 and in MCF-7, this element is also
16 unmethylated but not expressed (**Figure 7I**) supporting the idea that cell-type specific factors are
17 necessary to activate L1HS expression, or that alternative epigenetic pathways may supplant DNA
18 methylation in the latter cell lines.

DISCUSSION

19 Understanding the impact and regulation of L1 elements in humans requires genome-wide
20 strategies able to profile the DNA methylation of full-length elements. Those belonging to the human-
21 specific L1 (L1HS) family are especially relevant, as they form the only family capable of autonomous
22 retrotransposition in our genome, but other young primate-specific L1 elements also constitute an
23 important source of genetic innovation. These families are notoriously difficult to study as all copies
24 are almost identical to each other - an issue accentuated by the C-to-T conversion in bisulfite
25 sequencing protocols - and because individual genomes significantly differ from the reference human
26 genome with respect to the presence or absence of L1HS insertions^{34,68}. To overcome these
27 bottlenecks, we have developed bs-ATLAS-seq, which gives access to the position and methylation
28 state of L1HS, including non-reference insertions, as well as those of many L1PA elements, at single-
29 locus, single-nucleotide and single-molecule resolutions (**Figure 1**). Bs-ATLAS-seq offers specific
30 advantages, including excellent cost-effectiveness, since it requires only 10-20 million reads per
31 sample, and versatility with regard to genomic DNA quality, since it works with partially fragmented
32 genomic DNA, as is typically the case in clinical samples. It can be used in conjunction with other
33 emerging approaches based on nanopore long-read sequencing, which for their part can haplotype-
34 resolve DNA methylation over the entire locus^{89,110,111}, as illustrated by our allele-specific methylation
35 analysis (**Figure 4**).

36 We comprehensively located young full-length L1 elements and characterized their DNA
37 methylation in a panel of twelve normal, embryonal, or cancerous cell lines, providing one of the most
38 detailed catalogues of L1 DNA methylation in human cells so far (<https://L1methdb.ircan.org>). Most
39 cells studied here belong to ENCODE top-tier cell lines, enabling integration with a wide variety of
40 publicly available functional genomics data, and thus facilitating the exploration of retrotransposon-

1 host genome interactions. We observed that in most cell types but embryonic cells, the methylation
2 of intragenic L1s is largely influenced by gene expression (**Figure 3**). Global L1 DNA methylation has
3 been extensively used as a cancer biomarker, often as a surrogate for measuring global genome
4 methylation levels ¹¹². Our findings suggest that deconvoluting L1 methylation signal at the level of
5 individual loci, particularly those inserted in genes, may represent an alternative source of DNA-based
6 biomarkers capturing cell-type-specific gene expression.

7 Early observations at select loci showed that exogenous retroviruses and transposable element
8 insertions could be targeted by DNA methylation, which then spreads to neighboring regions ^{113–116}.
9 However, a more systematic search of mouse endogenous retroviruses (ERVs) capable of spreading
10 DNA methylation to nearby gene promoters has detected only a single example ^{117,118}. By contrast,
11 hundreds of transposable element loci may affect the methylation status of their adjacent sequence
12 in *Arabidopsis thaliana* ¹¹⁹. In most cases, DNA methylation propagates over a few hundred base pairs,
13 but can reach several kilobases in *A. thaliana* ¹¹⁹. In addition, hypomethylated CpG islands can induce
14 so-called methylation “sloping shores” in their upstream sequence, a property previously reported for
15 a GFP reporter gene containing a CpG island and mobilized by an engineered mouse retrotransposon
16 ⁸⁷, and for an active progenitor L1 element ⁶³. The extent and significance of these phenomena
17 remained uncertain for human L1 elements. In our survey, we found that approximately one third of
18 informative loci exhibit spreading of DNA methylation from a methylated L1 to the adjacent sequence,
19 while another third shows demethylation of the flanking region upstream of hypomethylated L1s
20 (**Figure 4**). We note that, in theory, allele-specific alterations of DNA methylation associated with L1
21 insertions could reflect L1 insertions into pre-existing epialleles. However, in most cases, methylation
22 follows a gradient starting from the L1 element, suggesting that the insertion is directly responsible
23 for the proximal epivariation in the flanking sequence, and not the contrary. Finally, we found that L1-
24 mediated alterations of DNA methylation do not extend beyond 300 bp. This is contrasting with long-
25 distance DNA methylation propagation that can reach several kilobases in *A. thaliana*, and may involve
26 plant-specific pathways such as RNA-directed DNA methylation ^{119,120}, or even longer distance effects
27 driven by retrotransposon transcriptional activity ¹²¹. Although L1 affects nearby DNA methylation only
28 at short distances, epivariation in the zone of influence is associated with differential binding of
29 transcription factors and can affect the host transcriptome (**Figure 5**). These findings parallel recent
30 observations in mice indicating that polymorphic ERVs and L1s can alter local chromatin accessibility
31 ¹²².

32 One of our original questions was to test whether all methylated L1s were repressed and whether,
33 reciprocally, all unmethylated L1s were expressed. We found that the majority of unmethylated L1s
34 remains silent (**Figure 6**). Consistently, only a fraction of L1s appear reactivable upon acute DNA
35 demethylation by a demethylating agent (**Figure 7**). We conclude that, for most loci, L1
36 hypomethylation alone is insufficient to induce its expression and that other mechanisms prevent L1
37 reactivation in the absence of DNA methylation. We uncovered two non-exclusive scenarios. First, L1
38 silencing pathways can function redundantly and cohabit with DNA methylation at individual loci.
39 Consistently, we found that L1HS elements not reactivated upon 5-aza treatment are enriched in
40 H3K9me3-bound heterochromatic regions and B-compartments *before* demethylation in the HCT-116
41 colon cancer cell line (**Figure 7F**). Deposition of this repressive mark could involve Setdb1 or other
42 histone methyl transferases ^{123–126}, depending on the cell type, and be tethered by KZFPs-TRIM28 ¹²⁷
43 or the HUSH complex ^{43–45}. In other cell types, repression could rather involve SIN3A and the local

1 recruitment of histone deacetylases¹²⁸. Incidentally, we note that HUSH-mediated L1 silencing was
2 first discovered through a CRISPR screen in K-562 cells⁴³, in which L1PA elements appear to be virtually
3 devoid of DNA methylation (**Figure 2**). Knocking out any component of the HUSH complex in K-562
4 cells leads to a massive increase of L1 expression, but has more modest effects in other cell types⁴³.
5 Second, the expression of cell-type-specific TFs binding within or nearby L1, such as ESR1, can be
6 required to switch from an activable – but quiescent – state to an active state¹²⁹. Accordingly, knocking
7 down ESR1 expression limits L1 expression in the breast cancer cell line MCF-7 (**Figure 5**).

8 Retrotransposons and their chimeric transcripts represent a rich source of tumor-specific antigens,
9 which can be specifically recognized by infiltrating T cells or targeted by CAR-T cells^{130–133}.
10 Furthermore, they have the ability to induce a viral mimicry state, which stimulates innate immunity
11 through the sensing of double-stranded RNA and cytosolic DNA species^{45,134–138}. By modulating
12 retrotransposon expression, epigenetic drugs can thus enhance both specific and innate antitumoral
13 immune responses. Our findings underscore the need to precisely delineate the specific pathways
14 controlling the expression of individual loci. This knowledge will be critical for the development of
15 rational drug combinations capable of specifically re-expressing L1 elements and L1-derived tumor-
16 specific antigens of interest for immunotherapy, while minimizing off-targets.

17 ***Limitations of the study***

18 In our study, we identified a set of TFs associated with distinct L1HS or L1PA2 methylation states.
19 Given the high degree of identity between individual copies of these young L1 families and the
20 resolution of ChIP-seq experiments, only TFs binding sufficiently close to the 5' end of the element can
21 be unambiguously assigned to individual elements. Therefore, TFs that potentially bind L1s more
22 internally might be missed, even if documented in Unibind. As approaches capable of mapping TF
23 binding sites within repeated sequences, such as PAtChER⁷⁴, DiMeLo-seq¹³⁹, nanopore-DamID¹⁴⁰, or
24 nanopore-based NOME-seq¹⁴¹, become more widely available, this problem will become less acute in
25 the future. Additionally, we present data showing association between L1 methylation state and other
26 genomic features. In some cases, we could confidently infer causality (L1-mediated epivariation of the
27 proximal genomic region, transcription-mediated methylation of intronic L1s, ESR1-driven L1 chimeric
28 transcript synthesis). However, in other cases this remains an experimental challenge. A preponderant
29 difficulty is that L1 methylation could have been established in a different cellular context through
30 factors not necessarily present anymore, and this methylation pattern could have been maintained
31 since then.

STAR*METHODS

1 Detailed methods are provided in the online version of this paper and include the following:

- 2 • Key resources table
- 3 • Resource availability
 - 4 ○ Lead contact
 - 5 ○ Materials availability
 - 6 ○ Data and code availability
- 7 • Experimental model and subject details
- 8 • Method details
 - 9 ○ Bs-ATLAS-seq
 - 10 ○ Cas9-targeted nanopore sequencing
 - 11 ○ Methylated DNA immunoprecipitation (MeDIP)
 - 12 ○ LUMA
 - 13 ○ Infinium Human Methylation 450K BeadChip analysis
 - 14 ○ RNA-seq
 - 15 ○ 5-aza-deoxycytidine treatment
 - 16 ○ CHIP-seq
 - 17 ○ Transcription factor enrichment at unmethylated L1
- 18 • Quantification and statistical analysis

ACKNOWLEDGMENTS

19 This research was funded, in whole or in part, by the Agence Nationale de la Recherche, Grant ANR-
20 21-CE12-0001. A CC-BY 4.0 public copyright license has been applied by the authors to the present
21 document and will be applied to all subsequent versions up to the Author Accepted Manuscript arising
22 from this submission, in accordance with the grant's open access conditions.

23 We thank C. Baudoin and the IRCAN Genomics Core Facility (GenoMed) for sequencing, O. Croce
24 and IRCAN bioinformatics service for computing resources, B. Meyer for deploying the web portal on
25 IRCAN server, and members of the Cristofari lab for helpful discussions. We are grateful to the ENCODE
26 Consortium for RNA-seq and CHIP-seq data, and to J-L Garcia-Perez (Univ. of Edinburgh, UK) for
27 providing H1 genomic DNA. This work was supported by joint grants awarded to PAD and GC, and to
28 DvE and GC from the Agence Nationale de la Recherche (RETROMET, ANR-16-CE12-0020; ActiveLINE,
29 ANR-21-CE12-0001), as well as other grants awarded to GC from the Fondation pour la Recherche
30 Médicale (FRM, DEQ20180339170), the Agence Nationale de la Recherche (Idex UCAJEDI, ANR-15-
31 IDEX-01; Labex SIGNALIFE, ANR-11-LABX-0028; ImpacTE, ANR-19-CE12-0032), the Institut National du
32 Cancer (INCa PLBIO 2020-095), the Canceropôle Provence-Alpes-Côte d'Azur, INCa and the Provence-
33 Alpes-Côte d'Azur Region (Projet Emergence), Inserm (GOLD cross-cutting programme on genomic
34 variability), CNRS (GDR 3546). Equipment acquisition for the GenoMed facility was supported by
35 FEDER, Région Provence Alpes Côte d'Azur, Conseil Départemental 06, ITMO Cancer Aviesan (plan
36 cancer) and Inserm. Work in the laboratory of PAD was also supported by LabEx "Who Am I?" (ANR-
37 11-LABX-0071), Université Paris Cité IdEx (ANR-18-IDEX-0001) funded by the French Government
38 through its "Investments for the Future" program, Fondation pour la Recherche Médicale, and
39 Fondation ARC (Programme Labellisé PGA1/RF20180206807).

AUTHOR CONTRIBUTIONS

- 1 GC and PAD conceived the study and secured funding. CP developed the bs-ATLAS-seq procedure.
- 2 SL and GC designed and conducted the computational analyses. DP developed the web interface to
- 3 interrogate the data. CP, AS, CD, LF, AJD, DvE and SS contributed to other experiments. SL, PAD and
- 4 GC wrote the manuscript with inputs from all other authors. GC supervised the project.

DECLARATION OF INTERESTS

- 5 GC is an unpaid associate editor of the journal *Mobile DNA* (Springer-Nature).

FIGURES

Figure 1 – Bisulfite-ATLAS-seq (bs-ATLAS-seq) profiling of human L1 element promoters.

(A) Principle of the bs-ATLAS-seq method. The internal L1 promoter region (~ 900 bp) is illustrated (top). Transcription start sites for the sense (SP) and antisense (ASP) promoters are represented as broken arrows and overlap with the L1 5'UTR. Bs-ATLAS-seq interrogates the first 15 CpG sites of the L1 promoter, shown as vertical bars in the magnified view (bottom). The L1-specific primer used to amplify L1 junctions is shown as a green arrow. Genomic DNA is fragmented by sonication and ligated to a single-stranded methylated linker. Linker-ligated DNA is then treated with bisulfite and L1-containing fragments are specifically amplified by suppression PCR. In this approach, the linker is single-stranded and possesses the same sequence as the linker-specific primer (not its complementary sequence, grey arrow). Consequently, amplification only occurs upon prior extension from the L1-specific primer (green arrow) and synthesis of the linker complementary sequence (not shown). This strategy prevents linker-to-linker amplification. The L1-specific primer was designed to enrich for the L1HS family, but older related L1PA elements are also amplified (see **Figure 1E**). Finally, asymmetric paired-end sequencing provides the genomic location as well as the methylation levels of each L1 locus. R1 and R2 refers to reads #1 and #2, respectively. Note that 5-methylcytosine (5mC) and 5-hydroxymethylcytosine (5hmC) are both protected from bisulfite-induced deamination, thus bs-ATLAS-seq cannot discriminate between these two DNA modifications.

(B, C) Genome browser view of bs-ATLAS-seq results in the breast cancer cell line MCF-7 for a reference (B) and a non-reference (C) L1HS element in the TTC28 and NEDD4 genes, respectively. In the track showing the percentage of methylation, called CpG are indicated by a vertical gray bar, and the percentage of methylation as an overlapping black bar. In the 'coverage' and 'reads' tracks, vertical colored bars correspond to non-methylated CpG (blue) and methylated CpG (mCG, red). Since bisulfite-sequencing-based methods cannot discriminate between hydroxymethylated CpG (hmCG) and methylated-CpG (mCG), methylation status is indicated as mCG + hmCG. (C) For non-reference L1HS, only the genomic flank covered by read #1 (R1; bottom left) is visible in the genome browser view. Soft-clipped reads supporting the 5' L1 junction (split reads) are framed in pink. The proportion of mCG at each site and the frequency of the most common methylation

patterns deduced from read 2 (R2; bottom right) are indicated on the charts (right). The positions of the CpGs are given relative to the L1HS consensus sequence (see Methods).

(D) Number of full-length L1HS elements detected in the different cell lines by bs-ATLAS-seq, and their subfamilies. Pre-Ta, Ta0 and Ta1 represent different lineages of the L1HS family, from the oldest to the youngest, and were deduced from diagnostic nucleotides in L1 internal sequence (Boissinot et al., 2000) and thus could only be obtained for reference insertions as bs-ATLAS-seq provides only limited information on L1 internal sequence.

(E) Fraction and count of full-length reference L1 elements detected by bs-ATLAS-seq for each L1 family. Bars represent the average number of full length reference L1 elements detected by bs-ATLAS-seq (dark green, mean \pm s.d., n=12 cell lines), as compared to the total number of these elements in the reference genome (light green). Full length elements were defined as elements longer than 5,900 bp as annotated in UCSC repeatmasker track. The ratio of detected/total elements is indicated as a percentage on the right of each bar. Note that any given sample only contains a subset of reference L1HS due to insertional polymorphisms in the human population.

See also **Figure S1** and **Table S1**.

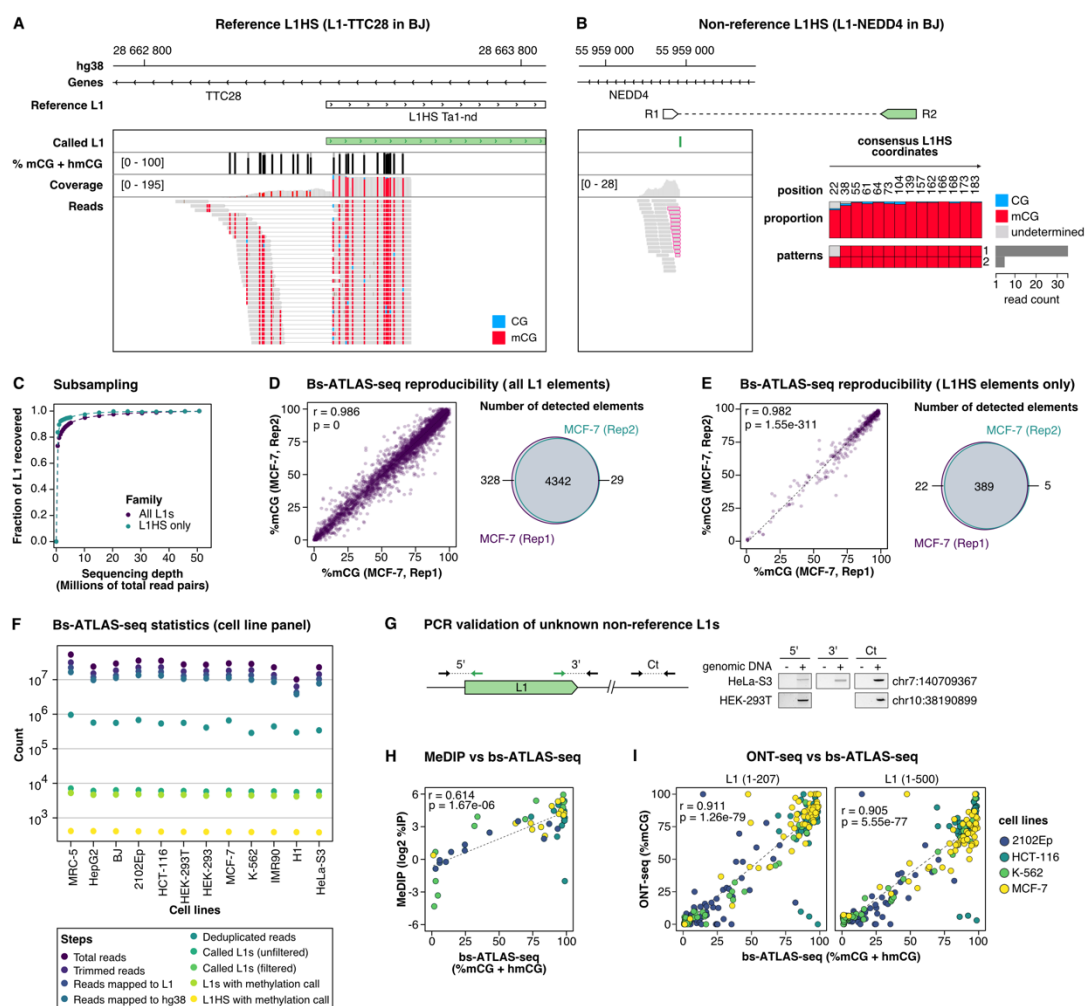

Figure S1 related to Figure 1 – Optimization, sequencing statistics and validation of bs-ATLAS-seq.

(A, B) Genome browser view of bs-ATLAS-seq results in BJ foreskin fibroblasts at the reference L1HS-TTC28 locus (A) and at the non-reference L1HS-NEDD4 locus (B). In the track showing the percentage of methylation, called CpG are indicated by a vertical gray bar, and the percentage of methylation as an overlapping black bar. In the ‘coverage’ and ‘reads’ tracks, vertical colored bars correspond to non-methylated CpG (blue) and methylated CpG (mCG, red). For non-reference L1HS, only the genomic flank covered by read #1 (R1 ; bottom left) is visible in the genome browser view. Soft-clipped reads supporting the 5’ L1 junction (split reads) are framed in pink. The proportion of mCG at each site and the frequency of the most common methylation patterns deduced from read #2 (R2 ; bottom right) are indicated on the charts (right). Positions of CpGs are related to L1HS consensus sequence (see Methods).

(C) Sensitivity analysis. Computational down-sampling of high depth bs-ATLAS-seq sequencing data (MCF7) shows that L1 recovery reaches a plateau above 10 million of total read pairs. Thus, all samples were subsequently sequenced to a depth greater than 10 million of total reads.

(D, E) Reproducibility of bs-ATLAS-seq. Two independent libraries of MCF-7 (from two subsequent MCF-7 passages) and sequencing runs are compared with respect to L1 elements of all families (E) or to L1HS elements only (F). Replicate 1 (MCF7, Rep1) was down sampled to the sequencing depth of replicate 2 (MCF7, Rep2) for comparison purpose. Left panels, correlation of methylation levels for shared detected L1 loci. Right panels, Venn diagram showing the overlap of detected L1 loci between the two libraries.

(F) Statistics of bs-ATLAS-seq for the 12-cell line panel. See also **Table S1**.

(G) PCR validation of unknown non-reference insertions. PCR was done with genomic DNA of the indicated cell lines (+) or with water as non-template control (-). The insertion in chr10 is pericentromeric and embedded in other repeats. Therefore, only primers to amplify the 5’ junction could be designed. Ct, unrelated locus used as PCR control.

(H) DNA methylation level of selected L1 elements was profiled using an antibody-based enrichment of DNA methylation (MeDIP) and compared with bs-ATLAS-seq data. The DNA methylation level of MeDIP data is expressed as log₂ of the percentage of immunoprecipitation (log₂ %IP). See also **Table S2**.

(I) Comparison of bs-ATLAS-seq with PCR-free targeted sequencing and methylation calling by Oxford Nanopore Technology sequencing (ONT-seq) for the L1 region common to both methods (1-207) or the full CpG island (1-500). See also **Table S4**.

For all correlation analysis, *r* and *p* represent Pearson correlation coefficient and *p*-value, respectively.

Figure 2 – L1 promoter DNA methylation is cell-type- and family-specific.

Distribution of DNA methylation levels (% mCG + hmCG) obtained by bs-ATLAS-seq, by family and cell type. Boxplots represent the median and interquartile range (IQR) $\pm 1.5 * IQR$ (whiskers). Outliers beyond the end of the whiskers are plotted individually.

See also **Figure S2** and **Table S3**.

Figure S2 related to Figure 2 – DNA methylation at different scales.

(A) Aggregate DNA methylation level of the L1 promoter for all L1 elements detected by bs-ATLAS-seq (L1HS to L1PA8) across normal (green), embryonal (hatched), or transformed and cancer (blue) cells.

(B) Barplot indicating the absolute numbers of unmethylated L1 copies (% mCG < 25% according to bs-ATLAS-seq) across the different cell lines, for L1HS (light green) and older copies (L1PA2 to L1PA8, dark green).

(C) Comparison of methylation levels for reference and non-reference L1HS elements across the different cell lines. Differences are not significant (two-sided two-sample Wilcoxon test).

(D) Number of CpGs per element analyzed by bs-ATLAS-seq for each L1 family.

(E) Genome-wide global CpG methylation measured by LUMInometric Methylation Assay (LUMA). A subset of the cell line panel assayed by bs-ATLAS-seq showing low- or high- levels of L1HS methylation were tested for genome-wide global CpG methylation by LUMA (green). HCT-116 DKO and WT refers to a double *DNMT1* and *DNMT3B* knock-out, and its parental cell line, respectively (white). These additional cell lines were used as controls in the LUMA assay. Bars represent the average percentage of methylated CCGG sites (mean \pm sem, n=3 technical replicates).

In panels (A), (C) and (D), boxplots represent the median and interquartile range (IQR) \pm 1.5 * IQR (whiskers). Outliers beyond the end of the whiskers are plotted individually.

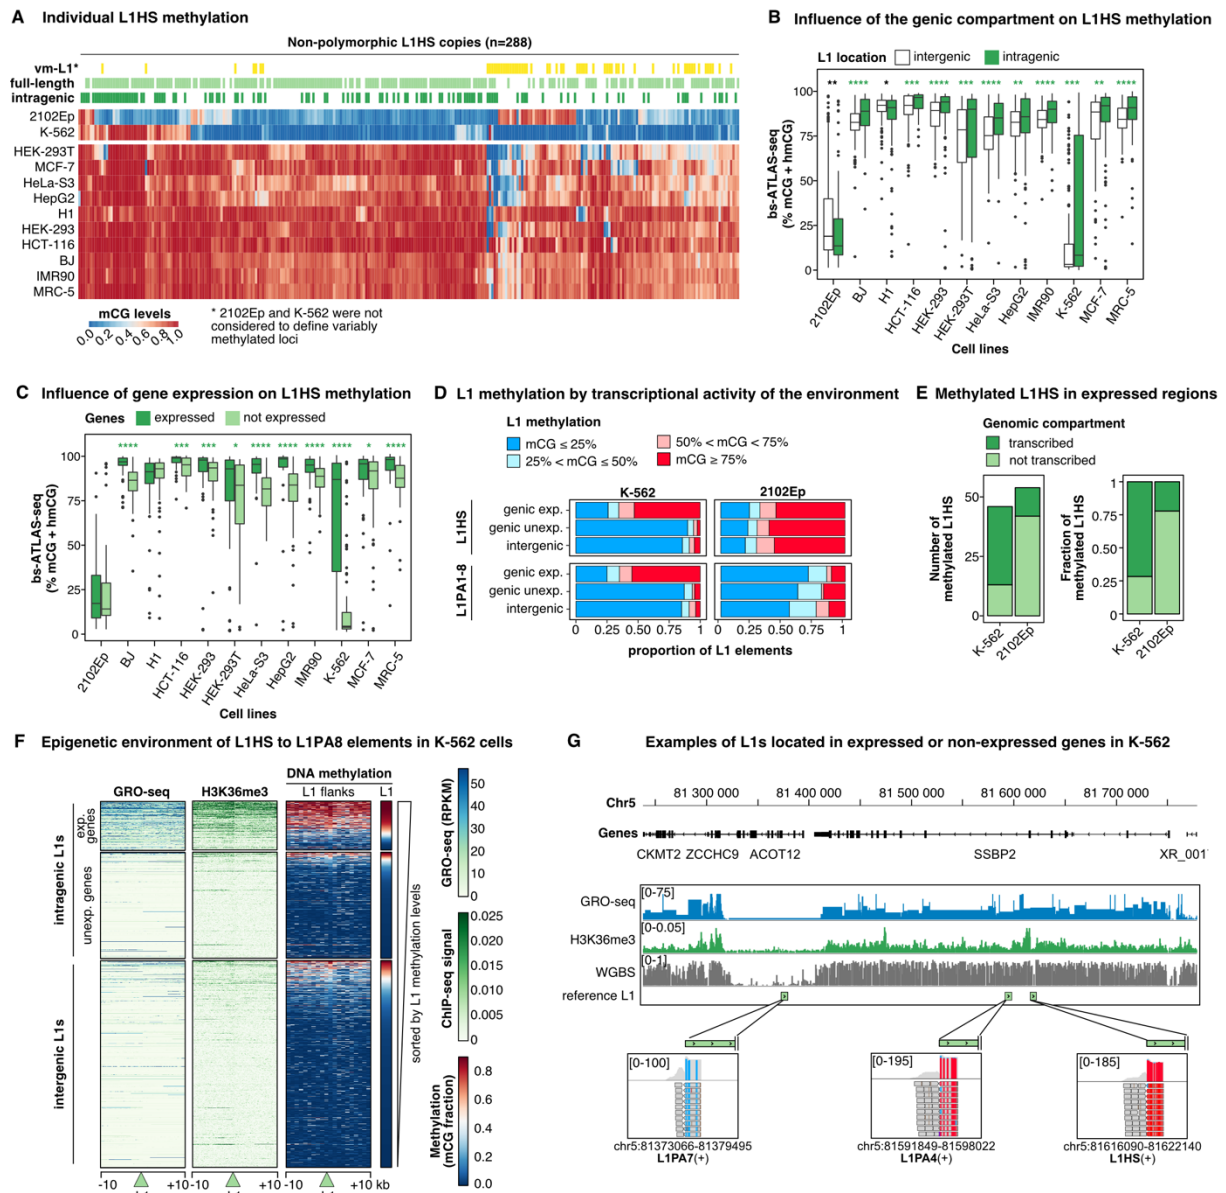

Figure 3 – L1HS promoter DNA methylation is locus-specific and influenced by the local environment.

(A) Heatmap of bs-ATLAS-seq methylation levels (% mCG + hmCG, from blue for unmethylated to red for fully methylated) for individual L1HS loci across a panel of 12 cell lines. Each column represents an L1HS locus. Only loci shared by all cell lines are shown here. For a heatmap including polymorphic L1HS elements, see **Figure S3B**. Rows and columns were ordered by hierarchical clustering based on methylation values. Intragenic L1HS are indicated in dark green above the heatmap and full-length L1HS copies in light green. Variably methylated L1 elements (vm-L1s, yellow) were defined as showing a greater difference between the second highest and the second lowest values of DNA methylation at this locus. K-562 and 2102Ep values were not considered to define vm-L1s.

(B) Comparison of L1HS methylation levels obtained by bs-ATLAS-seq for intra- (green) vs inter-genic (white) elements.

(C) Comparison of the methylation levels of intragenic L1HS obtained by bs-ATLAS-seq for expressed (dark green; TPM≥1) vs non-expressed genes (light green; TPM<1)

(D) Proportion of L1 elements in different methylation level categories according to their genic environment and activity in K-562 (left) or 2102Ep (right) cells. Note that L1PA1 is synonymous with L1HS.

(E) Distribution of methylated L1HS elements in transcribed (dark green) vs non-transcribed (light green) genomic compartments in K-562 and 2102Ep cells.

(F) Heatmaps illustrating nascent transcription (GRO-seq), H3K36me3 histone modifications (ChIP-seq), and DNA methylation (whole genome bisulfite sequencing, WGBS), in 10 kb-windows upstream and downstream L1 elements from the L1HS to the L1PA8 family (green triangle). Loci are separated according to their position relative to genes (left), separating expressed and unexpressed genes, and sorted by decreasing L1 methylation levels (bs-ATLAS-seq, right). Data are shown in 10 bp-bins. A similar heatmap restricted to the L1HS family is shown in **Figure S3C**.

(G) Genome browser view of a region on chromosome 5 encompassing three full-length L1 elements (green rectangles) with distinct promoter DNA methylation profiles, integrated with nascent transcription (GRO-seq), H3K36me3 histone modifications (ChIP-seq), and DNA methylation (WGBS) datasets in K-562 cells. The bottom inserts show L1 methylation as measured by bs-ATLAS-seq. The methylated L1HS and L1PA4 elements are inserted in a transcribed gene marked by high H3K36me3 and DNA methylation levels over the entire gene body, while the unmethylated L1PA7 is inserted in an unexpressed gene with low gene body DNA methylation and H3K36me3 levels.

In panels (B) and (C), boxplots represent the median and interquartile range (IQR) $\pm 1.5 \times$ IQR (whiskers). Outliers beyond the end of the whiskers are plotted individually. * $p < 0.05$, ** $p < 0.01$, *** $p < 0.001$, and **** $p < 0.0001$, one-sided two-sample Wilcoxon test (green for increase and black for decrease).

See also **Figure S3** and **Table S3**.

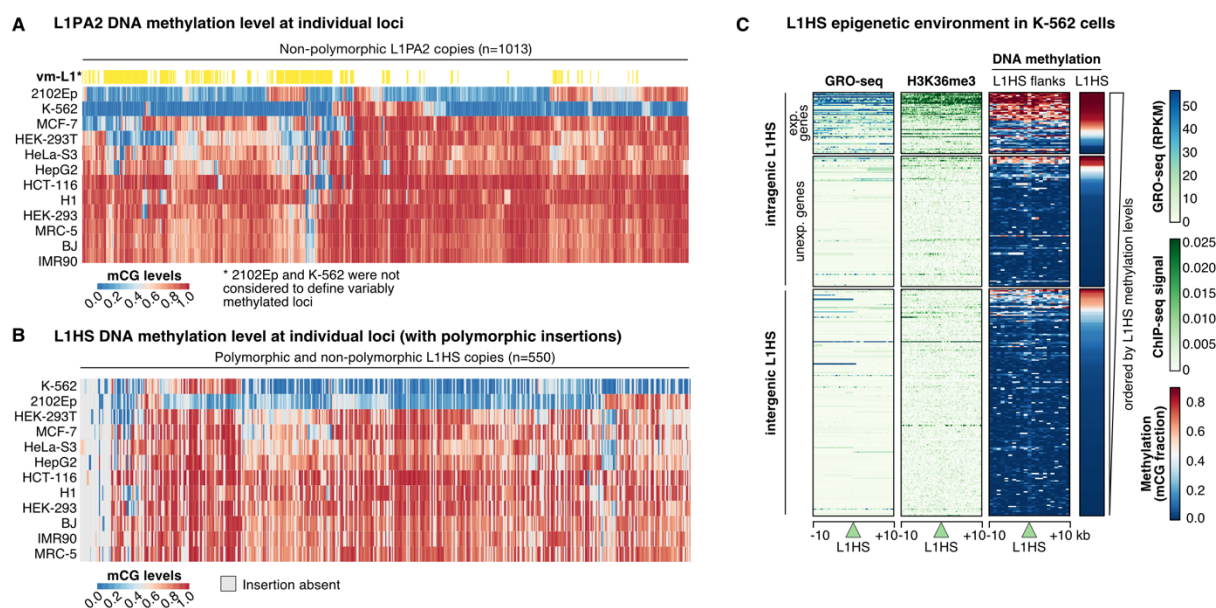

Figure S3 related to Figure 3 – Methylation level of the youngest L1 subfamilies.

(A) Heatmap of bs-ATLAS-seq methylation levels (% mCG + hmCG) for individual L1PA2 loci across a panel of 12-cell lines. Vm-L1, variably-methylated L1 loci (see **Figure 3** for definition).

(B) Heatmap of bs-ATLAS-seq methylation levels (% mCG + hmCG) displaying values for both reference and non-reference L1HS across cell lines. When an insertion is absent in a given cell line, the heatmap cell is colored in grey.

(C) Heatmaps illustrating nascent transcription (GRO-seq), H3K36me3 histone modifications (ChIP-seq), and DNA methylation (whole genome bisulfite sequencing, WGBS), in 10 kb-windows upstream and downstream L1HS elements (green triangle). Loci are separated according to their position relative to genes (left), separating expressed and unexpressed genes, and sorted by decreasing L1 methylation levels (bs-ATLAS-seq, right). A similar heatmap including all families (from L1HS to L1PA8) is shown in **Figure 3F**.

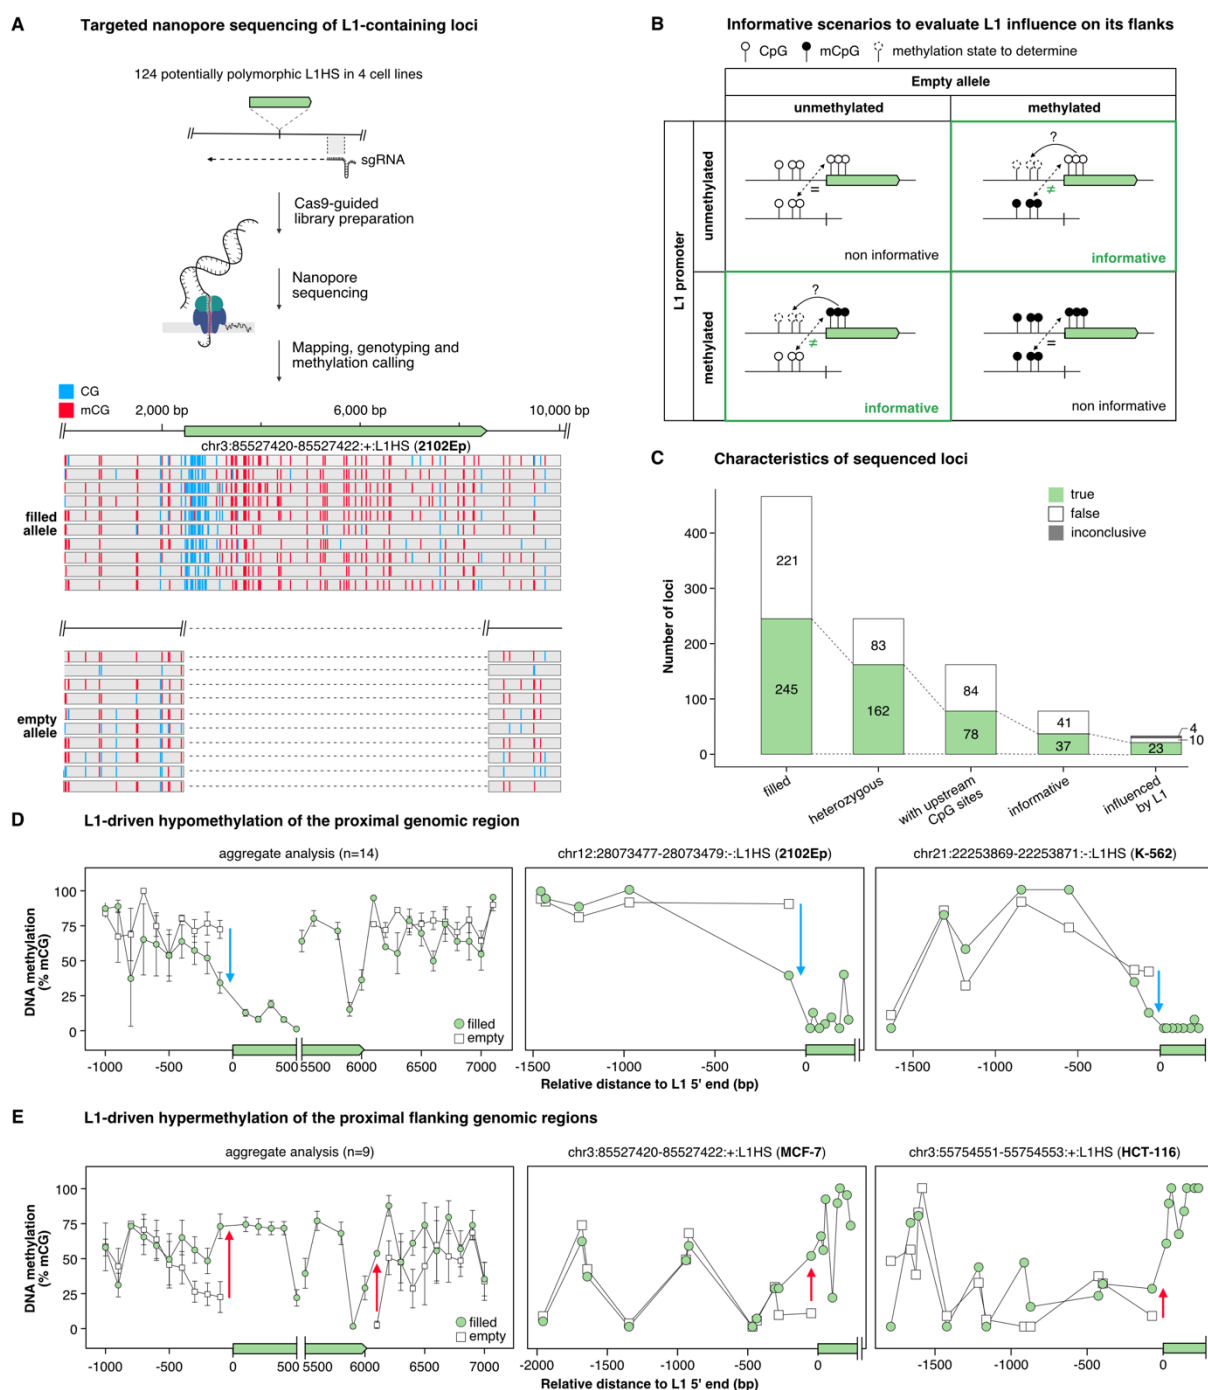

Figure 4 – L1s frequently induce proximal epivariation.

(A) Scheme summarizing the strategy to genotype and assess DNA methylation profiles of loci containing polymorphic L1HS elements by Cas9-guided nanopore sequencing. Single-guide RNAs (sgRNAs) designed to bind ~ 1 kb downstream of each L1HS insertion (green solid arrows), were synthesized *in vitro* as a pool and assembled with recombinant Cas9. Cleavage of genomic DNA with the pool of Cas9 RNPs allows the subsequent ligation of sequencing adapters downstream of L1s and targeted nanopore sequencing of the selected loci (see Methods). As an example, a genome browser screenshot is shown for the insertion chr3:85527420-85527422:+:L1HS:NONREF in 2102Ep cells (top: filled allele, bottom: empty allele). The targeted L1HS (green), as well as methylated (red) and unmethylated (blue) CpG are indicated. Only the first 10 reads are shown for each allele, and the 3' end of the reads (on the left) have been truncated for layout.

(B) Theoretical methylation profiles at heterozygous L1 insertions (green solid arrow). The influence of L1 methylation on the surrounding genomic region can only be detected in situations where the methylation state of L1 differs from that of the empty locus (assumed to represent the pre-integration state). For these informative scenarios, the DNA methylation level of the region upstream of L1 is then analyzed and compared to the empty locus.

(C) Characteristics of the loci profiled by nanopore sequencing. The y-axis represents the number of loci characterized in the 4 cell lines as filled, heterozygous and with CpG sites upstream of L1 (~ 300 bp). Among them, 37 loci were considered

as informative: 23 with a profile consistent with L1-induced epivariation, 10 showing no evidence of L1-induced epivariation, and 4 being inconclusive (see Methods).

(D) L1-driven hypomethylation of the proximal upstream genomic region. Left, average DNA methylation levels in 100 bp-bins at loci with an upstream slopping shore (n=14, mean \pm s.d.). Middle and right, examples of L1-induced upstream flank hypomethylation.

(E) L1-driven methylation of the proximal flanking genomic region. Left, average DNA methylation levels in 100 bp-bins at loci with DNA methylation spreading from L1 to the external flanks (n=9, mean \pm s.d.). Middle and right, examples of L1-induced flanking sequence DNA methylation.

For **(D)** and **(E)**, the empty (white squares) and filled (green circles) alleles are overlaid. Blue and red arrows denote hypo- and hyper-methylation relative to the empty locus, respectively. The x-axis represents the relative distance to L1 5' end (bp) and the y-axis the percentage of DNA methylation.

See also **Figure S4** and **Table S4**.

Figure S4 related to Figure 4 – DNA methylation profiles of L1s and their target loci.

(A) DNA methylation profiles of methylated (mCG \geq 75%, red) and unmethylated (mCG \leq 25%, blue) L1 (L1HS to L1PA4) 5' junctions obtained by bs-ATLAS-seq data. Data represent average DNA methylation levels in 10 bp-bins aggregated from the 12 cell lines (mean \pm 95% C.I.).

(B) DNA methylation profiles of methylated (mCG \geq 75%; red) and unmethylated (mCG \leq 25%; blue) L1HS 5' junctions obtained by ONT-seq in 4 different cell lines (K-562, 2102Ep, HCT-116, MCF-7). Note that for the sake of comparison, the distinction of methylated vs unmethylated L1 is based on the first 15 CpG, as for bs-ATLAS-seq. Given the small numbers, unmethylated L1 in HCT-116 and MCF-7 (n=3 and n=3, respectively), and methylated L1s in K-562 (n=4) were not plotted. Data points represent average mCG levels in 100 bp-bins for each cell line (mean \pm s.d.).

(C) Example of locus with DNA methylation spreading from L1 to the external flanks. Red arrows denote hypermethylation relative to the empty locus.

(D, E) Large-scale allele-specific epivariation associated with an L1 insertion. (D) Methylation levels and (E) genome browser view (top: filled allele, bottom: empty allele). The L1 insertion is depicted as a green solid arrow. Methylated and unmethylated CpG are indicated in red and blue, respectively.

(F) Loci not influenced by L1 methylation state. Left, average DNA methylation levels in 100 bp-bins (n=10, mean \pm s.d.). Middle and right, examples of loci not influenced by L1 methylation.

For (A) to (D), and (F), the x-axis represents the relative distance to L1 5' end (green) and the y-axis the percentage of DNA methylation. For (C), (D) and (F), the empty (white squares) and filled (green circles) alleles are overlaid.

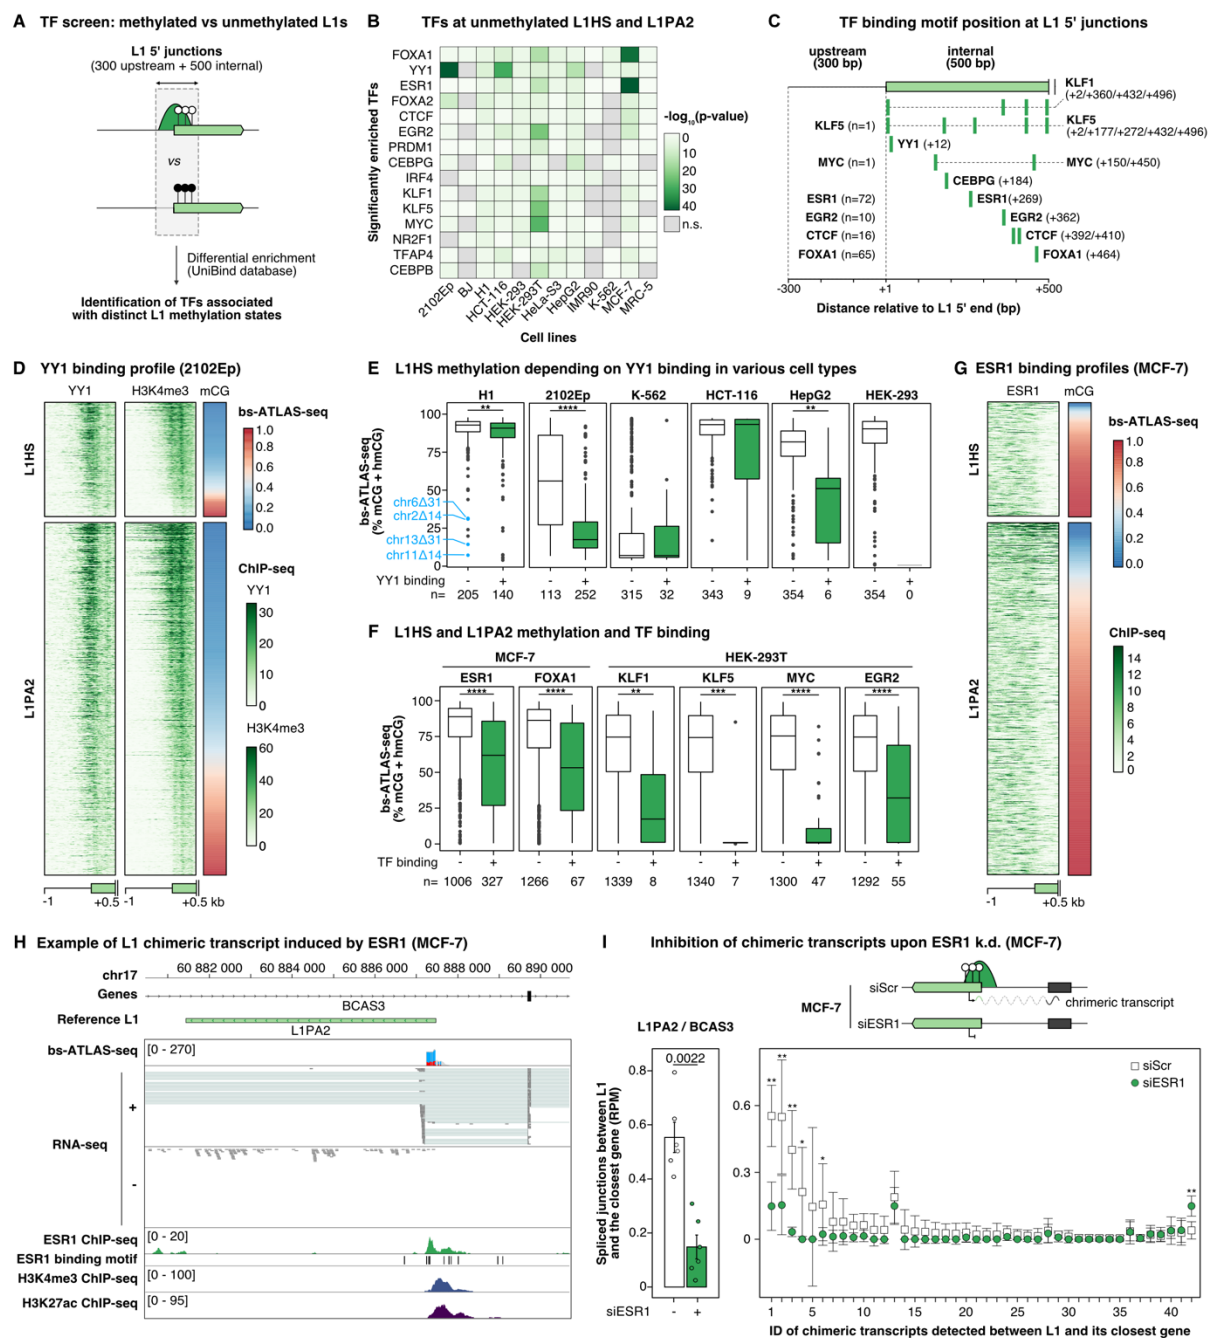

Figure 5 – Unmethylated L1 and their flanking sequences are bound by a specific set of transcription factors (TFs).

(A) Screening strategy to identify TFs differentially associated between unmethylated and methylated L1HS and L1PA2 copies using curated datasets publicly available in the UniBind database⁹⁰. Note that for each cell line in our panel, we compared each pair of methylated and unmethylated L1 subsets to all ChIP-seq data stored in Unibind (~3500 datasets), irrespective of the cell-type or conditions in which they were obtained. The rationale was that even if our specific cell line is not necessarily represented in Unibind datasets, a similar cell type may be represented. The main hits were then subsequently confirmed using matched datasets (see panels E and F).

(B) Heatmap showing the TF binding enrichment at hypomethylated L1HS and L1PA2 in our panel of cell types. Only the 15 most enriched TFs are shown.

(C) Schematic representation of the location of the motifs corresponding to the TFs identified in (B). For TFs binding upstream of L1 insertions, the number of loci with an upstream peak is indicated.

(D) Heatmap displaying L1 methylation (bs-ATLAS-seq), as well as YY1 and H3K4me3 binding (ChIP-seq), at the 5' junction (-1 to +0.5 kb) of L1HS and L1PA2 elements in 2102Ep cells. Loci are sorted by increasing levels of L1 methylation. ChIP-seq signal represents the number of normalized reads per 10-bp bin.

(E) DNA methylation level of L1HS bound (+) or unbound (-) by YY1 in embryonal cell lines (H1 and 2102Ep) and other cell lines for which matched YY1 ChIP-seq were also publicly available (K-562, HCT116, HepG2, HEK-293T). The number of L1HS

copies in each subset (n) is indicated at the bottom of the plot. In H1 cells, the four hypomethylated loci in blue refer to those studied in ⁶³.

(F) DNA methylation levels of L1HS and L1PA2 loci bound (+) or not bound (-) by ESR1, FOXA1, KLF1, KLF5, Myc and EGFR2 in the relevant cell types. ChIP-seq data are matched to the cell line. The number of L1HS copies in each subset (n) is indicated at the bottom of the plot.

(G) Heatmap displaying L1 methylation (bs-ATLAS-seq), as well as ESR1 binding (ChIP-seq), at the 5' junction (-1 to +0.5 kb) of L1HS and L1PA2 elements in MCF-7 cells. Loci are sorted by increasing levels of L1 methylation. ChIP-seq signal represents the number of normalized reads per 10-bp bin.

(H) Genome browser view of the *BCAS3* locus integrating L1 methylation (bs-ATLAS-seq), expression (poly(A)⁺ RNA-seq), ESR1 binding, as well as H3K4me3 and H3K27ac histone modifications (ChIP-seq). Note the distinctive spliced RNA-seq reads, antisense relative to the L1 element, linking L1 antisense promoter with the adjacent *BCAS3* exon.

(I) siRNA-mediated knock-down of ESR1 leads to reduced L1 chimeric transcripts. Top, schematic representation of chimeric transcripts initiated from L1 antisense promoter and leading to truncated or alternative isoforms of the surrounding gene. Upon siRNA-mediated knock down (siESR1), the number of L1 chimeric splice junctions is expected to decrease if ESR1 drives chimeric transcript synthesis, as compared to a scrambled siRNA control (siScr). Bottom left, chimeric transcripts at the *BCAS3* locus quantified by the number of normalized spliced-RNA-seq reads (RPM) detected in MCF-7 cells treated by an siRNA against ESR1 (+) or a control scrambled siRNA (-) (data from GSE153250). Bars represent the mean \pm s.d. (n=6) and are overlaid by data of individual replicates (one-sided two-sample Wilcoxon test). Bottom right, average chimeric transcripts quantified as the normalized number of splice junctions between L1 and its closest gene in RPM for 42 loci (n=6, mean \pm s.d.). The 42 loci are sorted by descending order according to the difference of chimeric transcript levels between cells treated by siESR1 and the control siScr, and the associated number corresponds to the transcript ID in **Table S5**. For 37 loci out of 42 (88%), L1 chimeric transcription is reduced upon ESR1 knock down. The difference is statistically significant for 5 loci (one-sided two-sample Wilcoxon test).

In panels (E) and (F), boxplots represent the median and interquartile range (IQR) \pm 1.5 * IQR (whiskers). Outliers beyond the end of the whiskers are plotted individually. *p < 0.05, **p < 0.01, ***p < 0.001, and ****p < 0.0001, two-sided two-sample Wilcoxon test.

See also **Figure S5** and **Table S5**.

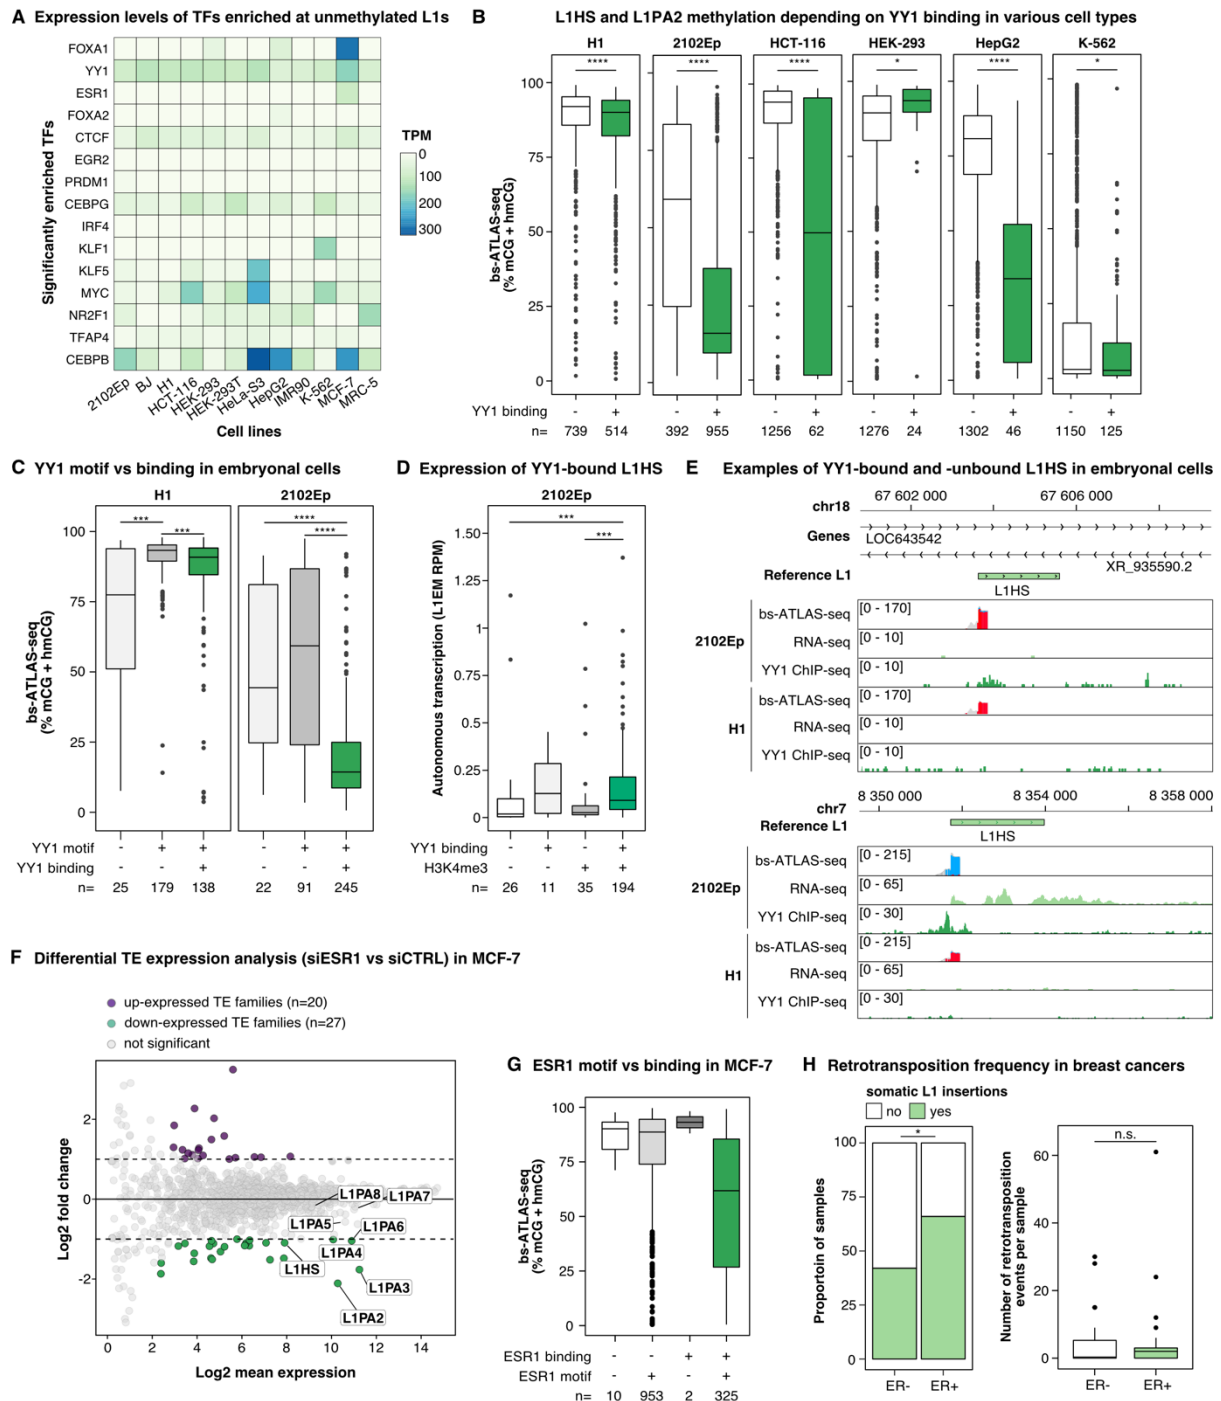

Figure S5 related to Figure 5 – Unmethylated L1HS and L1PA2 are bound by YY1 in embryonal cells.

(A) Heatmap showing the expression levels of the 15 most enriched TF identified in the screen across the panel cell lines. FOXA1 and ESR1 are more expressed in MCF-7 as compared to other cell types whereas YY1 is more ubiquitously expressed, even if it predominantly binds to L1 elements in embryonal cells (H1 and 2102Ep) (see **Figure 5E** and panel B). Expression level is measured as transcripts per million (TPM).

(B) DNA methylation levels of L1HS and L1PA2 elements bound (+) or unbound (-) by YY1 in embryonal cell lines (H1 and 2102Ep) and other cell lines for which matched YY1 ChIP-seq were also publicly available (K-562, HCT116, HepG2, HEK-293T). The number of L1HS copies in each subset (n) is indicated at the bottom of the plot.

(C) DNA methylation levels of L1HS loci with (+) or without (-) YY1 binding motifs in their 5' UTR, and actually bound (+) or not (-) by YY1 in H1 and 2102Ep cells.

(D) Expression level of L1HS element bound (+) or not (-) by YY1 and associated (+) or not (-) with H3K4me3 histone modification in 2102Ep cells. Locus-level expression was estimated by L1EM. The number of L1HS copies in each subset (n) is indicated at the bottom of the plot.

(E) Genome browser view of two example L1HS loci with distinct promoter DNA methylation profiles (bs-ATLAS-seq), integrated with RNA-seq and YY1 ChIP-seq data in H1 and 2102Ep. Top, locus in chromosome 18, the YY1 signal is close to the background level, the L1HS element is hypermethylated and non-expressed. Both cell lines have similar profiles. Bottom, locus in chromosome 7, a strong YY1 peak is detected in 2102Ep cells, where the L1HS is completely unmethylated and robustly expressed. In contrast, in H1 cells, the same locus does not appear bound by YY1, is hypermethylated and non-expressed.

(F) Differential expression of transposable element (TE) families between MCF-7 cells treated by an siRNA against ESR1 (+) or a control scrambled siRNA (-) measured by RNA-seq using Tetrascripts¹⁴² (data from GSE153250). In the MA-plot, each data point represents an aggregated TE family. TE families found significantly up- or down-regulated upon ESR1 knockdown are colored in purple and green, respectively, and data points corresponding to the L1HS to L1PA8 families are labelled (of which L1HS to L1PA6 are downregulated).

(G) DNA methylation levels of L1HS and L1PA2 loci with (+) or without (-) ESR1 binding motif in their 5' UTR and actually bound (+) or not (-) by ESR1 in MCF-7 cells. Note that the two loci without internal ESR1 binding motif but bound by ESR1 (dark grey) have a binding motif upstream (<300 bp) of the element.

(H) Somatic L1 retrotransposition in breast cancer according to the estrogen receptor (ER) status in PCAWG samples. Left, proportion of cancer samples with at least one somatic L1 insertion. Right, number of somatic L1 retrotransposition events per sample. ER status was obtained from¹⁰⁰ and somatic L1 retrotransposition events were identified in⁴⁸.

Figure 6 – L1HS promoter hypomethylation is not sufficient to trigger L1HS expression at the locus level.

(A) Genome-wide correlation between L1HS expression and methylation at individual L1HS loci in the entire cell line panel. L1 expression level is estimated through 3' readthrough transcription, a consequence of the weak L1 polyadenylation signal⁹. Briefly, we calculated the number of unique RNA-seq reads mapped within a 1 kb-window downstream of L1 and on the same strand, and subtracted the number of unique reads mapped within a 1 kb-window upstream of L1 to eliminate signal from surrounding pervasive transcription. Then, the value was normalized by the total number of mapped reads (RPKM). Negative values were set to 0. Most L1HS are not expressed and hypermethylated (lower right corners). r and p represent Pearson's correlation coefficient and p-value, respectively. A regression line is indicated in pink.

(B) Barplots indicating the absolute number of L1HS elements with low (mCG \leq 25%), medium (25% < mCG < 75%) or high (mCG \geq 75%) methylation levels obtained by bs-ATLAS-seq, and detected as unexpressed (white) or expressed (light green) by the combined 3' readthrough (3' RT) and L1EM¹⁰⁴ approaches.

(C) Barplots indicating the absolute number of expressed L1HS elements across the different cell lines, for non-intact (white) and intact copies (dark green). Among the expressed L1 elements, the associated pie charts show the proportion of copies with published evidence of retrotransposition competence.

(D) Genome browser views of 4 L1HS loci with distinct configuration of DNA methylation and expression in MCF-7 cells. L1 DNA methylation (bs-ATLAS-seq) is integrated with poly(A)⁺ RNA-seq and H3K4me3 ChIP-seq data. An unmethylated and expressed (top left), a methylated and unexpressed (top right), an unmethylated and unexpressed (bottom left) and a half-methylated and expressed L1HS (bottom right) are shown.

See also **Table S6**.

Figure 7 – Acute DNA demethylation only reactivates the expression of a minor fraction of L1HS loci.

(A) Metaplot of L1 DNA methylation profiles (bs-ATLAS-seq) at the L1HS promoter and upstream flanking region (300 bp) in HCT-116 treated with 5-aza-2-deoxycytidine (two replicates, AZA #1 and AZA #2; dark green) or with DMSO as negative control (two replicates: DMSO #1 and DMSO #2; light green).

(B) Fraction of fully unmethylated reads in 5-aza- or DMSO-treated HCT-116 cells. Boxplots represent the median and interquartile range (IQR) $\pm 1.5 \times$ IQR (whiskers). Outliers beyond the end of the whiskers are plotted individually. See (C) for legend.

(C) Differential expression of transposable element (TE) families between 5-aza- or DMSO-treated HCT-116 cells measured by poly(A)⁺ RNA-seq using Tetranscripts¹⁴². In the MA-plot, each data point represents an aggregated TE family. TE families

found significantly up- or down-regulated upon 5-aza treatment are colored in purple and green, respectively, and data points corresponding to the L1HS to L1PA8 families are labelled (of which all but L1PA8 are upregulated).

(D) Heatmaps showing the average difference of L1HS methylation (ΔmCG , bs-ATLAS-seq, 2 replicates) between HCT-116 cells treated by DMSO and 5-aza (AZA), as well as the expression levels of each L1HS in RNA-seq replicates (L1 3' readthrough, see legend of **Figure 6A**). Heatmaps were sorted by decreasing L1 expression (average of the 3 replicates).

(E) Barplot indicating the proportion of unexpressed (light green) and expressed (dark green) L1HS loci under 5'-aza treatment according to their genic environment and activity in HCT-116 cells. * $p < 0.05$, ** $p < 0.01$, two-sided two-proportions z-test.

(F) Association of L1HS elements that can be reactivated or not by 5-aza treatment, with pre-treatment histone modifications (left), chromatin states (18-state chromHMM, middle), or A/B-compartments (right) in HCT-116 cells. Heatmaps display the magnitudes of overlaps between L1 flanking sequences (± 100 bp) and the genomic feature of interest expressed as Z scores (blue for depletion and red for enrichment). Pie charts represent the proportion of L1HS elements in the A or B-type of compartment, for reactivable vs non-activable copies (p -value, two-sided two-proportions z-test). Chromatin segmentation and genome compartmentalization data for HCT-116 cells were obtained from ENCODE and ¹⁴³, respectively. Reactivated loci correspond to the 85 loci detected as expressed under 5'-aza treatment in HCT-116 by the two methods (union of 3' readthrough and L1EM).

(G) Genome browser view of the L1HS-CASC21 locus treated (AZA) or not (DMSO) by 5-aza, integrating L1 methylation (bs-ATLAS-seq) and expression (poly(A)+ RNA-seq).

(H) L1HS expression vs methylation in 5-aza-treated HCT-116 cells. L1 methylation is defined here as the mean fraction of fully unmethylated reads per L1HS locus and per condition (AZA or DMSO) and expression is estimated through L1 3' readthrough as described in the legend of **Figure 6A**. Each point represents an L1HS locus and a replicate and was colored in light (DMSO) or dark (AZA) green.

(I) Comparison of the expression and methylation levels of an intronic L1HS insertion located in the CASC21 gene, across cell types and conditions. This element is only expressed upon 5-aza treatment, but not in other cell types with similar or even completely abolished methylation (MCF-7, K-562, 2102Ep or HEK-293T).

RESOURCE AVAILABILITY

1 **Lead contact**

2 Further information and requests for reagents may be directed to, and will be fulfilled by, the
3 corresponding author, Gael Cristofari (gael.cristofari@univ-cotedazur.fr).

4 **Materials availability**

5 This study did not generate any new unique reagents or materials to report.

6 **Data and code availability**

1 Data were submitted to the ArrayExpress database (www.ebi.ac.uk/arrayexpress) under accession
2 numbers E-MTAB-10895 and E-MTAB-12240 (bs-ATLAS-seq), E-MTAB-12247 (ONT sequencing), E-
3 MTAB-12249 (ChIP-seq), and E-MTAB-12246 and E-MTAB-12245 (RNA-seq). The genomic location and
4 methylation levels of L1 insertions are summarized in **Table S3**. Single-molecule methylation patterns
5 for each locus are provided in Zenodo (<https://doi.org/10.5281/zenodo.7097319>). All L1 methylation
6 datasets can be interactively queried, filtered and downloaded through the web portal L1MethDB
7 (<https://L1methdb.ircan.org/>). The scripts written to call L1 insertions and CpG methylation from bs-
8 ATLAS-seq data, as well as useful annotation files used in the course of this study, are available at
9 <https://github.com/retrogenomics/bs-ATLAS-seq>.

EXPERIMENTAL MODEL AND SUBJECT DETAILS

10 The cell lines used in this study are identical to those previously characterized in ⁹ and include
11 primary fibroblasts (BJ, IMR90, MRC5), embryonic stem cells (H1) and cancer or transformed cell lines
12 (HCT-116, K-562, HEK-293, HEK-293T, HeLa S3, MCF-7, HepG2, and 2102Ep). All cells were directly
13 obtained either from ECACC (distributed by Sigma) or from ATCC (distributed by LGC Standards), apart
14 from 2102Ep cells (a kind gift of P. W. Andrews, University of Sheffield, UK) and HEK-293T (a kind gift
15 of Andrea Cimorelli, ENS-Lyon, France). H1 human embryonic stem cells were not grown in the
16 laboratory for regulatory reasons but genomic DNA of H1 cells grown in presence of LIF and serum was
17 a kind gift of J. L. Garcia-Perez (University of Granada, Spain). Cells were maintained in a tissue culture
18 incubator at 37°C with 5% CO₂ and grown in Dulbecco's modified Eagle medium (DMEM), McCoy's 5A
19 (HCT-116) or RPMI 1640 (K-562) containing 4.5 g/L D-Glucose, 110 mg/L Sodium Pyruvate, and
20 supplemented with 10% FBS, 862 mg/mL L-Alanyl-L-Glutamine (Glutamax), 100 U/mL penicillin, and
21 100 µg/mL streptomycin. Cell cultures tested negative for mycoplasma infection using the MycoAlert
22 Mycoplasma Detection Kit (Lonza). Cell line authenticity was verified by multiplex STR analysis
23 (Eurofins) and comparison with the DSMZ database (<https://celldive.dsmz.de/>) or with previously
24 published profiles for H1 and 2102Ep cells ^{158,159}.

METHOD DETAILS

25 *Bs-ATLAS-seq*

26 A practical protocol for bs-ATLAS-seq is provided in ¹⁶⁰ and his detailed below.

27 **DNA extraction.** Genomic DNA was prepared with the QiaAmp DNA Blood mini kit (Qiagen) and
28 quantified by fluorometry using the Quant-iT dsDNA HS Assay and a Qubit fluorometer (Thermo Fisher
29 Scientific).

30 **Mechanical fragmentation, end-repair and A-tailing.** Two micrograms of genomic DNA were
31 sonicated for 6 cycles (6 s on, 90 s off) at 4 °C with a Bioruptor NGS (Diagenode), generating average
32 fragments of 1 kb. Fragment size was controlled by capillary electrophoresis with the DNA high
33 sensitivity kit and a Bioanalyzer 2100 (Agilent Technologies). DNA ends were repaired using the End-It
34 DNA End-Repair Kit (Epicentre), and A-tailed with Klenow Fragment (3'-to-5' exo-, New England's
35 Biolabs) following manufacturer's protocol. At each step, DNA was purified with Agencourt AMPure
36 XP beads (Beckman Coulter) using a 1:1 ratio of beads to DNA solution (v/v).

1 **Linker ligation.** Oligonucleotides LOU2493 (with all C methylated) and LOU2494 (**Table S1**) were
2 mixed in 5 μ L of 1x T4 DNA Ligase buffer (50 mM Tris-HCl pH 7.5, 10 mM MgCl₂, 1 mM ATP, 10 mM
3 Dithiothreitol; New England Biolabs) at a final concentration of 80 μ M each and annealed by heating
4 at 65 °C for 15 min, followed by slow cooling down to room temperature. Four hundred nanograms of
5 fragmented genomic DNA were ligated with a 40-fold molar excess of the duplex linker overnight at
6 16 °C in 50 μ L of 1x T4 DNA Ligase buffer supplemented with 400 U of T4 DNA Ligase
7 (New England Biolabs). Excess linkers were removed by two successive rounds of purification with
8 Agencourt AMPure XP beads using a 1:1 ratio of beads to DNA solution (v/v). Note that only the single-
9 stranded methylated oligonucleotide LOU2493 is covalently bound to the 5' ends of the genomic DNA
10 fragments.

11 **Bisulfite conversion.** Two hundred and fifty nanograms of linker-ligated genomic DNA were
12 subjected to sodium bisulfite conversion for 210 min at 64°C using the EZ DNA Methylation Kit (Zymo
13 Research) according to the manufacturer's instructions. After clean-up, converted DNA was kept at 4
14 °C for up to 20 h.

15 **Suppression PCR.** L1 5' junctions were amplified in 40 μ L-reactions containing 16 ng of converted
16 and linker-ligated genomic DNA, 0.2 μ M of primers, 0.2 μ M dNTPs, 1.5 mM MgCl₂, 0.8 U of Platinum
17 Taq DNA Polymerase in 1X PCR buffer (Invitrogen). A first primer (LOU2565, or LOU2715 to LOU2724)
18 targets the L1-specific region with a 5' extension corresponding to Illumina Rd2 SP and P7 sequences,
19 with a 10-nt index specific to the sample between them. A second primer (LOU2497) targets the linker
20 (identical to Rd1 SP) and possesses a 5' extension corresponding to Illumina P5 sequence. Primer
21 sequences and annotations are provided in **Table S1**. Amplification was performed under the following
22 cycling conditions: 1 cycle at 95°C for 4 min; followed by 20 cycles at 95°C for 30 s, 53°C for 30 s, and
23 68°C for 1 min; and a final extension step at 68°C for 7 min. To reduce PCR stochasticity, each sample
24 was amplified in eight parallel 40 μ L-reactions and subsequently pooled. In addition, another reaction
25 was performed in the absence of the L1-specific primer to control for the absence of linker-to-linker
26 amplification. The amplified library was cleaned-up from primers and irrelevant products by double-
27 sided size-selection with Agencourt AMPure XP beads using a 0.55:0.65 ratio of beads to DNA solution
28 (v/v), to reach an average library size of 450 bp. Finally, a last purification was achieved with Agencourt
29 AMPure XP beads using a 1:1 ratio of beads to DNA solution (v/v) to eliminate potential remaining
30 traces of oligonucleotides.

31 **Sequencing.** Libraries were quantified by qPCR with KAPA library quantification kit for Illumina
32 (Roche) and their size range was checked by capillary electrophoresis using with the DNA high
33 sensitivity kit and a Bioanalyzer 2100 (Agilent Technologies). Libraries were diluted to 1 nM and pooled
34 equimolarly. Pooled libraries were paired-end sequenced with a NextSeq 550 system (Illumina) using
35 a high-output kit and 300 cycles and 20% of PhiX DNA spike-in. To gain access to the methylation state
36 of the first 15 CpG in L1 sequence, paired-end sequencing was performed asymmetrically with 90
37 cycles for read #1 and 210 cycles for read #2.

38 **bs-ATLAS-seq primary analysis.** Illumina paired-end sequencing reads were processed to locate L1
39 elements and to call their methylation status, using the script `bs-atlas-seq_calling.sh` (v 1.1,
40 available at <https://github.com/retrogenomics/bs-ATLAS-seq>), which steps are summarized below. In

1 each read pair, read #1 is 90 bp long and corresponds to the 5' flanking sequence of L1, while read #2
2 is 210 bp-long and corresponds to L1 5' UTR internal sequence.

3 **Read trimming, mapping, and filtering.** We demultiplexed FASTQ files according to their sample-
4 specific barcode using cutadapt (v 3.1, <https://github.com/marcelm/cutadapt>). We then verified the
5 presence of bs-ATLAS-seq adapters in the reads and trimmed them with cutadapt. Once trimmed,
6 reads #2 were mapped locally against the first 250 bp of L1HS consensus sequence (Rebase Rel. 10.01)
7 using Bismarck (v0.22.1)¹⁴⁷ allowing soft-clipping. Only pairs for which read #2 mapped to the L1HS
8 consensus in the correct orientation were subsequently analyzed (Samtools v1.3)¹⁵². The selected
9 pairs were mapped against hg38 reference human genome using Bismarck in end-to-end mode using
10 the following options: `--minins 250 --maxins 1250 --score_min L,-0.6,-0.6`. At
11 this stage, mapped read pairs support L1 elements included in the reference genome (reference L1s).
12 To identify non-reference L1 insertions, we extracted reads #1 from unmapped pairs using seqtk (v1.3,
13 <https://github.com/lh3/seqtk>) and remapped them alone against hg38 with Bismarck in local mode.
14 This read rescue procedure allowed us to identify: (i) discordant pairs when read #1 mapped end-to-
15 end to hg38; and (ii) split read if the 5' end of read #1 mapped partially to hg38 but its 3' end mapped
16 to L1HS consensus sequence. We filtered out discordant pairs with read #2 showing more than 4.5%
17 divergence towards L1HS consensus sequence as they correspond to artefactual chimeras formed with
18 old L1 elements. Finally, properly mapped pairs and read #1 singletons were pooled in a single .bam
19 file, and deduplicated with Picard tools (v1.136, <https://broadinstitute.github.io/picard/>). As a
20 conservative assumption, we considered read pairs as redundant if their read #1 starts at the same
21 genomic position, since this situation reflects an identical random break site obtained upon sonication.

22 **L1 calling.** We identified reference L1 by intersecting properly mapped pairs with annotated L1
23 elements in UCSC repeatmasker track¹⁶¹ using BEDtools¹⁵¹. A minimum of 10 non-redundant reads
24 was required to call a reference L1 element. The coordinates of the elements were extracted from
25 UCSC repeatmasker track. To identify non-reference L1 elements, we clustered reads #1 of discordant
26 pairs and split reads less than 100 bp apart, excluding those intersecting with previously identified
27 reference L1s, using BEDtools. A minimum of 10 non-redundant reads, including at least 2 split reads,
28 was required to call a non-reference L1 element. We used the break point of split reads to precisely
29 define the insertion sites at nucleotide resolution (a 2-bp interval spanning the integration point with
30 0-based coordinates). Finally, candidate L1 elements not in assembled chromosomes (chr1 to chr22,
31 chrX or chrY) or falling in ENCODE Unified GRCh38 Blacklist regions (ENCFF356LFX) were filtered out
32 with BEDtools.

33 **L1 CpG methylation calling.** We called CpG methylation in individual read pair for each reference
34 and non-reference L1 locus, including any covered upstream L1 flanking sequence, using the
35 `bismark_methylation_extractor` script from Bismarck. CpG methylation patterns for
36 individual loci were summarized and visualized using MethPat¹⁵³.

37 **Assessment of bs-ATLAS-seq recovery rate.** To estimate the fraction of elements detected by bs-
38 ATLAS-seq in each L1 family, we compiled a list of reference L1 elements using hg38 UCSC
39 repeatmasker track filtered to keep only the assembled chromosomes (chr1 to chr22, chrX and chrY)
40 and to remove elements in ENCODE Unified GRCh38 Blacklist regions. The recovery rate was calculated
41 for each sample, taking into account the sex of the donor (presence or absence of a Y chromosome).

1 Given the ongoing activity of L1HS elements in modern humans, and the fact that the reference human
2 genome is a composite assembly obtained from a small number of individuals, it is expected that a
3 given sample only contains a fraction of reference L1HS elements. Thus, the calculated rate is a lower
4 estimate. Reference L1 elements were considered as full length if their length is >5900 bp. Non-
5 reference L1 were assumed to be full-length. L1HS subfamilies were deduced from diagnostic SNPs in
6 the reference sequence ¹⁶².

7 **Assessment of *bs-ATLAS-seq* false positive rate.** To estimate the percentage of false positive L1
8 detected by *bs-ATLAS-seq*, we compared candidate L1 elements with databases of known non-
9 reference insertions (KNR), such as euL1db ²⁹, the 1000 genome project (1KGP) ²³ or previous mapping
10 of L1HS in the same cell lines using 3' junction amplification and Ion Torrent-based single-end
11 sequencing (3'-ATLAS-seq) ⁹. Only 3 candidate non-reference insertions appeared unknown (**Table S3**).
12 chr18:15193133-15193135:-:L1HS:NONREF was validated by nanopore sequencing (**Table S4**). The two
13 others, chr7:140709367-140709369:-:L1HS:NONREF and chr10:38190899-38190901:+:L1HS:NONREF,
14 were validated by PCR of their junctions with the flanking sequence (**Table S1** and **Figure S1G**).

15 ***Cas9-targeted nanopore sequencing***

16 To sequence polymorphic L1 loci, we applied Cas9-targeted nanopore sequencing as described in
17 ⁸⁹ to 125 loci.

18 **Extraction of genomic DNA.** High molecular weight genomic DNA was extracted from freshly
19 pelleted cells using the Monarch Genomic DNA Purification kit (New England Biolabs). Immediately
20 after extraction, DNA was quantified by fluorometry using a Qubit fluorometer and the dsDNA HS
21 Assay kit (Thermo Fisher Scientific). Fragment length (>10kb) was verified by resolving 100 ng of DNA
22 on a 0.8% agarose gel. DNA was stored at 4°C until library preparation, usually the following day.

23 **Design and synthesis of single guide RNAs (sgRNAs).** We designed one sgRNA for each of the 124
24 potentially polymorphic L1HS loci (*i.e.* empty in at least 50% of the cell lines of the panel as determined
25 by *bs-ATLAS-seq*). Using precomputed SpCas9 sgRNA target prediction and scoring by the CRISPOR tool
26 ¹⁶³ available in the 'CRISPR Targets' track of the UCSC Genome Browser, we selected sgRNAs in the
27 region 900 to 1,500 bp downstream of the targeted L1s, and with the highest scores (at least 55 for
28 the MIT specificity score ¹⁶⁴ and 35 for Moreno-Mateos (MM) efficiency score ¹⁶⁵). A control sgRNA
29 (LOU3161) targeting a unique site on chromosome 9 was included as a positive control. The 125
30 sgRNAs were synthesized as a pool using the EnGen sgRNA Synthesis kit (New England Biolabs), and
31 purified with the Monarch RNA Cleanup kit (New England Biolabs). The sgRNA pool was quantified
32 with the Qubit RNA Assay kit (Thermo Fisher Scientific), aliquoted and stored at -80°C.

33 **Library preparation.** Cas9 ribonucleoprotein particles (RNPs) were assembled by mixing 60 μmol of
34 the sgRNA pool and Alt-R *S. pyogenes* HiFi Cas9 nuclease V3 (IDT) in equimolar amounts in 30 μL of 1X
35 CutSmart Buffer (New England Biolabs) to reach a final concentration of 2 μM. After a 30min
36 incubation step at 25°C, RNPs were kept on ice. For each cell line, 5 μg of genomic DNA was
37 dephosphorylated by 3 μL of Quick Calf Intestinal Phosphatase (CIP, New England Biolabs) in a total
38 volume of 30 μL for 10 min at 37°C. Then CIP was inactivated by heating the reaction at 80°C for 2 min.
39 Cas9-mediated cut and A-tailing was achieved by adding 10 μL of the Cas9 RNP pool, 1 μL of 10 mM
40 dATP (Thermo Fisher Scientific) and 1 μL of Taq Polymerase (5 U/μL, New England Biolabs) to the CIP

1 reaction. Reactions were incubated at 37°C for 1 h, at 72°C for 5 min, and then kept at 4°C. As a quality
2 control, we performed qPCR using 1 µL of the reaction saved before and after the incubation step to
3 quantify the relative copy number of the intact *RASEF* locus (the target of sgRNA LOU3161) using a pair
4 of primers flanking the cut site (LOU3322: TCACAGGTTGCACACTGGAA, and LOU3323:
5 AGCTCAGCCACTTTTCAGCT) and a pair of primers in *Sox2* as loading control (LOU0695:
6 CATGGGTTCTGGTGGTCAAGT, and LOU0696: TGCTGATCATGTCCCGGAGGT). Cleavage was considered as
7 successful if the number of intact target sites decreased by ~10 to 15-fold. Then, sequencing adapters
8 were ligated to the digested products using the Ligation Sequencing kit (SQK-LSK-110, Oxford
9 Nanopore Technologies) in reactions containing 40 µL of sample, 20 µL of Ligation buffer LNB, 10 µL of
10 NEBNext Quick T4 DNA Ligase (New England Biolabs), 5 µL of Adapter mix AMX-F and 3 µL of nuclease-
11 free water. After 10 min incubation at 20°C, DNA was cleaned up using AMPure XP beads (Beckman
12 Coulter) with a beads-to-sample ratio of 0.3:1 (v/v), washed with the long-fragment buffer (LFB) to
13 retain fragments ≥ 3kb, and eluted from the beads in 13 µL of elution buffer (EB) at room temperature
14 for 30 min to further enrich for fragments longer than 30kb. The purified eluate (~12 µL with 40-45
15 fmol of DNA) was ready for sequencing on a MinION flow cell and was kept at 4°C until loading.

16 **Sequencing of DNA library.** A MinION flow cell (R9.4.1, Oxford Nanopore Technologies) was loaded
17 on a Mk1B sequencer and primed with a mix of Flush buffer FB and Flush Tether FLT. Then 75 µL of the
18 DNA library (12 µL of eluate, 37.5 µL of Sequencing buffer SBII and 25.5 µL of Loading beads LBII) were
19 loaded into the flow cell and sequenced for 72 h with the MinKNOW interface (v20.10.6). Base-calling
20 was performed during the sequencing run using Guppy (v4.2.3).

21 **Bioinformatic analysis.** To map reads obtained by the protocol described above, we prepared a
22 custom genome including the two possible alleles (empty or filled) for each target locus. Both alleles
23 contained 50 kb upstream and 1 kb downstream of L1, extracted from the human reference genome
24 hg38. L1 insertion sites were deduced from bs-ATLAS-seq experiments. If the targeted L1 is present in
25 the reference genome, the empty allele was made by removing the L1 sequence with bedtools
26 maskfasta (v2.3). If the targeted L1 was absent from the reference genome, the filled allele was built
27 using *reform* (<https://github.com/gencorefacility/reform>) by introducing an L1 consensus sequence at
28 the insertion point. Thus, the custom genome comprises 250 sequences concatenated in a multifasta
29 file. After indexation, nanopore reads were mapped to the custom genome with minimap2 (v20.2)
30 using the following options: `-a -x map-ont`¹⁴⁹. Reads with a mapping quality score (MAPQ) of
31 minimum 20 were sorted and filtered using samtools (`samtools view -b -q 20`). As reads
32 partially spanning an L1 element without reaching the upstream flank tend to be soft-clipped and to
33 be wrongly mapped, we kept only reads longer than 7 kb. Zygosity was evaluated by calculating the
34 coverage of each allele with bedtools coverage (v2.3). If a single allele (filled or empty) was covered,
35 the locus was considered as homozygous. Inversely, if both alleles were covered, the locus was
36 considered as heterozygous. For each covered allele, methylation calling was performed with
37 nanopolish (v0.13.2)¹⁵⁰. We considered only CpG covered by at least 5 reads. Alignments and
38 methylation were visualized with IGV genome browser (v2.12.3)¹⁵⁴.

39 **Methylated DNA Immunoprecipitation (MeDIP)**

40 MeDIP was performed using the Auto MeDIP Kit on an automated platform SX-8G IP–Star Compact
41 (Diagenode). Briefly, 2.5 µg of DNA was sheared using a Bioruptor Pico to approximately 500-bp

1 fragments, as assessed with D5000 ScreenTape (Agilent). Cycle conditions were as follows: 15 s ON /
2 90 s OFF, repeated 6 times. A portion of sheared DNA (10 %) was kept as input and the rest of the
3 sheared DNA was immunoprecipitated with α -5-methylcytosine antibody (Diagenode), bound to
4 magnetic beads, and was isolated. qPCR for selected genomic loci was performed and efficiency was
5 calculated as % (me-DNA-IP/total input). Primer sequences are listed in **Table S2**.

6 **LUMA**

7 To assess global CpG methylation, 500 ng of genomic DNA was digested with MspI+EcoRI and
8 HpaII+EcoRI (NEB) in parallel reactions, EcoRI was included as an internal reference. CpG methylation
9 percentage is defined as the HpaII/MspI ratio. Samples were analyzed using PyroMark Q24 Advanced
10 pyrosequencer.

11 **RNA-seq**

12 **RNA extraction.** Total RNA was purified from the same cell pellet (split in half) as the genomic DNA
13 for bs-ATLAS-seq by two successive cycles of TRI Reagent extraction (Molecular Research Center) and
14 recovered in 50 μ L of milli-Q water. Subsequently, 8 μ g of total RNA was treated with 2 U of TURBO
15 DNase (Life technologies) for 20 min at 37°C followed by a 5 min incubation step at room temperature
16 with the DNase Inactivation Reagent. After centrifugation at 10,000 x g for 1.5 min, the supernatants
17 containing the RNA samples were transferred to new tube. RNA was quality-controlled and quantified
18 by UV-spectroscopy (NanoDrop 2000), microfluidic electrophoresis (Agilent 2100 Bioanalyzer) and
19 fluorometric Qubit RNA Assay (Life Technologies).

20 **Library preparation and sequencing.** Directional poly(A)+ RNA-Seq libraries were prepared using
21 300 ng of DNase-treated RNA using the Poly (A) mRNA Magnetic Isolation Module and NEBNext Ultra
22 II Directional RNA Library Prep kit for Illumina (New England Biolabs) according to manufacturer's
23 instructions. Samples were multiplexed and sequenced with 2x75 bp pair-end reads on a NextSeq 500
24 instrument (Illumina).

25 **RNA-seq mapping.** RNA-seq raw reads were trimmed to remove fragments of sequencing adapters
26 and regions of poor sequencing quality using the sliding-window mode of Trimmomatic (v0.32)¹⁴⁵ and
27 parameters recommended for paired-end reads by the Trimmomatic manual. Read quality before and
28 after trimming was then verified using FASTQC (v0.11.2)
29 (<http://www.bioinformatics.babraham.ac.uk/projects/fastqc>). Trimmed reads were mapped against
30 the human reference genome hg38 (with GENCODE comprehensive release 29), using STAR (v2.7.5c),
31 with the following non-default parameters: `-outFilterMultimapNmax 1000` (1000 alignments
32 allowed per read-pair), `-alignSJoverhangMin 8` (minimum overhang for unannotated
33 junctions).

34 **L1 expression measurement.** The extent of L1 expression driven by L1 sense promoter was first
35 approximated through the level of readthrough transcription in the downstream flanking sequence
36^{9,34}. Because the R2 read is in the same direction as the RNA fragment, only mapped R2 reads with
37 MAPQ \geq 20 were considered for the following analyses. They were first extracted from the bam file
38 using samtools (`samtools view -b -f 128 -F 4 -q 20`). Then, the number of mapped R2
39 reads in a 1 kb-window upstream and downstream the L1 element and in the same orientation as L1

1 were counted using BEDtools (`coverageBed -s`). Annotated exons overlapping with these regions
2 and on the same strand as L1 were masked. Finally, the 5' signal was subtracted from the 3' signal to
3 remove potential noise due to pervasive transcription, and the result was normalized by the number
4 of mapped reads to give a value as L1 reads for 1kb per million of mapped reads (RPKM). Negative
5 values (more 5' signal than 3' signal) were set to zero. As a cross-validation, the expression levels of
6 individual L1HS copies were also measured with L1EM (v1.1) and recommended parameters¹⁰⁴. To
7 measure L1 expression aggregated at the family-level, we used Tetranscripts (v2.2.1)¹⁴², combined
8 with DESeq2 (v1.30.1) for differential expression analysis¹⁵⁷.

9 **Chimeric transcript discovery.** Splice junctions are counted during the mapping step and are
10 summarized in the table `SJ.out.tab` from STAR. Each splice junction is characterized by its
11 coordinates and the number of mapped reads which supports the junction. To detect chimeric
12 transcript between an L1 and a neighboring gene, the “start” and the “end” are dissociated and
13 separately analyze with bedtools intersect. Only splice junction for which one extremity mapped into
14 L1 and the other into an exon (GENCODE comprehensive release 29), and supported by at least 2
15 uniquely mapped reads, are retained. Then uniquely and multi-mapped reads are summed and
16 normalized by the number of mapped reads per million (RPM).

17 **5-aza-2'-deoxycytidine treatment**

18 HCT-116 cells were cultured in McCoy medium supplemented with 10% FBS, 100 U/mL penicillin
19 and 100 µg/mL streptomycin. For 5-aza-2'-deoxycytidine (DAC) treatment, cells were plated at a
20 density of 100,000 cells/well in 6-well plates and treated with DAC at a final concentration of 1 µM for
21 a total of 5 days. Fresh medium and drug were added daily for the first 3 days.

22 **ChIP-seq**

23 **Chromatin immunoprecipitation (ChIP).** For ChIP of the transcription factor YY1, exponentially-
24 growing 2102Ep cells were washed twice with PBS and fixed at room temperature by addition of
25 disuccinimidyl glutarate to a final concentration of 2mM and incubation for 45 minutes, followed by
26 two washes in PBS and addition of formaldehyde to a final concentration of 1% and incubation for 15
27 minutes. For ChIP of histone H3K4me3, 2102Ep cells were fixed by addition of formaldehyde to a final
28 concentration of 1% directly to the cell growth medium. Fixation was stopped by addition of glycine to
29 a final concentration of 125 mM. Fixed cells were washed once quickly and twice for 10 min each with
30 ice-cold PBS, and collected by scraping and centrifugation for 10 min at 500 xg at 4 °C. Nuclei were
31 collected by centrifugation for 5 min at 500 xg at 4 °C and resuspended at 5×10^7 cells/mL in 900 µL of
32 ice-cold L2 buffer (50 mM Tris pH 8.0, 5 mM EDTA, 1% SDS) containing protease inhibitors. Chromatin
33 was fragmented by sonication to an average size of 600–700 bp (typically 9 cycles of 10 s sonication, 1
34 min recovery on ice, using a micro-tip sonicator) and insoluble debris was pelleted by centrifugation.
35 A 50 µL-aliquot was removed from each sample and analyzed by agarose gel electrophoresis after DNA
36 extraction to verify fragmentation. Fragmented chromatin was diluted with 9 volumes of buffer DB (50
37 mM Tris pH8, 200 mM NaCl, 5 mM EDTA, 0.5% NP40), and 1 µg of anti-YY1 antibody (C15410345,
38 Diagenode) or anti-H3K4me3 antibody (ab8580, Abcam) was added to each 1 mL of chromatin and
39 incubated overnight at 4 °C with rotation. Antibody-bound chromatin was pulled-down by addition of
40 25 µL of protein-A Dynabeads (Invitrogen) for anti-YY1 ChIP, or by addition of 15 µL of protein-A

1 sepharose for anti-H3K4me3 ChIP, incubated for 30 min at 4°C, and collected using a magnet for
2 dynabead-bound chromatin, or by centrifugation. Chromatin-bound beads were washed once quickly
3 and 4 times for 5 min each with 900 µL of ice-cold buffer WB (20 mM Tris pH 8.0, 500 mM NaCl, 2 mM
4 EDTA, 1% NP40, 0.1% SDS), followed by washing for 5 min each with 900 µL of ice-cold TE followed by
5 350 µL of ice-cold 10 mM Tris pH 8.0.

6 **Library preparation and sequencing.** For YY1 ChIP, immunoprecipitated chromatin was tagmented
7 on beads based on the Diagenode ‘TAG kit for chipmentation’ protocol, using a total tagmentation
8 time of 15 minutes, and sequencing libraries were prepared from tagmented samples by PCR
9 amplification using Kapa HiFi polymerase (Roche). For H3K4me3 ChIP, immunoprecipitated chromatin
10 was released by incubating beads three times in buffer EB (TE + 2% SDS) for 5 min at room temperature
11 with periodic tickling, and pooling the supernatants after collection; fixation was then reverted by
12 overnight incubation at 65 °C, and DNA was directly purified using the MinElute PCR purification kit
13 (Qiagen), eluted in 30 µL elution buffer, and sequencing libraries were prepared using the NEBNext
14 Ultra II DNA library kit (New England Biolabs). Samples were sequenced using a paired-end strategy on
15 a NextSeq500 instrument (Illumina).

16 **ChIP-seq analysis.** Sequencing reads were trimmed with cutadapt (-q 10) and were aligned to the
17 human reference genome hg38 using bowtie2 (v2.4.1) with options `--very-sensitive` and `--`
18 `end-to-end`. Peaks were called with MACS2 (v2.2.7.1) and the following parameter: `-g 2.9e9`
19 using input DNA as background. For H3K4me3, the broad peak option (`--broad`) was also selected.
20 Coverage was calculated using `deeptools (bamCoverage --minMappingQuality 10 --`
21 `normalizeUsing RPKM --binSize 10)`, and visualized in IGV.

22 **Transcription factor enrichment at unmethylated L1**

23 Differential transcription factor binding between unmethylated (mCG<25%) and methylated
24 (mCG>75%) L1HS and L1PA2 subsets was analyzed for each cell line using the Unibind enrichment
25 command line tool (UniBind_enrich.sh, available at https://bitbucket.org/CBGR/unibind_enrichment)
26 and the entire Unibind database (Hg38_robust_UniBind_LOLA.RDS) using the `twoSets` option⁹⁰.

27 **Enrichment of genomic features**

28 To allow a fair comparison of the associations of reactivated and non-reactivated L1HS upon 5-aza
29 treatment with a wide range of genomic features, we used a statistical approach in which we generate
30 a large number of controlled *in silico* randomizations of each dataset, and we express the magnitudes
31 of each association as a z-score, which reflects the number of standard deviations by which the
32 measured similarity of any pair of datasets differs from the similarity expected by chance, as previously
33 performed⁶⁷.

QUANTIFICATION AND STATISTICAL ANALYSIS

34 Statistical tests were performed in R and are explicitly stated in each Figure legend.

SUPPLEMENTAL INFORMATION

1 Supplemental information includes 5 figures, 6 tables and 1 dataset, and can be found with this
2 article online.

SUPPLEMENTAL DATA

Table S1 – Bs-ATLAS-seq oligonucleotides and sequencing statistics.

3 Related to **Figure 1** and **Figure S1**.

4

Table S2 – MeDIP results and primers.

6 Related to **Figure S1**.

7

Table S3 – Genomic coordinates and methylation levels of all L1 insertions recovered by bs-ATLAS-seq across all cell lines.

9 All genomic coordinates are related to the hg38 reference genome. Related to **Figure 2**, **Figure 3**, **Figure S2**, and **Figure S3**.

10

Table S4 – Methylation levels of polymorphic L1HS elements obtained by Cas9-guided nanopore sequencing and sgRNA sequences used in this study.

13 All genomic coordinates are related to the hg38 reference genome. Related to **Figure S1**, **Figure 4** and **Figure S4**.

14

Table S5 – Chimeric L1 transcripts associated with ESR1-bound L1 loci in MCF-7.

16 All genomic coordinates are related to the hg38 reference genome. Related to **Figure 5** and **Figure S5**.

17

Table S6 – L1HS expression levels across all cell lines.

19 All genomic coordinates are related to the hg38 reference genome. Related to **Figure 6** and **Figure 7**.

20

Data S1 – Single-molecule methylation patterns of full-length and 3' truncated L1 obtained by bs-ATLAS-seq.

22 Related to **Figure 1**. Can be downloaded from <https://doi.org/10.5281/zenodo.7097318>. Coordinates are related to the
23 hg38 reference genome (REF insertions) or to L1HS consensus sequence (NONREF insertions).
