Abstract

Postsynaptic density (PSD) is a protein condensate located under the postsynaptic membrane that influences the localization of glutamate receptors and thus contributes to synaptic plasticity. Recent *in vitro* studies have revealed the formation of droplets of various soluble PSD proteins via liquid-liquid phase separation. However, it is unclear how these protein condensates are formed beneath the membrane and how they specifically affect the localization of glutamate receptors in the membrane. In this study, focusing on the mixture of a glutamate receptor complex, AMPAR-TARP, and a ubiquitous scaffolding protein, PSD-95, we constructed a mesoscopic model of protein-domain interactions in PSD and performed comparative molecular simulations. The results showed a sharp contrast in the phase behaviors of protein assemblies in three-dimension (3D) and those under the membrane (denoted as 2D). A mixture of a soluble variant of the AMPAR-TARP complex and PSD-95 in the 3D system resulted in a phase-separated condensate, which was consistent with the experimental results. However, with identical domain interactions, AMPAR-TARP embedded in the membrane formed clusters with PSD-95, but did not form a stable separated phase. The results indicate that the phase separation behaviors in the 3D and 2D systems were distinct. Stable phase separation is more difficult to achieve in and beneath the membrane than in 3D systems.

Significance

Synaptic plasticity is a key factor in memory and learning. Upon learning, protein condensates that form beneath the postsynaptic membrane are known to change their nature. Recent studies have suggested that condensate formation is related to liquid-liquid phase separation based on *in vitro* experiments of soluble parts. However, the phase behavior can be strongly dependent on physical dimensions. The mechanism by which condensate grows beneath the membrane is not well characterized. Taking advantage of the ease of systematic comparison using computer simulations, we investigated the phase behaviors of postsynaptic protein assemblies in 3D and 2D systems. The results revealed that even when a 3D system exhibited clear phase separation, the corresponding 2D system did not exhibit it stably.

INTRODUCTION

Recently, biomolecular condensates in cells have received considerable attention (1). Biomolecular condensates are heterogeneous assemblies that are composed of many proteins and RNAs. As these condensates are considered to have cellular functions but are not surrounded by membranes, they are often called membrane-less organelles. Classic examples include Cajal bodies, nuclear speckles, stress granules, and postsynaptic density (PSD), whereas recent studies have revealed many more examples, such as signalosomes (2). These condensates are formed mainly by two types of interactions: interactions mediated by disordered regions with less sequence specificity, and specific and stoichiometric interactions between protein domains(3–7). Notably, these condensates can form either in solutions, as in the case of Cajal bodies (the 3D system), or under the membrane, as in the case of PSD (5, 8) (the 2D system). Biomolecular condensates often form via liquid-liquid phase separation (LLPS). As phase transition behaviors are, in general, strongly dependent on the underlying physical dimension, the 3D and 2D LLPS behaviors can be different. However, to the best of our knowledge, the possible differences between the two cases have not been well explored.

PSD is a protein condensate beneath the postsynaptic membrane that was first observed by electron microscopy at the distal tip of the spine head (9). In hippocampal CA1 pyramidal cells, PSD has an area of 0.05–0.3 μm^2 and a thickness of approximately 20 nm (10) containing several hundreds to thousands of proteins, as estimated from proteomic analysis (11–14). Proteins identified as components of PSD are diverse and have a hierarchical structure ranging from membrane-embedded proteins such as AMPA receptors (AMPARs) and cell junction proteins to cytoplasmic proteins, including scaffolding, signaling, and cytoskeletal proteins (14–16). As these proteins have diverse signaling pathways (17), PSD is regarded as a membrane-less organelle specializing in signal transmission and synaptic plasticity. PSD protein condensates or clusters have been suggested to be driven by LLPS (8).

The scaffolding protein PSD-95, a member of MAGUKs, is one of the most abundant proteins in PSD, with approximately 300 PSD-95 molecules estimated to exist in each PSD (18, 19). PSD-95 is localized near the postsynaptic membrane in the upper part of the PSD hierarchy, and as a scaffolding protein, contributes to the formation and maintenance of protein condensates beneath the membrane. PSD-95 contains three PDZ domains, each of which has relatively weak one-to-one specific interactions with the carboxyl tail regions (the PDZ binding motif (PBM)) of target proteins, such as Shank, SAPAP, and TARP(20). The former two proteins further bind to proteins such as Homer, which are eventually associated with cytoskeletal proteins at the bottom of the PSD hierarchy. Thus, PSD-95 is involved in the facilitation of PSD condensation.

Glutamate receptors in the postsynaptic membrane are also components of PSD at the top of the

PSD hierarchy and are directly involved in postsynaptic signaling. AMPAR, a representative transmembrane glutamate receptor, forms a tetrameric structure and interacts with PSD-95 via the regulatory protein TARP (transmembrane AMPA receptor regulatory protein). Specifically, each AMPAR subunit stoichiometrically binds to one TARP at its transmembrane regions. The C-terminal tail of TARP with PBM binds to PSD-95 in the cytoplasm beneath the membrane. Observations of postsynaptic membranes by STORM and others have shown that AMPARs are compartmentalized into their "nanodomains" (21). Simulations (22–25) suggest that not only the number of AMPARs but also the localization of AMPARs strongly affects the amplitude of excitatory postsynaptic currents (26). The spatial arrangement of AMPARs plays a key role in the efficiency of the postsynaptic response, and is controlled by the formation of protein condensates with PSD-95 via TARP.

Recent *in vitro* experiments have demonstrated that PSD-95 forms a liquid condensate with the C-terminus of stargazin, one of the subtypes of TARP (27, 28), or with NR2Bc, the C-terminus of NMDAR (8, 28) in solution, primarily via protein-domain interactions. However, nearly all previous *in vitro* experiments demonstrating phase separation used soluble variants in the 3D system (27), and thus can be different from the behavior that would occur in and beneath the postsynaptic membrane. The detailed molecular mechanisms by which PSD-95 regulates AMPAR localization on the membrane remain unresolved.

The purpose of this study was to compare the phase behavior and interaction network of the protein condensate containing AMPARs, TARPs, and PSD-95 under the postsynaptic membrane (2D system) with that containing soluble variants in solution (3D system) via computer simulations of mesoscopic models. The soluble system does not directly reflect the 2D system embedded in the postsynaptic membrane. The 2D system should be more restricted than the 3D system to form a dense protein network in the condensate. However, clarifying the differences between 2D and 3D systems through experiments is inherently difficult. Thus, in this study, we took advantage of computational modeling.

In this study, we constructed a mesoscale model in which each protein domain was simplified as a single spherical particle and performed comparative molecular simulations of AMPARs, TARPs, and PSD-95s under the membrane (2D system) and their soluble counterparts in the 3D system. The proposed domain-resolution mesoscopic model makes comparative simulations of the LLPS dynamics tractable (29, 30). In this model, specific interactions between protein domains are treated as virtual chemical bonds formed by reactions, which ensure one-to-one stoichiometric binding within the mesoscopic representation. The key parameters in the model were calibrated using a 3D system based on *in vitro* experimental data. We analyzed the protein domain interaction networks formed in the 3D and 2D systems, and found significantly reduced network edges in the 2D system. While the 3D system exhibited clear phase separation, scaling analysis of the 2D system indicated that the mixture of AMPARs, TARPs, and PSD-95 beneath the membrane formed finite-sized clusters, but not the separated phase. In general, the results suggest that the phase separation behaviors are markedly

different between the 3D and 2D systems. The droplet formation in a soluble 3D system does not directly prove phase separation in the corresponding 2D system.

METHODS

Mesoscopic model: Molecular representation

Based on previous experimental assays (27, 28), we simulated the mixture of a glutamate receptor AMPAR (or its soluble counterpart), a regulatory protein TARP, and a scaffolding protein, PSD-95, using a mesoscopic model (29, 31, 32). In the mesoscopic model, each globular domain was represented by a single spherical particle. The neighboring domains are connected by interactions derived from the Gaussian polymer model, which represents flexible linkers.

In this study, we considered two simulation systems: 1) a system containing soluble variants of AMPAR and TARP, together with PSD-95s. AMPAR and TARP were replaced with DsRed2 and the soluble C-terminal part of TARP (TARPc), respectively, based on the experiment (28) (denoted as the 3D system) (Fig.1A top); and 2) the system that contained AMPAR and TARP restrained to the membrane surface, in addition to palmitoylated PSD-95 (denoted as the 2D system) (Fig.1B top).

Although AMPAR forms a tetrameric structure constituted by GluA1-4 subunits, in this study, we regarded it as a single sphere, assuming that its tetrameric structure was maintained throughout the simulation. The AMPAR is assumed to be composed of a homo-tetramer of the GluA2 subunit (PDB ID: 3kg2). TARP is a regulatory protein that binds to the GluA subunit on a one-to-one basis, thereby regulating AMPAR protein levels, synaptic localization, and channel activity (33). As a representative of TARP proteins, we chose the TARP $\gamma2$ subunit, also known as "stargazin" since it has been studied as the most well-known TARP subtype in numerous preceding researches. We modeled the TARP (or TARPc) protein as a single spherical particle. Throughout the simulation, we assumed that four TARP particles were always connected to one AMPAR (or DsRed2) and never dissociated from AMPAR. It can thus be denoted as DsRed2(TARPc)$_4$ and AMPAR(TARP)$_4$ for the 3D and 2D systems, respectively. PSD-95 contains five globular domains: three PDZ domains (PDZ1, PDZ2, and PDZ3), one SH3 domain, and one GK domain (27, 34). In addition, an additional small particle representing the first five amino acids of PSD-95 with two cysteine residues, which are palmitoylated in the case of 2D system, is added to the N-terminus and tethered to the postsynaptic membrane (35). We represent a PSD-95 molecule as six spherical particles connected by a Gaussian chain. In the 3D system, a single sphere representing an AMPA receptor in the 2D system was substituted by a soluble fluorescent protein called DsRed2, which also has a tetrameric structure (28). The N-terminal particle of PSD-95 was also replaced with a sphere, with no restraint on the membrane.

The radii R_n and diffusion coefficients D of globular domains were set using the formula below as a function of the number of amino acids N in the domain (36):

$$R_n = 2.24\, N^{0.392} \tag{1}$$

$$R_{\text{h}} = 1.45\,R_n \tag{2}$$

$$D = \frac{RT}{6\pi\eta R_h} \tag{3}$$

where R_{h} is the hydration radius, R is the gas constant, T is the temperature, and η is viscosity. Viscosity in the 3D system and that in the cytosol in the 2D system were determined by water viscosity at 300 K (0.89 cP). The membrane viscosity in the 2D system was set to be 100 times that of the cytosol.

Mesoscopic model: Potentials

Based on the molecular representation in each system, the molecular system is subject to the total potential energy function as follows:

$$V_{\text{total}} = V_{bond} + V_{angle} + V_{spe} + V_{nonspe} + V_{system} \tag{4}$$

where V_{bond} is of two types: harmonic bonds $V_{\text{bond-h}}$ and interactions derived from the Gaussian polymer chain $V_{\text{bond-g}}$. We set the bond between AMPAR and TARP as a harmonic bond. The spring coefficient of the harmonic bonds was set to 10 kJ/mol/nm². On the other hand, protein linkers in PSD-95 are represented by a Gaussian polymer chain, which is easy to extend and shrink, reflecting the flexibility of the protein linker. The spring coefficient was determined by the number of amino acids (N) contained in the linker.

$$V_{\text{bond-h}} = \sum k_b (r - r_0)^2 \tag{5}$$

$$V_{\text{bond-g}} = \sum \frac{3k_B T}{2Nl^2}\, r^2 \tag{6}$$

where k_b is the spring constant of the harmonic bond (set as 10 kJ/mol/nm²), r_0 is the natural length of the harmonic bond set as the sum of the radii of the interacting domains (corresponding to the sum of the AMPAR and TARP radii), k_B is the Boltzmann constant, l is the length between two amino acids (set as 0.38 nm), and r is the distance between neighboring domains. In addition, the angle potential V_{angle} was applied to TARP-AMPAR-TARP to reproduce the correct geometry of the complex.

$$V_{\text{angle}} = \sum k_\theta \left(\theta - \frac{\pi}{2}\right)^2 \tag{7}$$

where k_θ is the spring constant (set as 10 kJ/mol/nm²).

The V_{spe} represents the specific interaction between a TARP and PDZ domain. To accurately represent the one-to-one stoichiometric binding of the two domains, we used a virtual bond produced by a virtual reaction (Fig.1C). The virtual reaction is defined by the association and dissociation reactions. The association reaction occurs with a microscopic rate constant k_{on} when the distance between a TARP and a PDZ domain is within the threshold distance (set as r_0, the sum of the TARP

and PDZ radii). In the simulation, the association trial was examined every timestep Δt ($\Delta t = 0.25$ ns in the 3D system and 1.0 ns in the 2D system). In each trial, the association occurred with Poisson probability $P = 1 - \exp(-k_{on}\Delta t)$. In this model, the microscopic rate constant k_{on} was fixed at 100 /ns throughout all simulations. This rate constant value indicates that when two reactive molecules are in close proximity, a bond is created between them with a probability very close to unity. Thus, we effectively used the Smoluchowski model for diffusion-controlled reactions (37). The dissociation reaction occurred at a fixed dissociation rate constant, k_{off}. The equilibrium dissociation constant for the specific binding $K_{d,spe}$ is correlated with k_{off}/k_{on}. In this study, we enforced $K_{d,spe}$ as the experimental value by altering k_{off}, whereas k_{on} was fixed throughout. When, and only when a TARP and a PDZ were bound (within the same "topology"), we turned on a harmonic interaction between the particles.

$$V_{\text{spe}} = \sum k_{\text{spe}} (r - r_0)^2 \tag{8}$$

where k_{spe} was set to 10 kJ/mol/nm², which is the same as that for other harmonic bonds. Here, we call the interaction defined as a virtual bond as a "specific interaction." By appropriately defining virtual reaction systems, we can rigorously exclude the binding of PDZ domains to TARPs that are already bound to other PDZ domains, guaranteeing a one-to-one specific interaction. Although the C-terminus of TARP, which contains a PDZ binding motif, is said to interact mainly with PDZ1 or PDZ2 on the postsynaptic membrane(27), we assumed that all PDZ domains have the same binding ability to TARPc in this model, as the binding ability to PDZ3 has also been confirmed by artificially extending the C-terminal tail of TARP (34).

In addition to the virtual bond created by the virtual reaction, we implemented the nonspecific interaction V_{nonspe} which acts between any two protein domains, in contrast to the specific interaction. This interaction consists of a weak inter-domain force and an excluded volume term between the two particles. The potential function is obtained by connecting the three harmonic functions as follows (Fig.1D) (31):

$$V_{\text{nonspe}} = \sum \begin{cases} \dfrac{1}{2}k(r-d)^2 - E_{\text{nonspe}}, & r < d \\ \dfrac{E_{\text{nonspe}}}{2}\left(\dfrac{r_c - d}{2}\right)^{-2}(r-d)^2 - E_{\text{nonspe}}, & d \le r < d + \dfrac{r_c - d}{2} \\ -\dfrac{E_{\text{nonspe}}}{2}\left(\dfrac{r_c - d}{2}\right)^{-2}(r-r_c)^2, & d + \dfrac{r_c - d}{2} \le r < r_c \\ 0, & r \ge r_c \end{cases} \tag{9}$$

where the distance of the potential minimum d was set as the sum of the radii r_0. The cutoff distance r_c was set to $1.5r_0$. The spring constant k was set to 10 kJ/mol/nm². The depth of the potential minimum, E_{nonspe}, was tuned based on the experimental data, as described below.

To reproduce and compare the situation in an *in vitro* experiment of soluble counterparts and the state of the mixture of AMPARs and PSD-95 in the actual postsynaptic membrane, we performed simulations in 3D and 2D systems.

In the 2D system, transmembrane domains of proteins (AMPAR, TARP, and the palmitoylated N-terminus of PSD-95) diffused within the membrane space (defined as $|z| < D_{mem2}$), while other domains diffused in the cytoplasm under the membrane ($z < -D_{mem2}$), where the half membrane thickness D_{mem2} was set to 2.5 nm. To achieve this, we introduced an additional potential that implicitly represents the membrane. We used transmembrane domains (Fig.1E, right).

$$V_{system} = \sum \begin{cases} 0, & |z| < D_{mem2} \\ \frac{1}{2}k_{mem}(|z| - D_{mem2})^2, & |z| \geq D_{mem2} \end{cases} \tag{10}$$

where k_{mem} was set to 10 kJ/mol/nm^2. For cytoplasmic domains, we applied

$$V_{system} = \sum \begin{cases} 0, & z < -D_{mem2} \\ \frac{1}{2}k_{mem}(z + D_{mem2})^2, & z \geq -D_{mem2} \end{cases} \tag{11}$$

All potentials are made of soft-core potentials to realize efficient MD simulations for a dense mixture of proteins during liquid-liquid phase separation using a relatively large time scale.

The simulations were performed using ReaDDy 2 (31, 38). Protein dynamics were modeled using the overdamped Langevin equation. The time step of the simulation was 1.0 ns for the 2D system and 0.25 ns for the 3D system and the parameter tuning simulation. The time step used in the software does not necessarily correspond precisely to actual physical time. The temperature of the system was set at 300 K.

Simulation Protocol: Slab simulation in the 3D system

To confirm whether the mixture of DsRed2(TARPc)$_4$ complex and PSD-95 causes liquid-liquid phase separation through protein-domain interactions, we performed simulations in the 3D system and ran the simulation for 2×10^8 MD time steps after 200 molecules of DsRed2(TARPc)$_4$ and 200 molecules of PSD-95 were initially placed uniformly in a $50 \times 50 \times 500$ nm slab box with the periodic boundary condition (Fig.1A bottom). Simulations were first performed using only specific interactions. The same simulation protocol was used to simulate LLPS with both specific and non-specific interactions.

As described above, the specific interaction between TARPc and PDZ is represented by a virtual reaction such that close molecules are tied together by virtual bonds. Here, we call the groups of molecules linked by virtual bonds as "clusters."

Simulation Protocol: Parameter tuning in the 3D system

We tuned the parameters for the specific and nonspecific interactions ($V_{spe} + V_{nonspe}$) based on

experimental data. In the specific interaction, we fixed k_{on} and the threshold distance and altered k_{off} to control the specific interaction strength, $G_{spe} = -k_B T \ln K_{d,spe}$. In nonspecific interactions, we tuned the depth of the potential well, E_{nonspe}. To determine the balance between G_{spe} and E_{nonspe}, we conducted two assays.

The first assay aimed to reproduce the experimentally measured dissociation constant K_d between TARPc and PSD-95. The dissociation constant K_d of TARPc's and PSD-95 in experiments ranged between 0.63–2.09 μM (27, 39) (we used 1.0 μM as the representative experimental K_d in this study). We conducted simulations of a single pair of molecules: one molecule each of PSD-95 and TARPc were included in a 50 × 50 × 50 nm cubic box. Using molecular simulations with various values of G_{spe} and E_{nonspe}, the model dissociation constant was estimated using the following formula:

$$\text{TARPc} + \text{PSD95} \leftrightarrows \text{TARPc} \cdot \text{PSD95}$$

$$K_d = \frac{[TARPc][PSD95]}{[TARPc \cdot PSD95]} = \frac{(\Delta t_{unbound}/(\Delta t_{total} V N_A))^2}{\Delta t_{bound}/(\Delta t_{total} V N_A)} \tag{12}$$

where $\Delta t_{unbound}$, Δt_{bound}, and Δt_{total} are the cumulative durations of the unbound state, bound state, and total simulation time, respectively. V is the volume of the simulation box. N_A is Avogadro's constant. In this tuning step, we assumed that two molecules are in "bound state" when the distance between TARPc and any PDZ domain is smaller than $1.5 \, r_0$, which is the reference length at which two particles begin to interact. Conversely, "unbound state" is when the distances between TARPc and every PDZ domain are larger than the interaction length. This definition of bound/unbound state does not depend on the formation of a virtual bond created by specific interactions.

The second assay measured the concentration of the dilute phase when the system exhibited phase separation during the slab simulation. Experimentally, the critical concentration for phase separation, which corresponds to the concentration of the dilute phase in the phase-separated system, was $\lesssim$ 10μM. We note that DsRed2(TARPc)₄ and PSD-95 have four and three interacting domains that interact one-to-one, respectively, and that the simulation box contains 200 molecules of each. This indicates that there is an excess of DsRed2(TARPc)₄ as a client for specific interactions in this system. Therefore, we used the concentration of PSD-95 in the dilute phase as a reference for the dilute phase concentration. Adopting the slab simulation protocol described above, we repeated the molecular simulations with different parameter sets that provided appropriate K_d values. When well-separated phases were observed, we estimated the concentration of the dilute phase by counting the number of DsRed2(TARPc)₄ and PSD-95 molecules in the dilute phase and averaging them with the final 2000 snapshots at each parameter set. Based on these values, we determined the values of k_{off} and E_{nonspe}, which were compatible with the experimental K_d value and the critical concentration for phase separation.

Simulation Protocol: Fluidity analysis in the 3D system

Two types of validation analyses, FRAP experiment-like analysis and mean square displacement (MSD) measurements, were performed to assess the molecular fluidity in the 3D simulation of the mixture of DsRed2(TARPc)$_4$ s and PSD-95s.

In the FRAP experiment-like analysis, we first chose a reference time when most of the DsRed2(TARPc)$_4$s and PSD-95s were involved in one large cluster. At the reference time, we marked the DsRed2 molecules in the left quarter (i.e., the negative z side) of the condensate. We tracked the marked molecules at subsequent times. The difference in the z-coordinates of the center of mass of the marked molecules and that of the rest was calculated as a function of time from the reference time point. The decay of the difference corresponds to the recovery of fluorescence in the FRAP experiment. We took an average of 1000 snapshots over the reference time point to obtain a smooth recovery curve.

In the MSD calculation, we first separated the slab box into condensed and dilute phases as described above. Then, in each phase, we obtained the MSD of the molecules as a function of time. Even though we used the periodic boundary condition, we could obtain the absolute distance of diffusion by tracking the motion. As in the FRAP experiment, we took an average of 1000 snapshots over the reference time point to obtain smooth MSD lines. The diffusion coefficients of the molecule in each phase were estimated using the value calculated from the slope of the MSD.

Simulation Protocol: Simulation in the 2D system

We conducted a set of molecular simulations in and beneath the membrane of a mixture of AMPAR (TARP)$_4$ and palmitoylated PSD-95. At the central plane of the $300 \times 300 \times 300$ nm cubic box (the periodic boundary condition), we assumed an implicit membrane at $z \sim 0$ and applied the implicit membrane potential to the particles to be embedded, as described above (Fig.1B bottom). Fifty AMPAR(TARP)$_4$ complexes were uniformly placed on the membrane ($z \sim 0$). Fifty PSD-95 molecules were uniformly placed beneath the membrane. The N-terminal beads of PSD-95 were in the membrane, while the other particles were in the cytosol ($z < -D$). Starting from the configuration, we ran the simulation for 2×10^8 MD time-steps. The same simulation was repeated thrice for statistical analysis. Using the same simulation protocol, we also executed simulations at three different areal densities (25 AMPARs/S, where S = 90000, 45000, and 22500 nm^2) with the same number of AMPARs and PSD-95s. To monitor the stability of the clusters/condensates, we estimated the average number of molecules in the largest cluster for each configuration in the last 5,000 saved snapshots.

Next, with the areal density fixed to the dense value (25 molecules / 22500 nm^2), we performed simulations containing different numbers of AMPAR(TARP)$_4$ s and PSD-95s (n = 25, 50, 100, and 200). By investigating the scaling of the largest cluster size, we addressed whether the molecular assembly could be assigned as a separate phase. To assess the convergence of the cluster formation,

we adopted a pair of simulations starting from mutually opposite extremes: one from a completely homogeneous configuration (denoted as a forward simulation) and the other from a completely phase-separated configuration (a reverse simulation. See Fig.S1 for the preparation of the initial state). We regarded the merging of the largest cluster size in the pair of simulations as a signal of equilibration. Beyond the first crossing time of the two-simulation data, we calculated the largest cluster size averaged over 10000 snapshots.

Figure 1. The mesoscopic model in 3D and 2D systems. A) Schematic of the 3D system (top) and the simulation box (bottom). Soluble DsRed2 tetramer and each C-terminus of TARP are modeled by one spherical particle. B) Schematic of the 2D system (top) and the simulation box (bottom). The AMPAR and each TARP are modeled by one spherical particle. Particles representing AMPAR, TARP, and N-terminal of PSD-95 diffuse on the planar membrane (orange), while other particles diffuse in the cytosol just below the membrane (sky-blue). Among many, one representative box size is shown. C) The virtual reaction to represent one-to-one stoichiometric interaction (specific interaction) between TARP and PDZ domains. D) The non-specific inter-domain interactions. E) Implicit membrane potentials of the particles representing membrane embedded domains (red) and those representing

cytosolic domains (blue). Sky-blue: cytosolic region, Orange: membrane region.

RESULTS AND DISCUSSIONS

Model validation and phase separation in the 3D system

We first examined our mesoscopic modeling for the mixture of PSD-95 and DsRed2(TARPc)$_4$, a soluble counterpart of AMPARs bound to the four C-terminal cytoplasmic parts of TARPs, based on available experimental data. This system has recently been shown to exhibit LLPS in *in vitro* assays. The C-terminus of stargazin (TARP γ2 subunit) and PSD-95 exhibit phase separation at an average concentration of 10 μM (27). In addition, the dissociation constant K_d between C-terminus of stargazin and full-length PDZ-95 was measured to be 0.63 ± 0.6 (27), 1.2 (result from ITC assay), or 2.66 ± 0.07 μM (result from FP saturation assay) (39). We assumed the experimental K_d to be 1.0 μM. These experimental data can be used for calibration.

We adopted the slab simulation box, which is advantageous for realizing phase separation in MD simulations. This is because the slab shape enables the separation of the two phases by the interfaces of small areas, which alleviates the finite-size effects seen in other droplet simulations (40, 41). We began the simulations using homogeneous and random configurations.

We first tested modeling solely by the specific one-to-one interaction between the PDZ domain of PSD-95 and TARPc. We set the nonspecific interaction to zero, i.e., $E_{\mathrm{nonspe}} = 0$, and tuned the strength of the specific interaction G_{spe} so that the computed dissociation constant K_d in the system of a single pair of molecules agreed with that of the *in vitro* experiment (see the Methods section for details). Using the calibrated G_{spe} in the specific-interaction-only model, we performed a slab simulation containing 200 molecules of PSD-95 and DsRed2(TARPc)$_4$ at a concentration of 267 μM, which is much higher than the experimental critical concentration of ~10 μM. The simulation showed that the mixture did not exhibit phase separation, as illustrated in the top panel of Fig.2A. Thus, this specific interaction-only model contradicts experimental results.

In the opposite limit, we removed the specific interaction and tuned the strength of the nonspecific interaction E_{nonspe} so that it agreed with the experimental K_d in the limit of the dilute condition. Using the calibrated E_{nonspe}, we performed the same simulation as mentioned above, except for the interaction parameter. We found that PSD-95 and DsRed2(TARPc)$_4$ formed small clusters, which gradually coalesced into larger clusters (a final snapshot in the second panel of Fig.2A). At the end of the 20 ms (8×10^7 MD time step) simulations, we found no molecules in the dilute phase. We note that the concentration of the dilute phase corresponds to the critical concentration for phase separation (42), which indicates that the critical concentration of LLPS in this setup is much lower than 1 μM. This is inconsistent with the experimental results.

We then explored the two-dimensional parameter space $(E_{\mathrm{nonspe}}, G_{spe})$. First, we found a curve in which the computed K_d agreed with the experimental value (a contour with white crosses in

Fig.2B). Along the curve, we repeatedly conducted simulations of the mixture in the slab box and estimated the concentration of the dilute phase when the system exhibited a phase separation. The concentration of the dilute phase was estimated first by classifying bins along the long slab axis into dilute and condensed phases and then by determining the volume and number of molecules in the region classified as the dilute phase. Along the curve on which the computed K_d agrees with the experimental one, at $E_{nonspe} < 0.9$ kJ/mol, the system did not show the phase separation (Fig.2B). On the other hand, with $E_{nonspe} \geq 0.9$ kJ/mol, we found clear phase separation and a decrease in the concentration of the dilute phase as E_{nonspe} increased. Given that the critical concentration should be less than 10 μM, we chose $(E_{nonspe}, G_{spe}) = (28.7, 1.5)$ (kJ/mol) as the optimal set of parameters (a final snapshot in the bottom panel of Fig.2A).

These results clarified that both the dissociation constant K_d in the dilute phase and the critical concentration of the phase separation can be simultaneously matched with the experimental data only when both specific and nonspecific interactions are implemented for the mixture of PSD-95 and DsRed2(TARPc)₄. This finding is consistent with the results of recent studies (43, 44). Well-balanced combinations of specific and nonspecific interactions are necessary to describe phase separation in mesoscopic modeling.

Figure 2. Model validation and the phase separation of PSD-95 and DsRed2(TARPc)₄ complexes in the 3D system. A) Final snapshots in the three cases. (top) The case that contains the specific interactions alone. (middle) The case that contains nonspecific interactions alone. (bottom) The case that contains the balanced specific and nonspecific interactions. B) The computed K_d of PSD-95 and DsRed2(TARPc)₄ in the parameter space $(E_{\text{nonspe}}, G_{spe})$ (contours and red color) and the concentration of the dilute phase in the phase separated slab system on the counter of the computed K_d that agrees with the experiment (numbers above the figure, where "x" means the absence of the

phase separation). The yellow cross mark indicates $\left(E_{nonspe}, G_{spe}\right) = (28.7, 1.5)$ (kJ/mol), the parameter we adopted.

Figure 3 shows the phase separation dynamics of a mixture of 200 PSD-95 and 200 DsRed2(TARPc)$_4$ simulated in the slab box with the appropriately tuned parameter set. From a homogeneous and random configuration, many small and nearly spherical clusters of PSD-95 and DsRed2(TARPc)$_4$ appeared in < 10 μs, which coalesced into larger and larger droplets, and finally became one large condensed phase together with the low but non-zero density phase at 40 ms (three snapshots in Fig.3A and movie in the supplemental data, Movie S1). Figure 3B shows the time course of the number of virtual bonds, i.e., the one-to-one binding between TARPc and PDZ (blue) and the number of DsRed2 (orange) in the largest cluster. The increase in virtual bonds corresponds to the progress of domain-wise protein network formation, whereas the largest cluster size represents the progress of condensed phase formation. The state of the virtual bonds converged to equilibrium much faster than the phase behavior. As the fusion of two droplets doubles the number of particles in the largest cluster, we observed that the largest cluster grew step-by-step during the simulation. Notably, after the coalescence of two spherical droplets at early stages, the double-sized droplet rapidly assumed a nearly spherical shape. This is a hallmark of droplet fluidity.

To further assess whether the formed condensate has fluidity, we conducted fluorescence recovery after photobleaching (FRAP)-like analysis and calculated the MSD. FRAP experiments are often used to address the diffusivity of specimen molecules (45, 46). Recent FRAP experiments for mixtures of TARPc and PSD-95 showed that light photobleached fluorescence was restored, indicating the fluidity of the droplet (27). By mimicking the experiment, we marked DsRed2 molecules in a quarter volume of the condensed phase localized at one end (along the z-axis) at a reference time t_0 (purple at the top of Fig.3C) and tracked their movements in a subsequent time period. The DsRed2s molecules spread to the entire droplet after 600 μs (bottom of Fig.3C). To quantify the relaxation dynamics, we monitored the difference along the z-axis between the geometric centers of the marked DsRed2 and the other DsRed2 as a function of time from the reference time (Fig.3D), and found an exponential decay. This indicates that the formed condensates were liquid-like. We further calculated the MSD of DsRed2(TARPc)$_4$ particles inside and outside the condensate (Fig.3E). The MSD curves of molecules belonging to either phase showed a linear dependence with respect to the MD time step. This means that molecules belonging to the two phases show normal diffusion with distinct diffusion coefficients. This is a hallmark of liquid droplets (47). Fitting MSD curve by linear regression, we estimated the slope of each MSD curve as 172.3±0.27 and 14.2±0.03 nm^2/μs for the dilute and condensed phases, respectively. The diffusion coefficients of each phase were evaluated as 28.7±0.05μm^2/s in the dilute phase and 2.36±0.00 μm^2/s in the condensed phase. An order-of-magnitude slower diffusion in the condensed phase is qualitatively consistent with the experiment though, quantitatively, the estimated

diffusion coefficient of the condensed phase was about an order of magnitude larger than that can roughly be estimated from the FRAP experiment (27). This discrepancy could be attributed to somewhat arbitrary choices in the virtual reaction kinetic parameters; both protein binding and unbinding rates might be too large. However, this choice would not qualitatively change the behavior of a phase-separated condensate. Thus, we conclude that we have successfully built a mesoscopic model that reproduces the LLPS phenomenon with the soluble counterpart of the three-component postsynaptic density system (DsRed2-TARPc-PSD95) by combining specific interactions defined by virtual reactions and weak nonspecific interactions.

Figure 3. Phase separation dynamics for the mixture of 200 PSD-95 and DsRed2(TARPc)$_4$ complexes in the 3D system. A) Snapshots at the three time points. B) Time series of the number of domain-wise specific bindings, virtual bonds (blue) and the number of DsRed2 in the largest cluster (red). The vertical dashed lines represent the time points at which snapshots are depicted in A. C) The FRAP-like analysis. The distribution of marked and the remaining DsRed2s at the reference time (top) and at 600 μs after the reference (bottom). D) Averaged decay of the difference between the center of mass of marked (photobleached) DsRed2s and that of the other DsRed2 particles. E) The MSDs of DsRed2 in the condensed phase (red) and in the dilute phase (green), respectively, as a function of time

difference.

Cluster formation on and beneath the membrane (the 2D system).

To address the difference between the assembly of the soluble counterpart of AMPAR, i.e., DsRed2, in *in vitro* experiment and that of AMPAR on the postsynaptic membrane, we performed simulations in a 2D system. In contrast to DsRed2(TARPc)$_4$, AMPAR and TARP particles were restrained to the membrane. In addition, the N-terminal particle of PSD-95 was assumed to represent the palmitoylated group and was thus restrained to the membrane. These membrane-embedded particles have smaller diffusion coefficients in the membrane than their soluble counterparts in the solution. For interactions between TARP and the PDZ domain of PSD-95, we used the same parameter set as that used in the 3D system.

We first performed molecular simulations with 50 PSD-95 and 50 AMPAR(TARP)$_4$ on the 300 x 300 nm membrane, which falls into a range of typical areal densities of AMPARs in the postsynaptic membrane (see below). The results showed that many small complexes of a few PSD-95s and AMPAR(TARP)$_4$ appeared quickly (< 1 ms), which then coalesced into larger but unstable clusters (~ 160 ms). A few proteins remained in the dilute phase (three snapshots in Fig.4A and movie in the supplemental data, Movie S2). From a random configuration, the number of domain-wise specific bindings (the network edges) increased rapidly (Fig.4B) over the timescale of 16 μs – 16 ms to reach a plateau. The number of AMPARs in the largest cluster grew at a later stage of ~160 ms, as shown in the right snapshot of Fig.4A. The largest cluster size converged to ~20–30, which is approximately half the total number of AMPARs. In the same way as the 3D case, the one-to-one domain-wise binding of TARPs and PDZs progressed before the growth of the largest cluster size. Comparing the timescales, we found that domain-wise bindings grew more slowly in the 2D case than in the 3D case. This slower domain-wise binding can be attributed to smaller diffusion coefficients in the membrane. The increase in the largest cluster size (number of AMPARs) was also found to be stepwise. We plotted the distributions of the six domains of PSD-95 along the z-axis in Fig.4C, which shows that the domains closer to the N-terminus were, on average, located closer to the postsynaptic membrane. Although the spheres of the N-terminus of PSD-95 moving on the membrane due to palmitoylation can move freely in the membrane region (-2.5 nm < z < 2.5 nm), they are most abundant at z ~ - 2.5 nm since N-termini are likely to be pulled down by other PSD-95 domains. Spheres representing PSD-95 domains other than N-termini were distributed in the range -15.0 nm < z < -2.5 nm below the membrane region. Although the existing ranges of the three PDZ domains (PDZ1, PDZ2, and PDZ3) were highly overlapped, the peaks of their distributions moved slightly away from the membrane from PDZ1, which is closest to the membrane, to PDZ3, which is farthest from the membrane, suggesting that the distribution of molecules to the postsynaptic membrane correlates with their distance from the protein N-terminus.

Figure 4. Molecular assembly dynamics for the mixture of 50 palmitoylated PSD-95 and 50 AMPAR(TARP)$_4$ on and under the membrane of 90000 nm^2 area (the 2D system). A) Snapshots at the three time points (t= t_1, t_2, t_3). B) Time series of the number of domain-wise specific bindings, virtual bonds (blue) and the number of AMPARs in the largest cluster (red). The vertical dashed lines represent the time points at which snapshots are depicted in A. C) The distribution of domains in PSD-95 beneath membrane. The region -2.5 nm < z < 2.5 nm corresponds to the membrane (orange).

Next, we performed the simulations with three different areal densities: sparse condition (25 AMPARs/90000 nm^2), medium condition (25 AMPARs/45000nm^2), and dense condition: (25 AMPARs/22500nm^2). The areal densities of AMPARs in the sparse and medium conditions correspond to typical areal densities at the postsynaptic spines of the adult rat hippocampus (48) and adult rat cerebellum (49, 50), respectively. A dense condition was used to investigate the limiting case.

Figure 5A shows the final snapshots of the simulation from a random and homogeneous configuration in the three densities from two directions, viewpoints **a** and **b** in Fig.1B (bottom). The results showed that PSD-95s assembled AMPARs to form clusters on the membrane at any areal density. Viewpoint **b** shows that the formation of AMPAR clusters (red particles) was co-localized with the PSD-95 molecules beneath the clusters. The temporal changes in the largest AMPARs clusters under three different areal density conditions (Fig.5B) showed that the lower the density, the longer it takes for the molecules to assemble, mainly as the probability of encountering molecules decreases in

the lower density condition. While all the curves seem to converge by ~ 60 ms, the largest cluster size continues to fluctuate significantly. Thus, the clusters were marginally stable with repeated coalescence and division, regardless of the areal density. This is in sharp contrast to the 3D case where we did not observe the division of large condensates. Under dense conditions, the majority of AMPARs (on average, 19.0 out of 25 AMPARs, Fig.5C right) were incorporated into the largest cluster, which might imply phase separation. On the other hand, with the medium and sparse conditions, no such large single cluster was formed stably, and two clusters containing about half of the total number of AMPARs (12.6 out of 25 AMPARs in the sparse condition, 11.2 out of 25 AMPARs in the medium condition, Fig.5C, left and middle, respectively) were observed for most of the simulation time. Under all conditions, we observed that some AMPAR included in a cluster occasionally left the cluster, diffused freely, and were absorbed into another cluster. In addition to AMPARs belonging to large clusters, single or small groups of AMPARs were also observed on the membrane. The features of cluster formation in the 2D system, such as stepwise growth of the cluster and slower domain-wise binding, were shared with all three areal density cases.

Figure 5. AMAPR(TARP)$_4$ and palmitoylated PSD-95 assembly on and beneath the membrane in

three different areal densities. A) Final snapshots of the protein assembly in three areal densities: the sparse (left), the medium (center), and the dense (right) conditions. Top and bottom pictures are views from the top and from the side, respectively. B) Time series of the number of AMPARs in the largest cluster for the case of the sparse (green), the medium (orange), and the dense conditions (red). C) The mean and the standard error of the largest AMPAR cluster size for the three areal densities.

Receptor-scaffold network does not exhibit the phase separation on the membrane

Although both the mixture of DsRed2(TARPc)$_4$ and PSD-95 in the 3D system and that of AMPAR(TARP)$_4$ and PSD-95 in the 2D system formed clusters, we also observed that the stability of the large clusters differed between the two systems. Large clusters formed on and beneath the membrane are fragile, and breakage is often observed. On the other hand, we observed virtually no breakage of large clusters formed in the 3D system. In addition, the observed cluster sizes in the 2D system differed among the areal densities: a large cluster of receptors constituted by almost all the receptors in the system was observed in the dense condition but not in other conditions. While phase separation was clearly visible in the 3D system, it is unclear whether the cluster formation of receptors and scaffold proteins in the 2D system can be regarded as phase separation.

To address this problem, we examined the scaling behavior in a 2D system. We note that for a cluster (droplet) formed in a multicomponent system to be regarded as a "phase," the size of the phase should grow linearly with the system size in a set of self-similar systems (51, 52). Thus, we examined the self-similarity of droplets in a series of 2D systems of different sizes with identical areal densities. In this study, with the areal density fixed to the dense condition, we repeated simulations for the mixture of AMPAR-(TARP)$_4$ and PSD-95 for four different numbers of AMPARs and PSD-95s at 25, 50, 100, and 200, and measured the number of AMPARs in the largest cluster. To check the convergence of simulations, which is not easy, particularly for larger systems, we employed a pair of simulations for each system size: a run from a random and homogeneous configuration (termed "forward") and another run from a perfectly phase-separated configuration (termed "reverse"). Forward simulations are expected to show cluster growth, whereas reverse simulations are expected to exhibit cluster breakage. The trajectories from the two starting configurations are expected to sample an overlapping ensemble when they reach equilibrium. Thus, we ensured convergence of the simulation.

For the fixed areal density corresponding to the dense condition, we show a pair of trajectories for the system containing 25, 50, 100, and 200 AMPAR(TARP)$_4$s and PSD-95s (Fig.6A). The results show that the time courses of the largest AMPAR cluster size in the forward and reverse trajectories merge at approximately 10, 50, 200, and 200 ms for 25, 50, 100, and 200 AMPARs, respectively. The distributions of the largest AMPAR cluster size after merging the two trajectories (the right panels in Fig.6A) show broad distributions, indicating large intrinsic fluctuations. Snapshots in the final

simulation step (Fig.6B) suggest that the molecules form essentially one cluster for the case of 25 AMPARs but have several clusters for the case of 200 AMPARs.

We plotted the average size of the largest AMPAR cluster as a function of the number of AMPARs in the system (Fig.6C). The results indicate that although the largest AMPAR cluster size increases gradually, the increase is not proportional to the number of AMPARs in the system. The largest AMPAR cluster size seemed to saturate below 100. Sublinear growth and plausible saturation of the cluster size are hallmarks of the lack of phase separation. To assess the finite-size effect of the simulation box, we also performed a 2D simulation in a 2D-variant of the slab box finding that the scaling of the largest AMPAR cluster size is not significantly affected by the different box setup Fig.S2).

We note that the areal density under this condition is probably larger than that of AMPARs on the actual postsynaptic membrane, as mentioned above. Even under such over-dense conditions, stable phase separation was not observed. With physiological AMPAR density, phase separation of the mixture of AMPAR(TARP)$_4$s and PSD-95s is less likely to occur. Therefore, we suggest that any AMPAR density found in the postsynaptic membrane, such as in the hippocampus or cerebellum, is unlikely to cause stable phase separations on and beneath the membrane with only the binary mixture of AMPAR(TARP)$_4$s and PSD-95s.

In general, the phase transition depends on physical dimensions (53, 54). One-dimensional systems with finite-range interactions cannot usually show phase transition. 3D systems often exhibit sharp phase transitions. 2D systems are marginal. For example, the Ising model shows the phase transitions in 2D and 3D systems, whereas the Heisenberg model of ferromagnetism shows the phase transitions only in 3D, but not in 2D systems. The current results agree with the general theories of phase transitions. In recent studies, LLPS has often been observed in *in vitro* 3D systems. It should be noted that the observation of spherical droplets in these 3D systems does not necessarily indicate the stable phase separation of systems that are restricted to 2D.

Figure 6. The scaling analysis of phase separation in the 2D system for the fixed areal density. A) The forward (red) and reverse (blue) trajectories of the largest AMPAR cluster size as a function of time for four different system sizes of self-similarity; 25, 50, 100, and 200 AMPAR(TARP)₄s and PSD-95s with the dense condition (left). The mean of the largest clusters at the beginning (denoted as initial) and the end (denoted as final) of each simulation (right). B) The final snapshots of the four systems. C) The mean of the largest AMPAR cluster size as a function on the total number of AMPARs in the 2D system. Black dashed line is the line assumed that the cluster growth is proportional to the cluster size in the system with 25 AMPARs.

Differences in network structure between the 3D and 2D systems

Finally, we investigated the multivalent interactions between AMPAR (or its soluble counterpart, DsRed2. Henceforth, we denote it AMPAR for simplicity), and PSD-95 via TARPs and PDZ domains leads to differences in the network structure between the 3D and 2D systems. As the specific interactions set up throughout this study are treated as virtual association and dissociation reactions, it is possible to specify which TARP specifically interacts with the PDZ domain. Using this property, we examine the distribution of virtual bonds.

We counted the average number of PDZ domains bound per AMPAR from the final 1000 snapshots of the simulation, with 200 of both molecules added to the simulation box. There was a somewhat interesting difference in distribution between the two systems: the results showed that the four TARPs per AMPAR had the highest population in the 3D system, whereas three PDZ domains per AMPAR were found to be the most common in the 2D system (Fig.7A). This suggests that the protein-domain network in the 3D system exhibits a dense and complicated entangled structure beyond the one-to-one binding of AMPAR complexes and PSD-95s.

To maximize the effect of multivalent interactions, which are the main driving force of phase separation, TARPs were assumed to bind to all four AMPAR subunits in the current work. However, since AMPARs have functional regulatory subunits other than TARPs that competitively bind to the same structural positions as TARPs, this assumption of AMPAR with four TARPs may be unlikely to occur at real synapses (55–57). The results of the virtual bond network analysis imply that even under the condition where the maximum number of TARP (four) is available as an interactive particle, three TARPs are sufficient for AMPARs to form collective structures on the actual postsynaptic membrane, owing to the spatial constraint imposed by the membrane.

The distribution of the number of TARPs bound per PSD-95 also showed slight differences between the two systems: the number of TARPs bound per PSD-95 was almost three in the 3D system, while two were also observed to no small extent in the 2D system (Fig.7B). Generally, PSD-95 is more readily incorporated into the condensed phase than AMPAR in both systems as there are four TARPs per AMPAR and three PDZ domains per molecule of PSD-95. The setting of the number of molecules may indicate that PSD-95 is relatively more likely to bind more TARPs than the tendency of PDZs to be bound by AMPAR (Fig.7A), which is consistent with the results for the number of bound TARPs in 3D. However, a surplus of PDZ domains that can interact with TARP was identified in the 2D system despite TARP outnumbering PDZ in the system. Similar to the AMPAR results, this result may be explained by the fact that the number of TARPs that each PSD-95 can access is spatially confined by the geometry of the postsynaptic membrane.

The multiplicity of virtual bonds between a pair of AMPAR and PSD-95 also revealed dimensional differences. The specific interaction between AMPAR and PSD-95 can form up to three virtual bonds (Fig.7C). The valences of the bonds observed from all pairs of bound AMPAR and PSD-95 pairs were nearly monovalent in both systems, indicating that multi-bonding within the two molecules was relatively rare. However, it was found that the bond valency tended to be higher in the 2D system than in the 3D system (Fig.7C).

The characteristics of the virtual bond networks in the 3D/2D systems shown in Figs.7A, B, and C become more prominent when compared with the graphical diagrams (Fig.7D and 7E).

Fig.7D and 7E illustrate the local bond networks from the final snapshots in the 3D and 2D systems, respectively. These diagrams were drawn starting from AMPAR in the center and tracing 11 bonds

(regardless of bond type). For particles shown with a single star, the AMPAR is closest to the center of gravity of the condensed phase in 3D or the largest cluster in 2D. The graphs show that almost all PDZ domains (yellow) are occupied by specific bonds, whereas some TARPs are not used for binding in either system. Notably, the network structure is more developed and densely formed in a 3D system than in a 2D system. The network diagram does not clearly show the difference in the multiplicity of virtual bonds as the formation of multivalent bonds seems to be a relatively rare in both the systems (Fig.7C). However, the difference in the development of a network is presumed to be correlated with binding multiplicity: in a 3D system, a single molecule, such as AMPAR or PSD-95, can interact with many other molecules. In contrast, the membrane in 2D systems restricts the existing area such that the molecules in and below the membrane can only interact with each other, thus preventing the formation of a dense network. This difference in network structure is hypothesized to be due to the special constraints imposed by the membrane, and it may be a reason why phase separation is less likely to occur in the 2D system than in the 3D system.

Figure 7. The interaction networks in the 3D and 2D systems. A) The average number of PDZ domains bound per DsRed2 in 3D (blue) and AMPAR in 2D (orange) systems. B) The average number of TARPc's and TARPs bound per PSD-95 in the 3D (blue) and 2D (orange) systems, respectively. C) The multiplicity of the virtual bond between each pair of an DsRed2 (AMPAR) and a PSD-95 in the 3D (blue) and 2D (orange) systems. D) Representative local network structures near the center (left) and in periphery (right) of the 3D condensed phase. E) Representative local network structures near the center (left) and in periphery (right) of the 2D cluster. In D and E, purple molecules with single star are those closest to the geometric center of the condensed phase in 3D system and largest cluster in 2D system, respectively. Data for the 2D system are from the case of 200 AMPAR(TARP)$_4$'s in the dense condition. Dashed line denotes that there is a further network structure continuing from the molecule.

CONCLUSIONS

In this study, to investigate how postsynaptic protein condensates can be formed in and beneath the membrane, we built a mesoscopic model of protein-domain interactions represented by virtual specific reactions and nonspecific interactions and applied it to a mixture of glutamate receptor complexes, AMPAR-TARP, and scaffolding proteins, PSD-95. Based on this model, we could reproduce the phase-separated condensate in the 3D system, which was consistent with the results of the *in vitro* experiment. Molecular simulations revealed a clear distinction between the physical properties of protein assemblies in the 3D and 2D systems. In the 3D system, a soluble variant of the AMPAR-TARP complex and PSD-95 merged into a large complex and produced a liquid-liquid phase-separated condensate. In the 2D system, AMPAR-TARP fixed in the membrane formed clusters with PSD-95, but did not form a stable phase-separated state despite identical domain interactions to the 3D system. Stable phase separation is more difficult to achieve in and under the membrane than in 3D systems. The difference in the network topology generated by the receptors and scaffolds in the 3D and 2D systems may explain the difficulties in phase separation in 2D systems.

PSD is a protein condensate formed beneath the postsynaptic membrane and is correlated with signal transmission and synaptic plasticity. This molecular architecture beneath the postsynaptic membrane has been observed using electron microscopy, suggesting that the condensate is stable (9, 15). However, the current simulation results suggest that AMPAR(TARP)$_4$ and PSD-95 alone form transient small clusters, but are not sufficient to form a stable phase immediately under the membrane. These are not contradictory as PSD is known to be organized in a hierarchical manner with other scaffolding proteins, such as SAPAP, Shank, and Homer, which are also prone to form protein condensates in *in vitro* 3D systems (8, 58, 59), other than PSD-95, which is generally located in the upper hierarchy of PSD. At the bottom of the PSD hierarchy, the actin cytoskeleton further contributes to retaining the protein network and anchors the condensate to the cell body. With this hierarchy,

protein networks may physically be between 2D and 3D systems, which could enhance the stability of the condensate. Incorporation of these additional scaffolding and cytoskeleton proteins into mesoscopic computational modeling would be future challenge.

Author contributions

RY and ST conceived and designed the study. RY constructed a mesoscopic model of proteins in PSD, set up the simulation program ReaDDy 2, performed the molecular simulation, and conducted the analysis. RY and ST wrote the manuscript.
