10 **Summary**

11

12 Brain computation depends on intricately connected yet highly distributed neural networks. Due to the
13 absence of the requisite technologies, causally testing fundamental hypotheses on the nature of inter-
14 areal processing have remained largely out-of-each. Here we developed the first two photon holographic
15 mesoscope, a system capable of simultaneously reading and writing neural activity patterns with single
16 cell resolution across large regions of the brain. We demonstrate the precise photo-activation of spatial
17 and temporal sequences of neurons in one brain area while reading out the downstream effect in several
18 other regions. Investigators can use this new platform to understand feed-forward and feed-back
19 processing in distributed neural circuits with single cell precision for the first time.

21

22 **Introduction**

23

24 The neural computations that support sensation, cognition and behavior depend on the precise
25 coordination of neural activity patterns within and across widely separated brain areas. Recent advances
26 in optogenetics and three-dimensional (3D) light patterning (Adesnik and Abdeladim 2021, Ronzitti 2017)
27 have enabled investigators to causally probe how the activity of specific neural ensembles impact
28 computation and drive behavior (Chettih 2019, Carillo-Reid2016, Oldenburg 2022, Marshel 2019,
29 Dalgleish 2020, Russel 2019, Daie 2021, Buetfering 2022), but only in small, circumscribed regions of the
30 brain on the order of <1-2mm^2. These techniques rely on phase modulation of the optical wavefront with
31 a spatial light modulator (SLM) allowing the user to selectively target and photo-stimulate neural
32 ensembles of interest. Despite the power of these new read/write optogenetic approaches, the inability
33 to apply them to distributed brain networks has prevented investigators from causally probing the logic
34 and principles of inter-areal communication that are central to brain function. A new technology that
35 could overcome this technical barrier would allow neuroscientists to address key outstanding questions
36 for the first time, which could have profound importance for understanding brain function in health,
37 disease, and neural development.

38 The recent introduction of mesoscale two photon (2p) microscopes, which can sample neural
39 activity with micron precision across up to 25mm^2 of brain tissue, have vastly increased the ability of
40 investigators to acquire physiological data on distributed neural populations in behaving animals
41 (Sofroniew 2016, Stirman 2016, Yu 2021, Rumyantsev 2020, Kim and Shnitzer 2022, Ota 2022, Machado
42 2022). While these 2p mesoscopes can monitor cellular activity, they have no ability to perturb it with
43 high spatiotemporal precision, preventing the user from probing causal relationships between patterns
44 of activity in connected brain areas and behavior. Thus, if it were it possible to develop a 2p mesoscope
45 that can not only measure but also manipulate neural activity with cellular resolution, neuroscientists
46 could use such a system to address longstanding mysteries of long-range neural communication in the
47 brain.

48   However, there are multiple significant technical challenges to achieving high holographic
49   resolution optogenetics in a 2p mesoscope. These include addressing the lower numerical aperture (NA)
50   of the optical system and the need for mechanical rotation of the entire imaging system for accessing
51   lateral brain areas. Furthermore, existing commercial 2p mesoscopes were not designed for the
52   integration of holographic systems, requiring a significant redesign of the mesoscope build. To overcome
53   these challenges, we designed and optimized a flexible 3D holographic system fully integrated onto a 2p
54   random-access mesoscope (2p-RAM) that enables single-cell resolution holographic photo-stimulation of
55   neural ensembles in the brain. We tested and validated the optical capabilities of this new read/write
56   platform to measure and recreate highly specific patterns of activity in the brain within a large FOV. In
57   particular, we demonstrated holographic emulation of visually evoked neural activity at the mesoscale by
58   specific co-activation of functionally defined ensembles. We further showed how one can use this system
59   to probe functional interactions between distant brain regions. Finally, we showed that we can decode
60   the identity of the specific photo-stimulus purely from the modulation of activity of postsynaptic neurons
61   in downstream areas.
62   Together, these data illustrate how our 2P holographic mesoscope enables the user to probe
63   causality both at the local and the interareal level with single-cell resolution. By providing the means for
64   whole new classes of experiments, this novel technology could have a substantial impact on neuroscience
65   research and on potential therapeutic applications.
66
67   **Results**
68
69   **A 2P-RAM mesoscope with temporally focused 2P holographic illumination**
70
71   We designed a mesoscale all-optical read/write platform around a two-photon random access mesoscope
72   (2P-RAM, Sofroniew 2016) system (**Fig. 1a-c, Supplementary Fig. 1**) that is commercially available
73   (Thorlabs, Inc.). The key features of this imaging system that make it a powerful tool for studying inter-
74   areal communication are its nominal 5x5mm FOV, a fast remote focusing system for FOV curvature
75   correction and multiplane imaging, and four automated axes of motion for positional flexibility (**Fig. 1c**).
76   We sought to develop a mesoscale holographic optogenetics system that achieves single cell resolution
77   photo-stimulation despite the lower numerical aperture of the optical path and that could likewise
78   address the imaging plane curvature. Furthermore, we aimed for an optical design that does not
79   compromise the 4-axis movement capabilities of the 2P-RAM system, since they are essential for
80   executing a diverse array of neurobiological experiments. We therefore designed a compact and re-
81   dimensioned 3D holographic module that employs temporal focusing to confine excitation axially ('3D-
82   SHOT', three-dimensional sparse holographic optogenetics with temporal focusing Mardinly 2018, Pégard
83   2017). To preserve all translational axes of the entire system, we built the holographic module on an
84   extension breadboard attached to the movable main frame of the microscope (**Fig. 1b, Supplementary**
85   **Fig. 1, Supplementary note 2**). In 3D-SHOT, an initial blazed grating generates a temporally focused disc
86   of light that is magnified and replicated in multiple locations within a 3D volume by a spatial light
87   modulator (SLM). The 3D light pattern is then relayed onto the objective image space through a set of 4f-
88   systems (**Fig. 1c**). Given the large distance on the mesoscope between the photostimulation laser output
89   and the 3D-SHOT module, we added a non-magnifying telescope after the laser to control the divergence
90   of the beam impinging on the diffraction grating. Preserving the alignment invariance of the holographic
91   path with the motorized movements of the mesoscope is a key challenge. To address this (**Fig. 1c**), we
92   first combined the imaging and photostimulation beam before entering the multi-stage periscope so that
93   the photostimulation beam maintains invariance with X and Y frame translations. Second, we replaced
94   the last periscope mirror with a long-pass dichroic that directs the imaging beam (920nm) onto the vertical
95   breadboard and the photostimulation beam (1030nm) onto the extension breadboard so that the latter

96   maintains invariance with rotation. Third, we recombined both beams with a short-pass dichroic placed
97   right before the mesoscope tube lens on the vertical breadboard. Consequently, the holographic module
98   is invariant within all dimensions controlled by the motorized microscope frame, X, Y translations and
99   rotation. We recovered axial translation by adding a motorized stage for animal positioning along the
100 vertical axis, additionally mounted on a goniometer to ensure that imaging and photo-stimulation are fully
101 orthogonal to the cranial window surface.

103 To quantify the optical resolution of the mesoscale holographic system, we first measured the spatial
104 profile or 'point spread function' (PSF) of single two-photon excitation spots (**Fig. 1d-e**) which measured
105 9μm ± 0.7 μm in the lateral dimension and 32μm ± 1.6 μm in the axial dimension (mean ± s.d, n=538
106 holograms arranged in a 2D grid, see also **Fig. 1g, Supplementary Fig. 2**). Although the axial resolution
107 values are slightly larger than those previously reported for 3D-SHOT in a conventional 2p microscope
108 (~20 μm in Mardinly et al., ~28 μm in Pégard et al.), they are consistent with the modestly lower NA of
109 the mesoscope objective (**Supplementary note 1**). Nevertheless, the range of optical PSFs across the
110 entire photostimulation field is within the range of axial resolutions reported in previous single-cell 2P
111 holographic optogenetics studies (Pégard 2017, Mardinly 2018, Packer 2012) and allows for quasi single-
112 cell resolution targeted photostimulation. We then determined the extent of our holographic field-of-
113 view (FOV) which is equivalent to the total accessible FOV range of the SLM at the system's magnification.
114 We set the FOV limits to the farthest accessible holograms without aliasing which corresponded to a total
115 lateral FOV of ~950 μm × 990 μm (**Fig. 1g**), corresponding to 80% usable SLM FOV over the nominal 1.2
116 mm FOV of the SLM at this magnification. We compensate for the inherent decrease of diffraction
117 efficiency laterally across the FOV by adjusting the power delivered to each spot according to its spatial
118 location (**Supplementary Fig. 2**). Next, we generated multiple holograms spatially arranged in a 3D point-
119 cloud (**Fig. 1f**). We then measured the axial optical PSFs in 3D and found that they were mostly invariant
120 within a digital defocusing range of 220 μm (**Fig. 1h**). A potential challenge for holographic targeting on
121 the 2P-RAM mesoscope is the large microscope field curvature, 160 μm over the 5mm imaging FOV,
122 mostly introduced by the mesoscope objective. We hence quantified the flatness of our holographic FOV,
123 by measuring the axial locations of holograms generated with equi-Z SLM coordinates and found the
124 maximal peak-to-valley to be $\sim 40\ \mu m$ which is well within the addressable defocus range of the SLM and
125 can be corrected for without compromising 3D targeting (**Supplementary Fig. 2**). Another potential
126 challenge for multiphoton holographic optogenetics on the 2P-RAM mesoscope is the introduced
127 dispersion from the 4f lenses and the large mesoscope optics. We estimated the total group delay
128 dispersion (GDD) introduced by the holographic path to be $\sim 15000\ fs^2$ (**Supplementary table 2**). For
129 relatively broad pulses commonly used in multiphoton optogenetics ($\sim 400 fs$), the broadening of the
130 pulse width at the objective focus is minimal, thus discarding the need for a pulse compression unit on
131 the holographic path.

133 Finally, we assessed holographic targeting stationarity with X, Y translations and rotation, which is
134 essential for accurate optical generation of neural activity patterns despite movement of the mesoscope
135 relative to the brain. We found that the error between original hologram location and at displaced stage
136 positions remained less than 3 μm over a ± 3mm translation range and a ± 2.5° rotation angle range
137 demonstrating alignment invariance with mesoscope frame movements (**Supplementary Fig. 3**).

139 ***In vivo* 2P photostimulation on the 2P-RAM mesoscope**

141 Next, we tested our system for *in vivo* all-optical control of neural ensembles in awake mice. We took
142 advantage of a transgenic line that we recently developed (Vglut1-Cre;Ai203) (Bounds, 2021) which
143 provides widespread and stable co-expression of the potent opsin ChroME and the sensitive calcium

144 indicator (GCaMP7s) (**Fig. 2a**). We were able to photoactivate selected individual cells within the
145 holographic FOV while recording from thousands of neurons within the mesoscale imaging FOV (**Fig. 2b-**
146 **e**). Sequential photostimulation at 75mW/spot (10 × 10 ms pulses at 50Hz) elicited significant time-locked
147 responses in 70% of targeted cells (**Fig. 2c,d, Supplementary Fig. 4**). This demonstrates effective
148 holographic photostimulation despite the slightly larger optical axial resolution. To carefully quantify the
149 effective spatial resolution of holographic photo-stimulation, we recorded physiological point-spread-
150 functions (PPSFs) all optically in awake animals by digitally offsetting the holograms relative to the center
151 of target cells and recording evoked calcium activity on the target cells. We estimated the lateral PPSF to
152 be 23 μm and the axial PPSF to be 49 μm (gaussian fit full-width-half-maximum, n=3 cells). Despite the
153 lower NA inherent to the mesoscope objective, the achieved effective axial resolution *in vivo* is even lower
154 than some reported PPSFs in 2p optogenetics studies (80 μm axial FWHM reported in Daie 2021 for
155 instance). Together, these results demonstrate that the 2p holographic mesoscope achieves single-cell
156 resolution holographic optogenetics on par with previous implementations on conventional 2P
157 microscopes.

159 To illustrate how one can use the 2P holographic mesoscope to address key questions related to inter-
160 areal processing, we sequentially targeted ensembles of neurons in different visual areas while recording
161 the same set of visual cortical areas via translation of the mesoscope, taking advantage of the system's
162 targeting invariance to spatial translation. We could thus sequentially activate neural ensembles from four
163 different cortical areas (V1, PM, RL, and LM) while simultaneously recording activity from six surrounding
164 visual areas (**Fig. 2f**). Indeed, photo-stimulation in each cortical area elicited robust response in the
165 holographically targeted cells regardless of where the holographic FOV (∼1×1 mm^2) was relative to the
166 selected imaging FOV (3.1×3.1 mm^2). This demonstrates that the new system achieves ensemble
167 stimulation in any chosen visual area while concurrently recording neural activity from thousands of
168 neurons in surrounding visual areas.

170 **Holographic stimulation of functionally defined ensembles at the mesoscale**

172 A major advantage of two-photon holographic optogenetics is the ability to co-activate ensembles of
173 neurons based on their functional properties. We thus asked if we could co-activate groups of visual
174 cortical neurons that share orientation preference (**Fig. 3**). In the mouse visual cortex, orientation
175 preference shows minimal spatial clustering and thus co-activating an ensemble of co-tuned neurons
176 required highly precise optical targeting (Ohki & Reid 2007). To test this capability, we measured
177 orientation tuning curves of V1 neurons and then constructed various ensembles of neurons with shared
178 orientation preference for 2p holographic stimulation (**Fig. 3b,c**). Indeed, we could successfully photo-
179 activate groups of co-tuned neurons in V1 (**Fig. 3d**) while recording activity from surrounding areas. To
180 test whether our holographic stimulation generated functionally specific patterns of neural activity, we
181 trained a machine learning decoder to discriminate between visual responses evoked by static gratings in
182 4 orientations. We then asked the decoder to assign responses evoked by photostimulation of co-tuned
183 ensembles to the 4 orientations of the visual stimulus. The decoder was able to classify holographic photo-
184 stimuli above chance across both targets and all recorded neurons (**Fig. 3f,g**), demonstrating emulation of
185 visually evoked activity.

187 **Mesoscale recording of long-range responses to holographic neural activation**

189 One of the major advantages of mesoscale 2p holographic optogenetics should be the ability to detect
190 and quantify long-range functional interactions between one area and several other brain areas
191 simultaneously, something not possible with conventional 2p holographic microscopes. To test this, we

192 stimulated ensembles of neurons in visual area LM while recording from neurons across 4-6 other visual
193 cortical areas in a total 3 mm × 1.8 mm FOV or 2.4 mm × 2.4 mm FOV at 5Hz and 4.5Hz respectively (Fig.
194 4). We detected both reliably activated and reliably suppressed neurons downstream (**Fig. 4a-c**). As a
195 control, we compared the distribution of significant responses in stimulation trials with the significant
196 responses on 'catch trials' where photo-stimulation power was set to 0mW (**Fig. 4b**) and showed that
197 holographic stimulation induces postsynaptic modulation above the statistical false positive rate (**Fig. 4b,**
198 **Supplementary Fig. 5,6**). We next quantified the net modulatory effect of LM photo-activation on the
199 other imaged visual areas as well as area LM itself, excluding cells less than 25 µm from the holographic
200 targets. We observed a significant albeit modest suppression of mean activity across all downstream
201 areas, with LM neurons showing the strongest suppression and PM neurons showing the least (**Fig. 4d,e**).
202 Finally, we asked if activating different neural activity patterns in one cortical area (LM) induces
203 differentiable patterns of modulation in downstream areas. To test this idea, we used machine learning
204 algorithms to decode, trial by trial, the identity of the holographically induced pattern in LM from the
205 neural responses in the other visual areas (**Fig. 4f,g, Supplementary Fig. 7**). Indeed, we could properly
206 predict the holographic pattern on each trial significantly above chance levels, despite excluding all
207 measurements taken from LM itself. This indicates that photostimulation of even relatively modestly sized
208 neural ensembles (n=3-20 cells) is sufficient to drive distinct, distributed, and informative patterns of
209 neuromodulation downstream at the cellular scale.
210
211 **Discussion**
212
213 We designed, built and validated the first multiphoton holographic mesoscope. This technology is the first
214 to offer targeted photostimulation with single-cell resolution with simultaneous large-scale recording of
215 neural activity across several cortical areas in a nominal 25mm^2 FOV. We demonstrated the new system's
216 ability to co-activate user-defined groups of neurons, selected based on their spatial or functional
217 properties, while simultaneously recording neural activity from several downstream areas. We could
218 identify individual downstream neurons that displayed time-locked excitatory or inhibitory responses
219 hundreds or even thousands of microns away. This demonstrates that one can use this new technology
220 to probe how both local and long-range functional interactions relate to specific neuronal computations
221 all within the same experiment.
222
223 We developed the mesoscale read/write platform based on a commercially available 2p mesoscope
224 (Thorlabs) that is a widely used mesoscope platform (Fahey 2019, Froudarakis 2020, Orlova 2021,
225 Kanamori 2022, Pandey 2022) and that has enabled a number of other recent technological advances (Lu
226 2020, Demas 2021, Tsyboulski 2018). We expect that adapting a commercially available system will
227 facilitate the adoption of the technology across both individual labs and new neurotechnology platforms.
228 In the current design, the holographic FOV is limited by the SLM accessible FOV which, given the system's
229 current magnification is in the millimetric range. Extending the holographic FOV to the entire mesoscale
230 nominal FOV of the objective can be achieved by serially combining two conjugated SLMs, combining one
231 SLM and one galvanometer mirror (Sun 2019), or spatially tiling multiple SLMs (Marshel 2019, Yang 2015),
232 albeit at the cost of increased setup complexity. Nevertheless, the current configuration is sufficient to
233 answer many fundamental outstanding questions in cortical function.
234
235 One recent study investigated inter-areal communication using a conventional two-photon microscope
236 by imaging across the boundary of two contiguous cortical regions (Rowland 2021). The mesoscale
237 platform presented here allows access to up to up to 25-fold more cortical surface (albeit at lower frame
238 rates or lower spatial sampling). This much larger FOV encompasses many more cortical areas, more

239 coverage of feature-space within selected areas and the ability to study non-contiguous areas that are
240 more than 1mm apart.
241
242 While there is substantial work detailing how individual cortical areas represent and encode information,
243 how neural representations are transformed across cortical areas remains elusive. Most studies
244 addressing cortico-cortical communication combined multi-site electrode recordings with correlative
245 analyses (Bressler 2011, Semedo 2019), or electrical or one-photon optogenetic stimulation. However,
246 electrical microstimulation provides limited spatial control and often (and perhaps preferentially)
247 activates axons of passage (Histed 2009). One-photon optogenetic stimulation has cell-type specific
248 control but cannot readily activate functionally defined subsets of neurons (such as neurons with the same
249 feature preference). Neither stimulation approach can recreate precise spatiotemporal patterns of
250 activity, nor can they drive different user-defined firing rates into different neurons to recreate specific
251 population activity vectors that might preferentially drive cortico-cortical communication (Semedo 2019).
252 2p holographic optogenetics can achieve these goals (Bounds 2017, Mardinly 2018), and this new 2p
253 holographic mesoscope can implement these perturbations while simultaneously measuring both local
254 and downstream neural activity. Thus, 2p mesoscale holography is set up to experimentally test major
255 hypotheses and theories of interareal communication, such as how cortico-cortical feedback implements
256 generative models of the external world such as in the framework of predictive coding (Rao and Ballard
257 1999, Markov and Kennedy 2013, Hertag and Clopath 2022). The 3D capability of the mesoscale
258 read/write platform both in photostimulation (3D-SHOT) and recording (3D remote focusing) can further
259 allow the user to test the role of different cortical layers in these models (Bastos 2012).
260
261 Previously, we showed that photostimulation with 3D-SHOT and potent and fast optogenetic proteins
262 enables millisecond-precise recreation of neural activity sequences across large ensembles of neurons
263 (Sridharan, 2022). The 2p mesoscope we developed should have similar capabilities since it also employs
264 3D-SHOT, although this is difficult to validate directly with in-vivo electrophysiology due to the bulky size
265 of the objective. Several prominent theories of cortico-cortical communication, and inter-areal
266 communication more generally, depend on the synchrony and/or oscillatory timing of activity in the
267 sender and receiver area (Bastos 2015). We expect that this 2p holographic mesoscope should be capable
268 of generating precise temporal sequences of neural activity in one area while monitoring the net impacts
269 downstream. If so, it should be possible to ask directly how synchrony or oscillatory coherence facilitate
270 communication, potentially in different frequency bands, between hierarchically organized brain areas.
271
272 The 2p holographic mesoscope could also guide the design of more effective brain-machine interfaces
273 (BMIs, Ersaro 2023). Signal transmission across areas can be iteratively optimized with single-cell
274 resolution and millisecond precision by identifying and testing optimal communication subspaces for
275 signal flow (Semedo, 2019) and/or dynamically adjusting spiking coordination. Obtaining access to
276 intermediate stages of processing between the perturbed population activity and behavioral output
277 should help optimize the photostimulation patterns that can maximize the fidelity of robotic limb control.
278 In the context of limb neuroprosthetics (Lebedev and Nicolelis, 2006), mesoscale 2P holography could
279 further incorporate fine tactile and proprioceptive-like feedback signals into the BMI that could make
280 prostheses seamlessly fit as a natural limb extension.
281
282 Finally, the large accessible FOV of the mesoscope will help scale two-photon optogenetics to species with
283 larger brains such as primates. It can also enable new experimental paradigms in species smaller than the
284 mouse, such as larval zebrafish, where one could perform targeted photostimulation in the central
285 nervous system (CNS) while recording from both the CNS and peripheral organs. It could even allow photo-
286 stimulation and recording from multiple small animals simultaneously, such as flies or worms, engaged in

287 social behaviors. Overall, we expect mesoscale two-photon holographic optogenetics to become a key
288 technology in systems neuroscience because it can establish whole new classes of perturbative
289 experiments to motivate and test previously untestable theories of brain function.

Methods

Animals

All experiments on animals were conducted with approval of the Animal Care and Use Committee of the University of California, Berkeley. All experiments were performed in mice of both sexes, aged two months and older. Two transgenic mouse lines were used: either Ai203 transgenic lines (Bounds et al) crossed in-house with Vglut1-Cre mice, or triple transgenic mice emx1-Cre;CaMK2-tTA;tetO-GCaMP6s obtained by crossing the corresponding lines in-house (JAX stock# 005628, Jax stock# 003010 and Jax stock# 024742). Mice were housed in groups of five or fewer in a reverse light: dark cycle of 12:12 hours. Experiments were conducted during the dark phase.

Surgery

Mice were anesthetized with isoflurane (2%) and given buprenorphine as an analgesic (0.05mg/kg) and dexamethasone (2mg/kg) to reduce brain swelling. Mice were then placed in a stereotaxic frame (Kopf) over a heating pad. The scalp was removed, the fascia pushed to the sides, and the skull lightly scratched for better cement adhesion. A 4 or 5mm craniotomy centered around V1 was made using a biopsy punch (Robbins Instruments) and/or a dental drill (Foredom). Bleeding was controlled with cold phosphate-buffered saline and Gelfoam (Pfizer Inc.) For mice that required viral injection (triple transgenics), the virus preparation (AAV9-CAG.DIO.ChroME2s-FLAG-ST.P2A.H2B.mRuby3.WPRE.SV40) was injected using a beveled glass pipette at 4-5 locations across visual cortex. A cranial window, made of 7 mm and 5 mm diameter glass coverslips or 6 mm and 4 mm diameter glass coverslips, for 5- and 4-mm craniotomies respectively, was then placed onto the craniotomy and held in place with Metabond (C&B). Finally, a titanium headplate was fixed to the skull with Metabond (C&B0 and Ortho Jet (Lang). All craniotomies were performed on the left hemisphere of the mouse brain. Animals were allowed to recover in a heated recovery cage before being returned to their home cage.

2P-RAM mesoscope with a temporally-focused holographic path

The mesoscale read/write platform was custom-built around a 2P random-access fluorescence mesoscope previously described in detail (Sofroniew 2016) and now commercialized by Thorlabs Inc. The system had a nominal 5mm FOV accessed through a 0.6 NA objective that can be rapidly and flexibly scanned-across with a set of four conjugated scanners, one 12kHz resonant scanner and three large-angle galvanometers. The system was also equipped with a voice-coil remote-focusing module (Botcherby 2008) for 3D multi-plane imaging. In addition, the mesoscope was built on a vertical breadboard and the whole system was motorized in 4 dimensions (X, Y, Z translation and one axis of rotation) to provide maximal flexibility for the user. Since the microscope moved with respect to the incoming laser beam, the beam was injected through a six-stage periscope for alignment invariance.

The 2P mesoscale imaging path relied on a Ti:sapphire laser (Mai Tai, Spectra Physics) used at 920 nm for calcium imaging. External power control was achieved through a Pockels cells (Conoptics, Inc). A prism-based group delay dispersion compensation module (Akturk 2006) was installed to compensate for dispersion introduced by the mesoscope imaging path optics (estimated at about 25,000 fs^2, Sofroniew 2016). The 2P holographic path relied on a 1030 nm femtosecond fiber laser (Aeropulse 50, NKT Photonics) with internal power control.

The holographic path was built on a 33" × 24"" breadboard attached to the main mesoscope frame with three custom mounts (see Supplementary CAD, and Supplementary note 2). The holographic beam was merged with the imaging beam with a 1000 nm cutoff dichroic (DMSP1000R, Thorlabs) and rigorously co-

464 aligned with the imaging beam through the system's periscope to maintain alignment invariance with
465 translation. The beam was then injected onto the 3D-SHOT optical path (see Supplementary partlist and
466 supplementary CAD) with specific care to maintaining beam horizontality to achieve alignment invariance
467 with rotation (see Supplementary note 2).

468 The imaging path hardware was controlled with ScanImage software (Vidrio Technologies,LLC). Custom
469 Matlab code was used for control of the photostimulation path hardware, synchronization with imaging
470 and control of the visual stimulation.

471 *Hologram characterization and system calibration*

472 To characterize the generated holograms, 2P fluorescence was recorded from a thinly coated fluorescent
473 slide with a substage objective (×4 Zeiss) coupled to a camera (Basler) with a f=125 mm achromatic
474 doublet which provided a 1.3 × 1.3 mm characterization FOV. For successful multiphoton optogenetics
475 experiments, precise co-alignment of the imaging and the photostimulation beams is required. To achieve
476 this, hundreds of holograms were generated in 3D and any arbitrary curvature or inhomogeneity on the
477 imaging remote-focusing planes or the SLM planes was taken into account in the computation of the
478 hologram to real space transform matrix (Supp Fig. 2), in a fully automated procedure (Oldenburg 2022).
479 The holographic FOV was then remapped onto the entire mesoscopic FOV so that photostimulation
480 targets could be flexibly selected in any imaging ROI configuration. The recorded holograms were also
481 used as a reference to correct for diffraction efficiency fall-off and deliver homogeneous powers across
482 the field-of-view *in-vivo*. To characterize hologram position invariance with translation and rotation, 2D
483 point-cloud holograms were generated to "burn holes" i.e photobleach a fluorescent slide. The 2P
484 fluorescence signal on the slide was then recorded with the mesoscope photomultiplier tubes (PMTs).

485 *Visual stimulation and retinotopy*

486 Visual stimuli were displayed on a 2048 × 1536 Retina iPad LCD monitor (Adafruit Industries) placed 10
487 cm from the right eye of the mouse and computed using Psychtoolbox-3 and custom MATLAB code. Visual
488 stimuli were presented to map retinotopy and to identify functionally-defined ensembles. Otherwise, no
489 visual stimulus was presented to the mouse during simultaneous imaging and photostimulation
490 experiments.

491 Retinotopy mapping was used primarily to identify visual cortical area boundaries. To map retinotopy, we
492 adapted the procedure used in Marshel et al., 2011 and Zhuang et al., 2017 for the 2-photon mesoscope.
493 Briefly, we imaged a 3.1 x 3.1mm FOV 100-200um below the dura at 3Hz when mice were viewing noise
494 bars drifting in the horizontal or vertical directions. The bars were 10' in width and spanned the vertical
495 or horizontal extents of the screen respectively. The noise was drawn from a gaussian distribution with
496 spatial frequency 0.03 cycles/deg and temporal frequency 3 cycles/deg. Each type of bar swept the screen
497 30 times with a period of 9s, for a total stimulation duration of 10 minutes. We smoothed the recorded
498 2-photon calcium frames with a 4-8 pixel square filter and downsampled them by 4-8x. For each pixel in
499 the reduced image, we computed the preferred azimuth and elevation by identifying the average
500 horizontal and vertical positions of the bar at which the pixel's response was maximal. This generated
501 azimuth and elevation preference maps for the full FOV. We then computed the sign of the gradients
502 between the two maps to generate a visual field sign map (Sereno, et al., 1994), and used sign flips in this
503 map to identify area boundaries as outlined in (Garrett et al., 2014, Juavinett et al., 2017).

504 *In vivo mesoscale two-photon imaging and photostimulation*

505 For *in vivo* 2-photon mesoscale calcium imaging in vivo, mice were head-fixed and allowed to run on a
506 freely moving circular treadmill. Mesoscale Imaging ROIs were set to 2.4 × 2.4 mm to 3.6 mm × 3.6 mm

507 FOVs with recording rates between 3 and 5Hz. The imaging laser was set at 920 nm. Opsin expressing
508 cells were automatically segmented online based on either the green channel signal (Ai203 mice) or the
509 red nuclear mRuby2 (virally injected mice).

510 *Optical physiological point-spread function measurements*

511 To estimate the PPSF, we first identified photoactivatable neurons near the center of the holography FOV
512 and selected 8 targets for multi-target stimulation. We generated 50 8-target holograms around and
513 including the central holograms, 17 for the lateral PPSF and 33 for the axial PPSF. For the lateral PPSF,
514 each hologram was offset in the [-40,40] um range with 5um increments along the x-axis. For the axial
515 PPSF, each hologram was offset in the [-80,80] um range with 5 um increments along the z-axis. Each
516 hologram was illuminated with 5 x 5ms pulses @ 30Hz and 25mW/target, with 10 repeats per hologram.
517 The responses of the targeted neurons were averaged over each condition's repeats to compute the PPSF.

518 *Multi-area targeting*

519 For the multi-area holography demonstration in Figure 2f, we first identified area boundaries using
520 retinotopy, and picked 4 visual cortical areas (V1, PM, RL, and LM) for same-session sequential targeting.
521 For each area, we moved the objective along both lateral axes until the holographic FOV (fixed with
522 respect to the objective) was positioned over the center of the area. We then adjusted the 2P-RAM scan
523 fields to image a contiguous 3.1 x 3.1 mm area covering a fixed portion of the window using the
524 vasculature as fiduciary markers. As a result, at the beginning of each area's experiment, the imaging FOV
525 was identical, but the holography FOV covered a different cortical area. In each experiment, we identified
526 10-15 of the most photoactivatable neurons with sequential single-neuron targeting. We then targeted
527 these neurons (V1-13, PM-12, RL-11, LM-12 neurons) in each area using a multi-target hologram, driving
528 them with a single 250ms pulse and 80 mW per target.

529 *Holographic Stimulation of Functionally Defined Ensembles*
530
531 For co-tuned ensemble stimulation experiments presented in Figure 3, we used Vglut1-Cre;Ai203 mice
532 (Ai203 refers to a transgenic line expressing the transgene TITL-st-ChroME-GCaMP7s-ICL-nls-mRuby3-
533 IRES2-tTA2; Bounds et al., 2022). We recorded 11 sessions from 2 female mice (5 and 6 sessions each
534 mouse). The holographic FOV was placed over V1 (white rectangle in Figure 3a). The imaging FOV
535 encompassed V1, LM, RL, AL, PM and AM (2400 X 2400 m2). The imaging and holographic FOV was fixed
536 throughout each recording session.

537 To holographically stimulate neural ensembles defined by their visual response properties, each
538 recording session consisted of 3 steps. In Step 1, we recorded visual responses of neurons in the FOV while
539 the mouse viewed various images on the monitor. To gauge the orientation preference of each neuron,
540 we presented static gratings in 4 different orientations (0, 45, 90, 135°), at a contrast of 0.75 and spatial
541 frequency of 0.04 cycles per degree. Gray screen 'blank' trials, as well as static gratings in each orientation,
542 was repeated 50 times, with randomized trial order. Each presentation, or trial, lasted for 1 s with 0 s
543 inter-trial intervals. As such, the static grating block lasted 250 s (5 trial types X 50 repeats X 1s duration).

544 In the Step 2, we analyzed the 2p imaging data collected in Step 1 by running Suite2p on the
545 computer where ScanImage was running. Before running Suite2p, we converted the ScanImage tif files
546 into an h5 file as follows: 1) loading the ScanImage tif files; 2) cropping it into region corresponding to the
547 holographic FOV; 3) keeping only the frames corresponding to the functional channel (e.g., every other
548 frame if both red and green PMTs were recorded); and 4) saving as an h5 file. It was important to convert
549 at least 5000 time points, because Suite2p identifies many more spurious ROIs with shorter recordings.

550 Next, we ran Suite2p on the cropped h5 file. Because there is insufficient time to manually curate the ROIs
551 during the online analysis, we analyzed tuning curves for every ROI returned by the Suite2p.

552 In Step 3, we holographically stimulated neural ensembles defined in Step 2. Each target received
553 50mW, and each stimulation consisted of 10 pulses of 10 ms duration at 16 Hz. In addition to the co-tuned
554 ensemble stimulation at 4 orientations, 0-power 'blank' trials and mixed-tuned ensemble stimulation
555 trials were interleaved (i.e., 6 trial types). Each trial type was repeated 20 times with an inter-trial interval
556 of 5 s.

557 *Holographic Stimulation of random multi-target ensembles*
558 For the targeted photostimulation experiment presented in Figure 4a-c, we used virally injected
559 transgenic mice (EMX1-Cre;CaMK2-tTA;tetO-GCaMP6s injected with AAV9-CAG.DIO.ChroME2s-FLAG-
560 ST.P2A.H2B.mRuby3.WPRE.SV40). The holographic FOV was placed over LM. The imaging FOV
561 encompassed V1, LM, RL, PM and AM (2400 X 2400 μm2). Stimulation consisted of long 250ms pulses, at
562 zero power, P=30mW and P=50mW, with 200 trials per power condition to maximize detectability of long-
563 range responses. P=30mW and P=50mW trials were averaged as the stimulation condition.

564 For the targeted photostimulation experiments presented in Figure 4d-g, we used Vglut1-
565 Cre;Ai203 mice. We recorded 4 sessions from 2 female mice (n=2 sessions each). The holographic FOV
566 was placed over LM. The imaging FOV encompassed V1, LM, RL, AL, A and AM (3000 X 1800 μm2). Each
567 target received 50mW, and each stimulation consisted of 10 pulses of 10 ms duration at 16 Hz. In each
568 session, 4 distinct holograms were used in addition to a zero power condition, with 80 trials per condition.

569
570 *Offline analysis of mesoscopic two-photon calcium data*

571 Motion correction and source extraction were done using Suite2p (Pachitariu, 2016), run through GPU for
572 faster processing. Calcium sources were manually curated based on morphologically identifiable neurons.
573 For downstream analysis, frames with stimulation laser artefacts were discarded and neuropil
574 fluorescence was subtracted from the fluorescence traces using a 0.7 neuropil coefficient. Each cell's
575 fluorescence trace was then z-scored (Figure 2) or the dF/F was computed prior to z-scoring (z-scored
576 dF/F). dF/F was defined as (F-Fmed)/Fmed where F is the neuropil corrected fluorescence trace and Fmed
577 the median of the neuropil corrected fluorescence trace across all trials. A baseline of 2-5 frames before
578 the stimulus onset was then subtracted for every trial (Figures 3,4). In long-range post-synaptic analyses
579 (Figure 4), calcium traces were smoothed by a gaussian filter with size = 1. Photostimulation targets
580 coordinates were remapped into the stitched mesoscale FOV. and assigned to the closest suite2P
581 identified calcium source.

582 *Decoding photostimuli pairs*

583 To discriminate between pairs of distinct photostimulation patterns, a gradient boosting decision tree
584 algorithm was used. The classifier was trained on 70% of the trials (n=112 trials per pair labeled as either
585 photostimulus 1 or photostimulus 2) and tested on the remaining trials (n = 48 trials). The decoding
586 accuracy was defined as the number of correctly predicted trials over the total number of test trials. For
587 each pair of photostimuli, the final reported decoding accuracy result was the average across 10
588 independent draws (cross-validation). For the shuffled control decoding, the classifier was trained on
589 randomly mislabeled trials and tested on the 30% held-out trials.

590 *Statistics*

591   All statistical analyses were performed using Python or Matlab. The analyses performed were paired t-
592   test, Wilcoxon sum-rank and Mann-Whitney U test and tests were two-sided unless stated otherwise. No
593   statistical method was used to predetermine sample size. Trial randomization was used in all applicable
594   experiments (Figures 2,3,4).

595

627   **Figure 3. Holographic stimulation of co-tuned ensembles emulates visually evoked activity**. **a)** Example
628   imaging FOV used in this experiment (2.4 × 2.4 mm^2, Vglut1-Cre;Ai203 mouse). The holographic FOV was
629   positioned over V1. **b)** Same FOV as **a**, with the cells color coded by their preferred orientation
630   (0/45/90/135° in magenta/yellow/cyan/blue, respectively). Significantly tuned cells are labelled with solid
631   colors while other cells are grayed out (p<0.05 Wilcoxon rank-sum test for preferred vs orthogonal
632   orientations). Right: enlarged image of the holographic FOV with thin circles indicating the holographic
633   targets that were activated by the 90°-tuned ensemble stimulation. **c)** Orientation tuning curves of a group
634   of neurons that were then co-activated as the 90°-tuned ensemble stimulation in d). **d)** Holographically
635   evoked activity in a population of neurons that were grouped into four distinct orientation-specific
636   ensembles. Imaging frames recorded during the holographic stimulation are grayed out due to the
637   holographic stimulation artifact. **e)** Classification accuracy of a linear support vector machine (SVM)
638   trained to classify visual response of 4 orientations, for neurons within 25 μm of each target in holographic
639   ensembles (average 77.7 neurons per session). 10-fold cross-validated decoding accuracy was 0.557 ±
640   0.019 mean ± standard error mean (SEM) across N=11 sessions ($p = 9.77 \times 10^{-4}$ Wilcoxon signed-rank
641   test compared to chance-performance of 0.25). **f)** Classification accuracy of the same SVM when probed
642   with orientation-specific holographically evoked activity without any visual stimulus (0.696 ± 0.043 mean
643   ± SEM, $p = 9.77 \times 10^{-4}$ Wilcoxon signed-rank test across N=11 sessions). Decoding accuracy was
644   measured as the proportion of holography trials that were classified as the corresponding grating
645   orientation. **g)** As in f) but when using Linear SVMs trained on all neurons in the FOV (average 1865
646   neurons, 0.360 ± 0.026 mean ± SEM, $p = 9.77 \times 10^{-4}$ Wilcoxon signed-rank test across N=11 sessions).

647
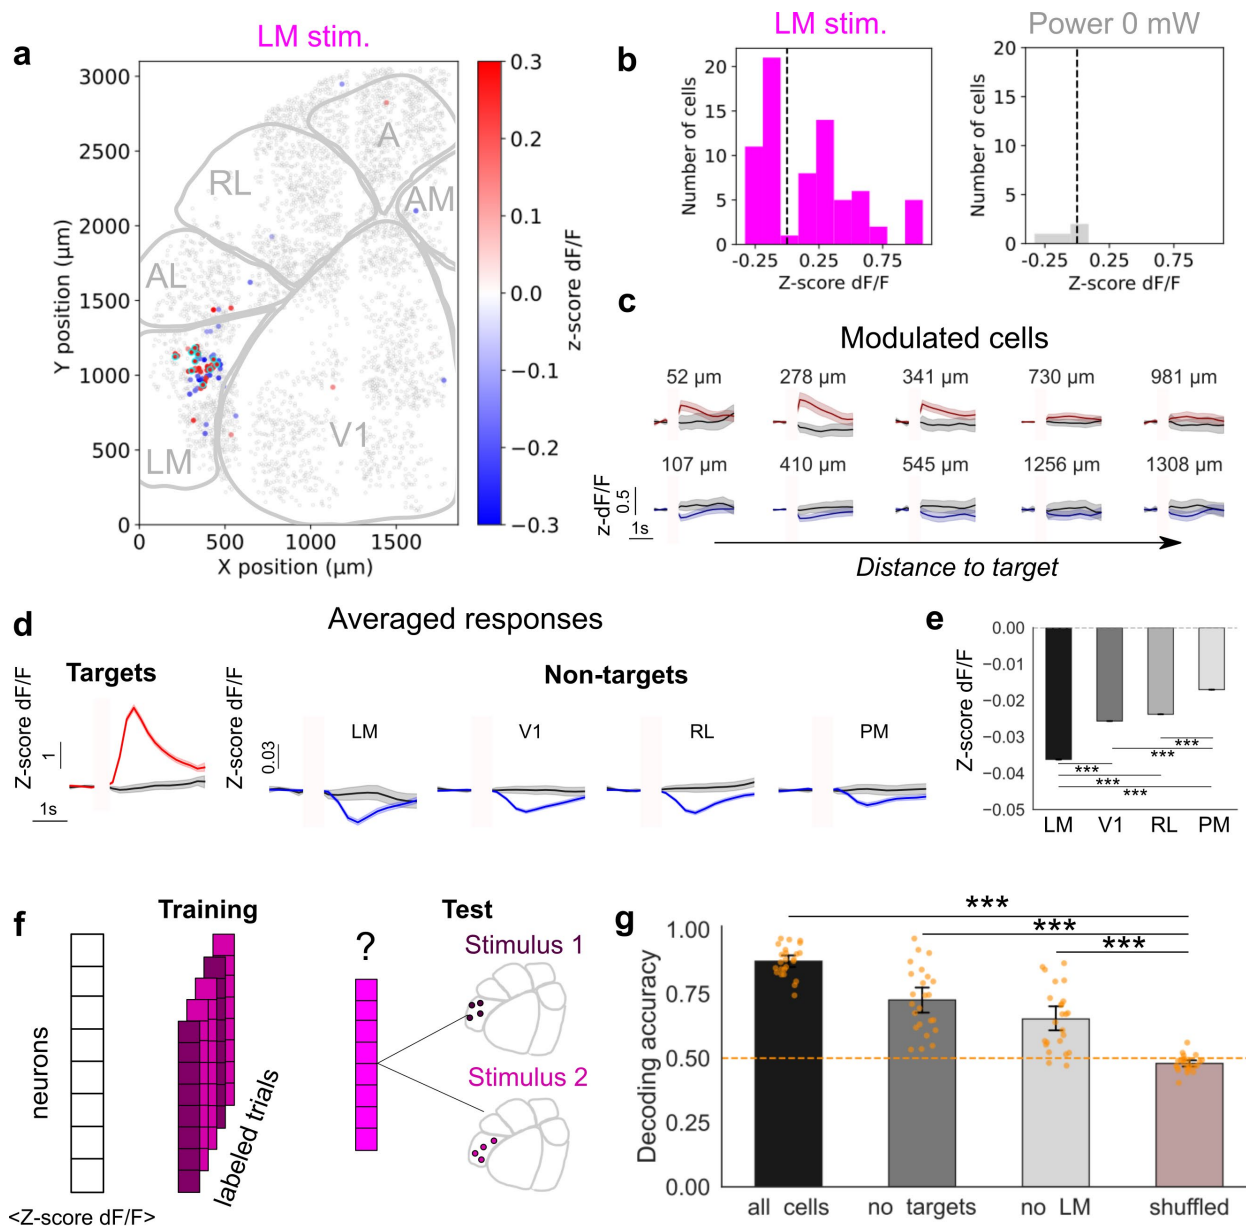

Figure 4. **Mesoscale recording of long-range, corticocortical responses to holographic activation**. **a)** An example mesoscale holographic 'influence' map measured in response to activation of an ensemble of LM neurons. Significantly modulated cells are colored according to the amplitude of their calcium responses. Non-modulated cells are displayed in gray. Holographic targets are circled in cyan. **b)** Distribution of the amplitude of the post-stimulation calcium responses of significantly modulated cells compared to control trials with no stimulation. **c)** Example average calcium responses of individual modulated cells. Red/Blue: average response on stimulation trials (n=200 trials). Black: average response on control (no stimulation) trials (n=200 trials). **d-e)** Average calcium responses across neurons in four areas (n=4 sessions, 2 mice) during multi-target (3-20 cells) stimulation in LM. Red/Blue traces: average across stimulation trials (80 trials × 4 sessions). Black traces: average across no-stimulation control trials. Mann-Whitney: LM/V1: 3.53E-20, LM/RL: 4.18E-24, LM/PM: 4.63E-59, V1/RL: 0.11, V1/PM: 8.66E-22, RL/PM:1.94E-17. **f)** Schematic of a decoder trained to discriminate different holographically induced patterns of activity from

661   downstream responses. **g)** Decoding accuracy of a classifier trained to discriminate the holographically
662   induced patterns in LM from different groups of non-targeted cells in the FOV. All cells: decoding from all
663   neurons in the mesoscale FOV. No targets: decoding from all neurons except the targeted cells. No LM:
664   decoding from all neurons outside area LM. Shuffled: decoding from all neurons outside area LM but with
665   training set labels shuffled. The cross-validated decoding accuracy across N = 4 sessions for all cells, no
666   targets, no LM and shuffled categories was, respectively, 0.88 ± 0.01, 0.73±0.03, 0.65±0.02 and 0.48±0.01
667   (mean ± SEM), the chance level being at 0.5.Wilcoxon signed-rank test across N = 4 sessions: All cells/ no
668   targets: 4.89E-05, all cells/ no LM: 1.67E-06, no targets/ no LM: 0.011, all cells/ shuffled: 1.67E0-7, no
669   targets/ shuffled: 1.32E-09, no LM/shuffled: 5.96E0-7. All groups (all cells, no targets, no LM) show highly
670   significant decoding performance (p-value <0.001) compared to the shuffled group.
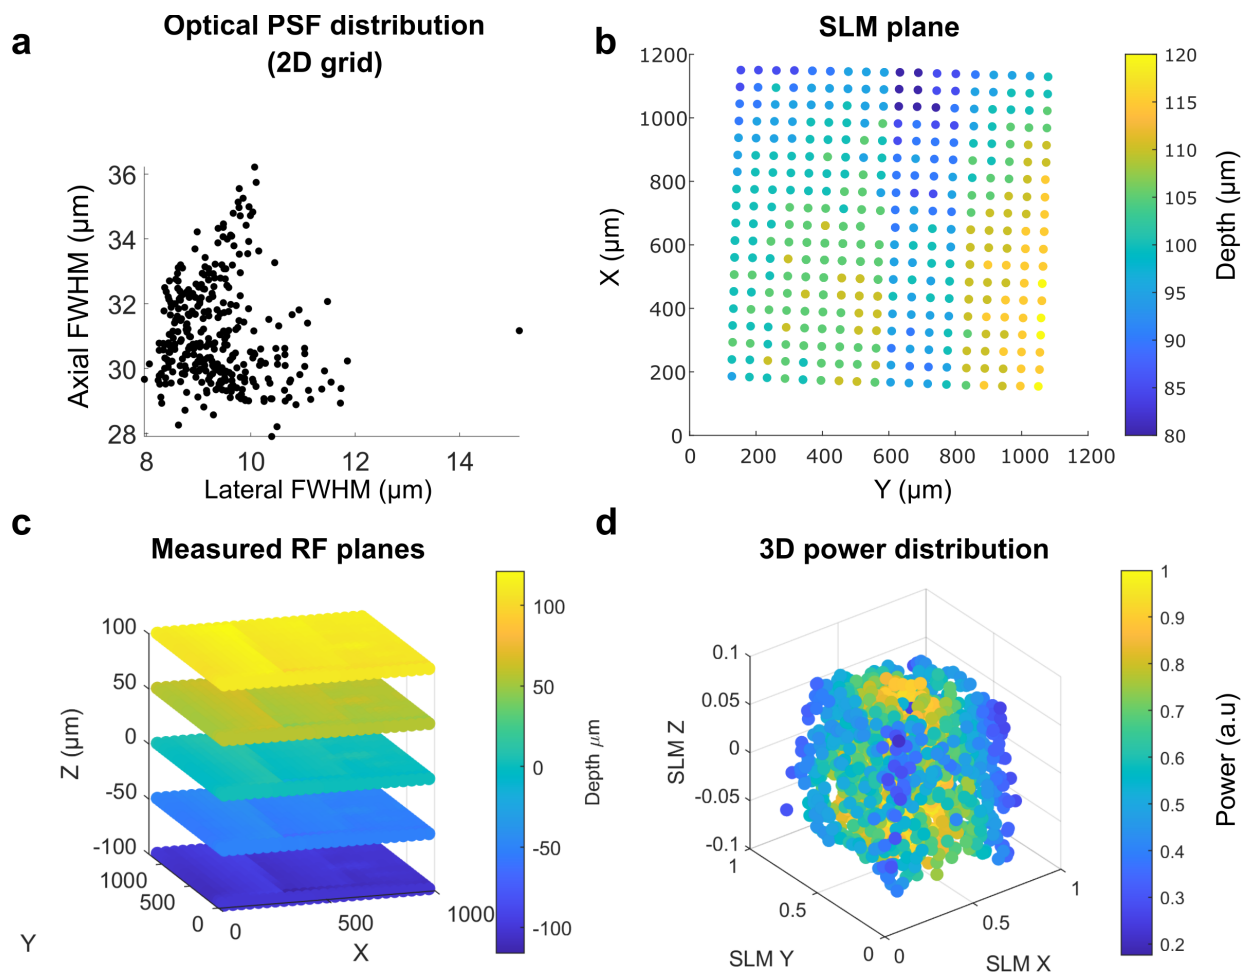

671
672

673   **Supplementary Figure 1. 2P holographic mesoscope optical setup.** EOM: electro-optic modulator, BE:
674   beam expander, P: prism, QWP: quarter waveplate, Dn: dichroic mirror, BS: polarization beamsplitter, VC:
675   voice coil, SLM: spatial light modulator. M6 mirror in the original mesoscope design has been replaced
676   with the D2 dichroic.

d 3D power distribution

678

Supplementary Figure 2. Optical characterization of the 2P holographic mesoscope. a) Distribution of optical point-spread-functions of holograms arranged in a 2D grid across the holographic FOV. **b)** Axial locations in real space (units: microns, arbitrary origin) of holograms with equi-Z SLM coordinates across the holographic FOV. **c)** 3D remote-focusing fluorescence imaging planes in real space measured with an inverted substage camera with voice-coil curvature correction on. **d)** Power distribution variation in 3D measured as the normalized square-root of the 2P fluorescence signal for a distribution of holograms randomly positioned in 3D space. This distribution is used to build a 3D model of diffraction efficiency that is used to dynamically correct the power allocated to each hologram as a function of its location in space, thus allowing to use a greater range of the SLM.

a

b Hologram position shift with translation and rotation
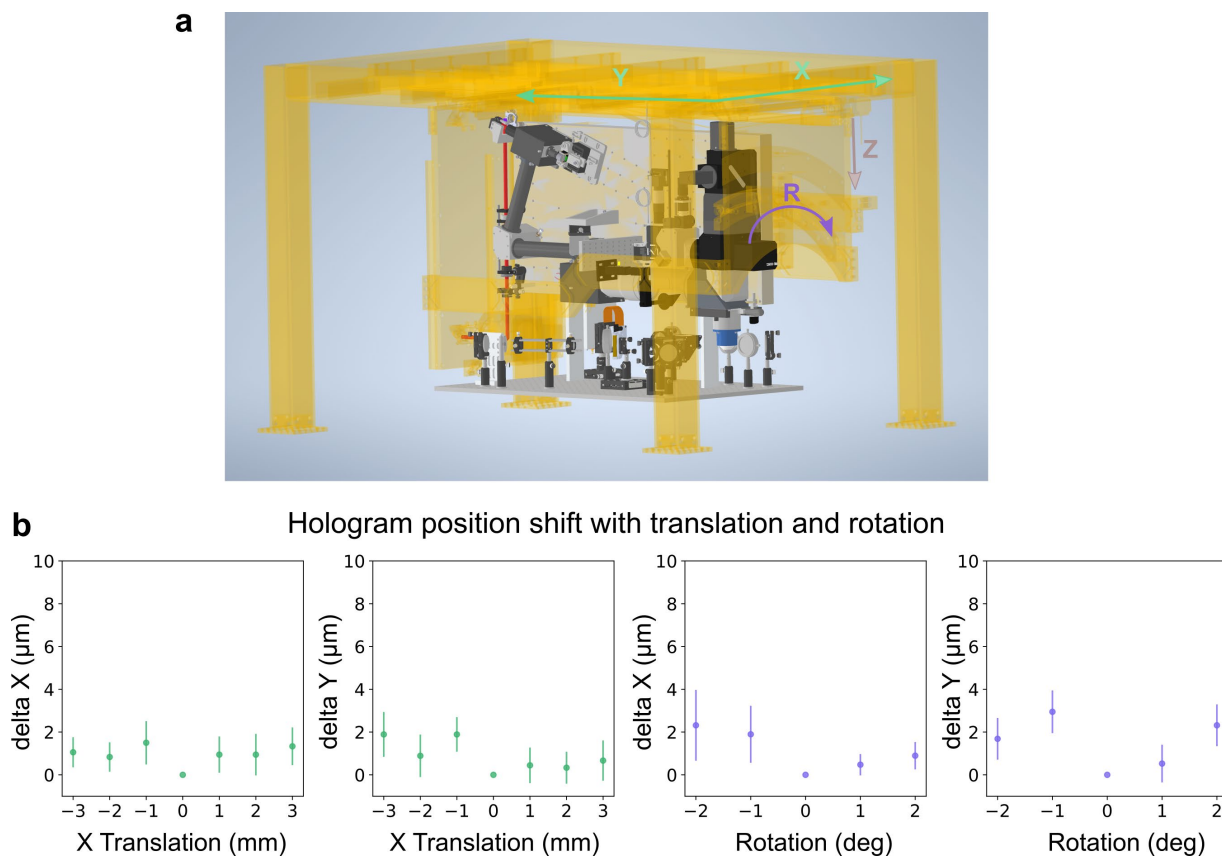

688

689 **Supplementary Figure 3. Targeting invariance with 2P-RAM mesoscope movement. a)** The microscope
690 main frame is motorized in X, Y translation and rotation. The holographic module was designed to be
691 solidary to the main frame thus preserving motion along these axes. Axial Z translation in the 2P-RAM
692 mesoscope is implemented by moving the vertical breadboard relative to the main frame. To maintain
693 holographic invariance, that axis was locked and replaced by a motorized lab jack (MLJ150, Thorlabs) to
694 translate the animal axially relative to the microscope. **b)** Targeting invariance measured for translation
695 and rotation of the microscope around a central reference position. Delta X and Y are computed,
696 respectively, as the difference between the X and Y location of the centroids of holographically burnt holes
697 in a fluorescent slide at the translated or rotated position and the X and Y location of the centroids in the
698 central reference position. Markers: mean value, error bars: standard deviation.

Supplementary Figure 4. Sequential stimulation at different laser powers. Heatmaps of stimulus-aligned calcium responses (z-scored dF) for 111 targeted cells in an example session (Ai203 × VGlut Cre transgenic). 13, 58 and 75 were significantly activated at 0, 50, and 75mW, respectively, signed rank test, one tailed p<0.025).

711

712

Supplementary Figure 5. Cross-validated influence maps for holographic stimulation and no stimulation control. **a)** Example mesoscale holographic 'influence' maps measured in response to no holographic stimulation (left) and to activation of an ensemble of LM neurons (right). Significantly modulated cells are

716   colored according to the amplitude of their calcium responses. Significantly modulated cells are selected
717   as the intersection of significantly modulated cells (t-test p-value <0.05) across two random splits of the
718   total number of trials. Non-modulated cells are displayed in gray. Holographic targets are circled in cyan.
719   **b)** Distribution of the amplitude of the post-stimulation calcium responses of significantly modulated cells
720   in response to holographic activation (magenta) compared to control trials with no stimulation (grey).
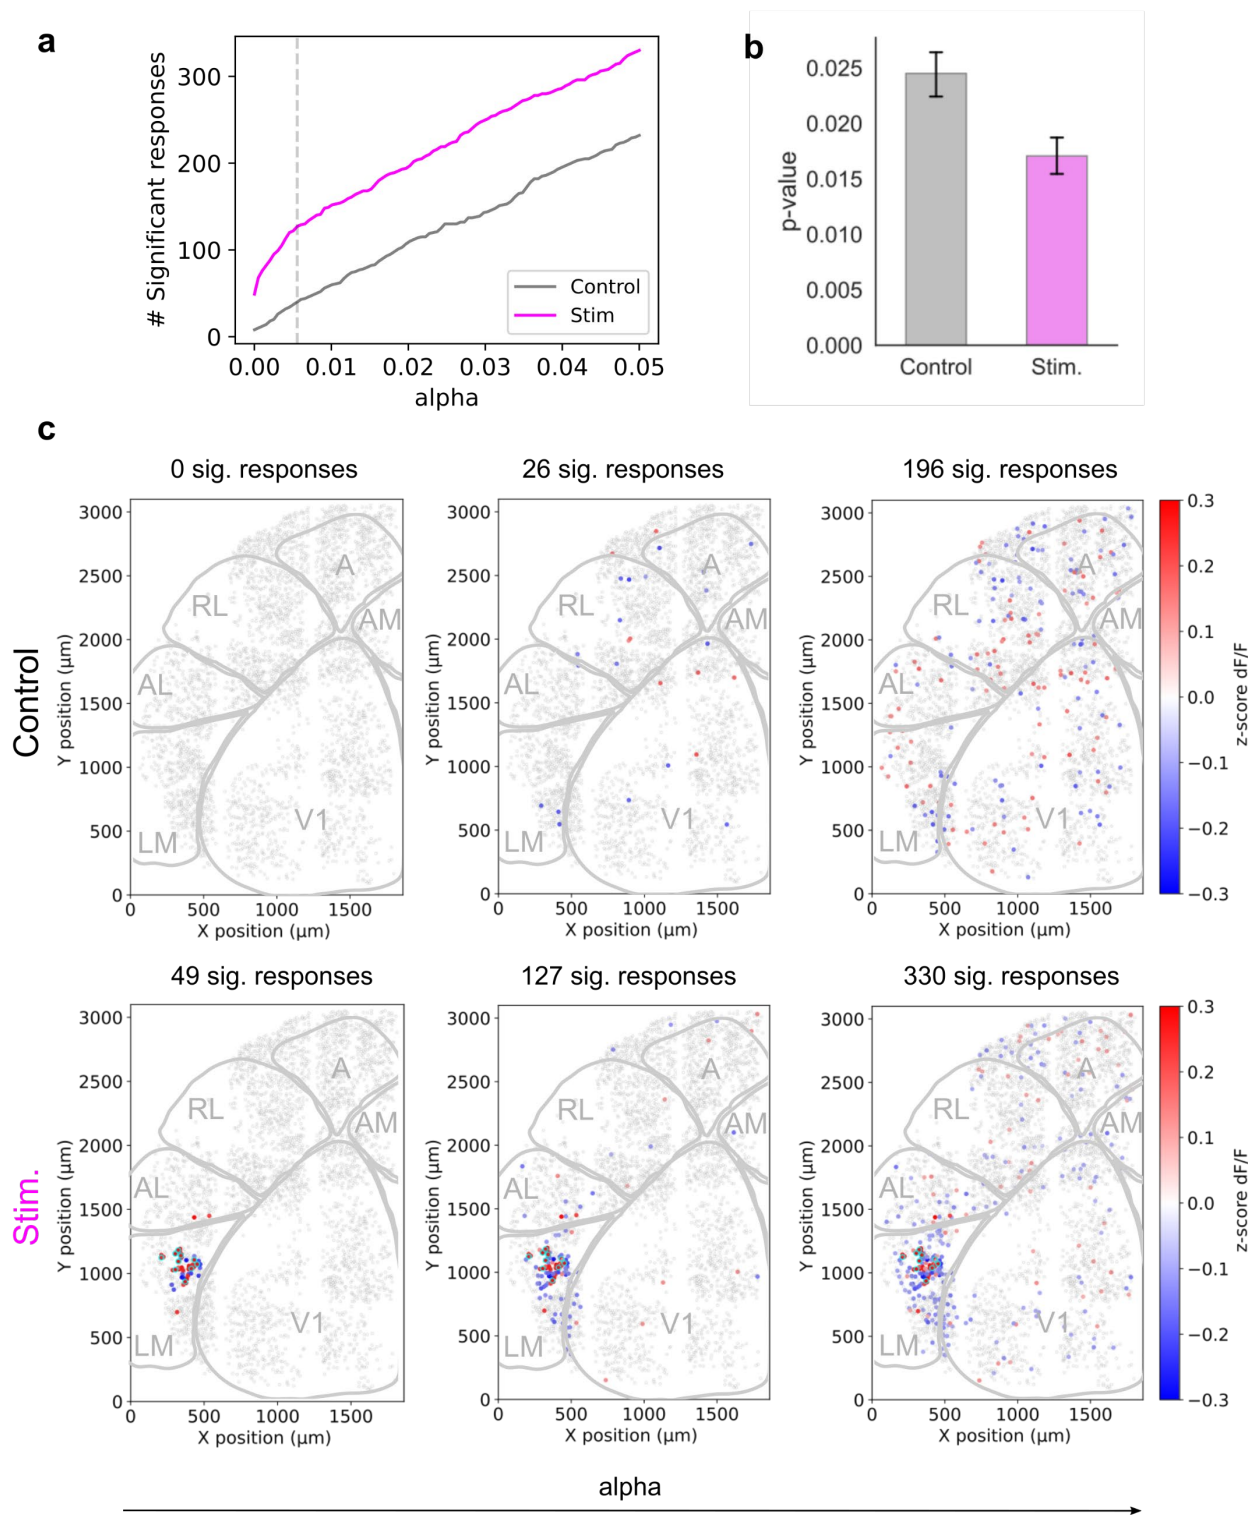

721

722 **Supplementary Figure 6. Significant modulations and false positive rates**. **a)** Number of significantly
723 modulated cells in response to holographic activation and in response to the no stimulation control as a
724 function of the significance level parameter alpha. Holographic stimulation consistently elicits more
725 significant responses than the false positive rate. **b)** Average of p-values for significantly modulated cells
726 (t-test, p-value <0.05) in the stimulation and no stimulation control condition. **c)** Maps of significantly
727 modulated cells as a function of the significance level alpha parameter. Alpha parameter from left to right:
728 Bonferroni (1.35E0-5), Inflection point value in a) (5.6E-03), and 0.05.

729

Results per session (LM stimulation)
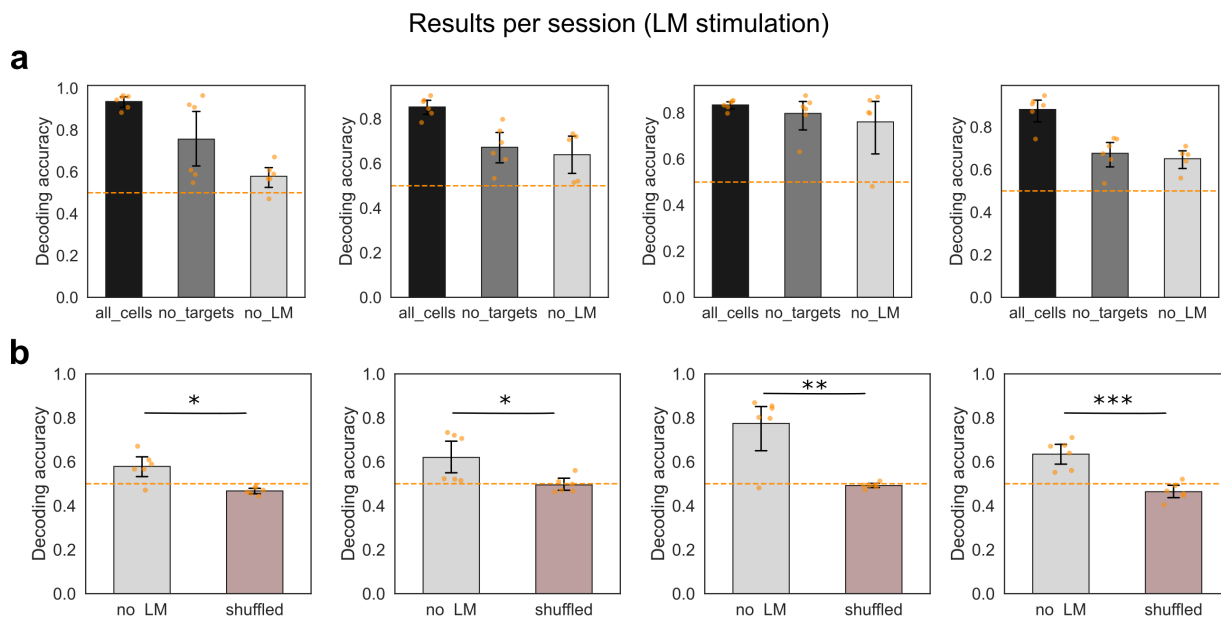

730

731 **Supplementary Figure 7. Photostimulus decoding results per session. a)** Decoding accuracy of a classifier
732 trained to discriminate the holographically induced patterns in LM from different groups of non-targeted
733 cells in the FOV, split per session. 6 pairs of stimuli are presented for discrimination in each session. All
734 cells: decoding from all neurons in the mesoscale FOV. No targets: decoding from all neurons except the
735 targeted cells. No LM: decoding from all neurons outside area LM. b) Decoding accuracy per session of a
736 classifier trained to discriminate the holographically induced patterns in LM from all neurons outside area
737 LM with correct and shuffled labels in the training set. Session1/Mouse1: p = 0.013, Session2/Mouse1: p
738 = 0.023, Session1/Mouse2: p=0.005, Session2/Mouse2 : p = 0.0006.

739

740

741

742

743

744

745 **Supplementary note 1: Hologram axial resolution**

746 The 2P fluorescence signal of a temporally focused gaussian spot at the focus of the objective can be
747 written as:

748
$$S(r,z,t) = \frac{1}{\tau(z)f} I(r,z,t)^2$$

749 With τ the pulse width, f the repetition rate, I the intensity profile at the focus, r the radial dimension(
750 $r = \sqrt{x^2 + y^2}$) and z the axial dimension, both defined with the center of the gaussian spot as origin.
751 Under the approximation that the linear chirp at the objective back aperture (αΩ, with α a constant
752 proportional to the grating groove density and Ω the FWHM of the pulse frequency spectrum) is
753 significantly smaller than the size of each monochromatic beamlet s ($\sqrt{2ln2}$ s the FWHM of each
754 monochromatic beamlet), the pulse width as a function of the axial depth z can be written as (cf.
755 Papagiakoumou et al, 2020):

756
$$\tau(z) \approx \frac{2\sqrt{2ln2}}{\Omega} \sqrt{1 + \frac{z^2}{z_R^2}}$$

757 With $z_R = \frac{2f_{obj}^2}{k_0(s^2 + \alpha^2\Omega^2)}$, f_{obj} the objective focal length, and k_0 the wavevector of the central frequency of
758 the pulse.

759 The 2P fluorescence signal can then be written as:

760
$$S(r,z,t) = \frac{\Omega}{2\sqrt{2ln2}f \sqrt{1 + \frac{z^2}{z_R^2}}} I(r,z,t)^2$$

761 When injecting into this model numerical values corresponding to a conventional 2P objective (here
762 Olympus 20X 1.0 NA f_{obj} = 9mm and 18mm back aperture size) and values corresponding to the 2P-RAM
763 mesoscope objective (0.6 NA f_{obj} = 21mm, 25mm back aperture size), we were able to obtain, for a 400 fs
764 pulse width at 1 MHz and at 1.03 μm wavelength, a cut-off threshold at the tail of the distributions
765 corresponding to empirically observed axial hologram sizes: $\sim 30\mu m$ for the 2P-RAM mesoscope and
766 $\sim 20\mu m$ for the conventional 2P microscope (cf. Pégard 2017, Mardinly 2018). The large back aperture of
767 the mesoscope objective seems to partially compensate for the lower NA regarding axial temporal
768 focusing resolution.

769 **Supplementary note 2: Assembly and alignment guide**

770 Detailed documentation on mesoscope assembly and alignment is available on the Janelia open wiki
771 https://wiki.janelia.org/wiki/display/mesoscopy/Documentation. We focus below on the specifics for
772 adding a 2P holographic module to the Janelia/Thorlabs mesoscope.

773 A) Prerequisites:
774 Adding a 2P holographic photostimulation path onto the mesoscope required some custom parts
775 and modifications to the original mesoscope parts. Items 1-3 below were designed in
776 collaboration with Thorlabs who manufactured the final parts. All the part designs are available

777 on the CAD file attached. We do however encourage scientists willing to upgrade their system to
778 reach to Thorlabs for assistance with the items 1-3 upgrades.
779

780 1. The third scan relay (scan lens and tube lens assembly) needs to be opened to merge the
781 imaging and photostimulation beams. See CAD file for aperture size and position.
782
783
784 *Modified relay mount.*
785

786 2. The 2P holographic path is set up on a horizontal custom 33"" × 24"" × 0.5"" aluminum
787 breadboard (Thorlabs) attached to the main motorized mesoscope frame (gantry). The
788 breadboard is attached to the gantry through two custom support clamps in the back
789 (Thorlabs) and one custom L-bracket on the front (Thorlabs). Securing the L-shape bracket in
790 place required drilling 4 ¼"-20 tapped holes on the mesoscope rotation hub.
791
792 *Back support clamps.*
793

794
795 *L-bracket attached to the mesoscope rotation hub.*
796

797 3. A custom threaded bracket (Thorlabs) was used to attach the recombination dichroic D3 onto
798 the vertical mesoscope breadboard.

799
800 *Bracket to attach the recombination dichroic holder to the mesoscope.*
801

802 4. A custom 3D-printed holder is used to flexibly position the recombination dichroic D3 on the
803 mesoscope scan path. The holder allows flexible positioning across 3 translation directions
804 and one rotation axis and was designed to hold a standard ½" Thorlabs post. The dichroic is
805 secured in place with a FFM1 holder (Thorlabs) secured on a B3C mount (Thorlabs).
806
807
808 *Recombination dichroic holder.*
809

810   5. To maintain axial alignment, the motorized axial movement of the vertical breadboard
811   relative to the gantry is locked and replaced with an external motorized lab jack (Thorlabs,
812   MLJ150).

813 B) <u>Assembly and alignment:</u>

814   1. Once the breadboard is installed, pre-position all breadboard optics to match the 4f
815 requirements using the CAD layout as a guide.

816   2. Align the imaging beam up until the rotation hub to be centered on each of the gantry periscope
817 mirrors (M1,M2,M3,M4,M5) and perfectly stationary with the gantry's X and Y translation.

818   3. Remove the last periscope mirror (M6) and place the provided rotation alignment tool. If step
819 2 is done properly, M5 is enough to steer the beam to be centered and leveled along the rotation axis and
820 to have the beam position invariant with rotation.

821   4. Inject the stimulation beam onto the periscope so that the beam is co-aligned to the imaging
822 beam i.e centered on all mirrors and invariant with X, Y and rotation. For this step only the D1 dichroic
823 and mirrors external to the gantry periscope can be used. Consider having the recombination dichroic D1
824 installed on a lateral translation stage to have an additional degree of freedom for co-alignment.

825   5. Given the natural divergence of the laser beam and the long distances on the mesoscope, the
826 beam should be quite expanded on the rotation alignment tool. To correct for that, we added a 1:1
827 telescope before the gantry (lenses L01 & L02) to have a more collimated beam impinging on the grating.
828 The lenses of the telescope need to be placed centered on the beam so that the beam remains
829 undeflected. L02 could be placed on a translation stage to allow for easier adjustment of the divergence
830 while maintaining the alignment. Fine adjustments of the imaging/stimulation beam co-alignment can be
831 made after the telescope is installed (again, only with mirrors external to the gantry or with the D1
832 dichroic).

833   6. Remove the rotation alignment tool and replace M6 with the D2 dichroic. At this stage, the
834 imaging and stimulation beams can now be aligned independently.

835   7. Remove the rotation alignment tool and replace M6 with the D2 dichroic. At this stage, the
836 imaging and stimulation beams can now be aligned independently.

837   8. Subsequent alignment of the imaging path on the vertical breadboard is now constrained since
838   only D2 can now be used to route the beam straight on the pre-RF vertical axis. Therefore, depending on
839   how the system has been originally set, the whole pre-RF vertical axis might need to be translated
840   horizontally so that the beam can be straight and vertical along that axis.

841   9. After steps 4 and 5, the stimulation beam should be perfectly leveled impinging on the grating.
842   Adjust the angle of the grating to minimize power lost at higher diffraction orders. Then iterate adjusting
843   the height and position of the relay rail and adjusting the tip/tilt on the grating mount so that ultimately
844   the beam is perfectly centered on L1 and L2.

845   10. Install the spinning diffuser and adjust the subsequent mirror to stay leveled at the beam
846   height and to hit the SLM injection mirror while being centered and on-axis on the L3 lens.

847   11. Load a flat phase on the SLM (or simply turn it off). Use the pre-SLM injection mirror and the
848   tip-tilt knobs on the SLM to make the beam centered and leveled on the L4 axis. Having the SLM set on a
849   translation stage can be helpful at this stage since it allows to correct for any clipping issue without
850   changing the angle of the SLM. If the beam is properly centered on the SLM, the beam after L4 should
851   look like a full rectangle beam on an IR card. With subsequent mirrors, the beam should then be aligned
852   to be centered and leveled on the L5 and L6 axes. Prior to this, the cage rail system holding L6 needs to
853   be pre-positioned precisely under the imaging relay aperture so that a 90° beam exiting the cage system
854   is centered on the imaging scan relay vertical axis.

855   12. Place the recombination dichroic D3 in order to have the stimulation beam centered on the
856   mesoscope objective back aperture. Iterate between the position and angle of D3 and the tip/tilt knob of
857   the last cage mirror to have the beam both centered on the back aperture of the objective and straightly
858   vertical on the objective axis.
