Abstract

Shared input to a population of neurons induces noise correlations, which decreases the information carried by a population activity. Inhibitory feedback in recurrent neural networks can reduce the noise correlations and thus increase the information carried by the averaged population activity. However, the activity of inhibitory neurons is costly. This inhibitory feedback decreases the gain of the population. Thus, depolarization of its neurons requires stronger excitatory synaptic input, which is associated with higher ATP consumption. Given that the goal of neural populations is to transmit as much information as possible at minimal metabolic costs, it is unclear whether the increased information transmission reliability provided by inhibitory feedback compensates for the additional costs. We analyze this problem in a network of leaky integrate-and-fire neurons receiving correlated input. By maximizing mutual information with metabolic cost constraints, we show that there is an optimal strength of recurrent connections in the network, which maximizes the value of mutual information-per-cost. For higher values of input correlation, the mutual information-per-cost is higher for recurrent networks with inhibitory feedback compared to feedforward networks without any inhibitory neurons. Our results, therefore, show that the optimal synaptic strength of a recurrent network can be inferred from metabolically efficient coding arguments and that decorrelation of the input by inhibitory feedback compensates for the associated increased metabolic costs.

Keywords: spiking neural network, metabolic efficiency, mutual

1. Introduction

The efficient coding hypothesis poses that neurons evolved due to evolutionary pressure to transmit information as efficiently as possible [1]. Moreover, the brain has only a limited energy budget, and neural activity is costly [2, 3]. The metabolic expense associated with neural activity should, therefore, be considered, and neural systems likely work in an information-metabolically efficient manner, balancing the trade-off between transmitted information and the cost of the neural activity [4, 5, 6, 7, 8].

The principles of information-metabolically efficient coding have been successfully applied to study the importance of the excitation-inhibition balance in neural systems. It has been shown that the mutual information between input and output per unit of cost for a single neuron is higher if the excitatory and inhibitory synaptic currents to the neuron are approximately equal if the source of noise lies in the stochastic nature of the voltage-gated Na^+ and K^+ channels [9]. In a rate coding scheme, where the source of noise lies in the random arrival of pre-synaptic action potentials, the mutual information per unit of cost has been shown to be rather unaffected by the increase of pre-synaptic inhibition associated with an excitatory input [10].

However, the balance of excitation and inhibition is likely to be more important in the context of recurrent neural networks than in the context of single neurons. In recurrent neural networks, the inhibitory input to neurons associated with a stimulus [11] arises as inhibitory feedback from a population of inhibitory neurons. The inhibitory feedback prevents a self-induced synchronization of the neural activity [12] and reduces noise correlations induced by shared input to neurons in the population [13, 14, 15]. Noise correlations are detrimental to information transmission by neural populations [16, 17] and information is likely transmitted by the activity of a population of neurons instead of a single neuron [18]. Therefore, when studying the effect of excitation-inhibition balance on information transmission, it is essential to consider the context of neural populations.

Several studies have analyzed the effect of noise correlations on information transmission properties [16, 17, 19]. However, these studies did not analyze the relationship between the noise correlations and the metabolic cost of neural activity. In our work, we consider a computational model of a

small part of the sensory cortex and the noise correlations caused by shared connections from an external thalamic population. The noise correlations may then be reduced by inhibitory feedback, which, however, increases the cost of the neural activity [10]. Our point of interest is the trade-off between improved information transmission due to lower noise correlations and the increase in metabolic costs due to stronger inhibitory feedback.

2. Methods

2.1. Network model

We modeled a network consisting of three subpopulations: external (ext), excitatory (exc), and inhibitory (inh). The external subpopulation consisted of Poisson neurons, defined by their firing intensity λ^0_{ext} (same for all the neurons in the subpopulation). Neurons in the excitatory and inhibitory subpopulations were modeled as leaky integrate-and-fire (LIF) neurons:

$$C_m \frac{\mathrm{d}V^i}{\mathrm{d}t} = g_L(E_L - V^i) + I^i_{\text{rec}}(V^i, t) + I^i_{\text{ext}}(V^i, t) + I_{\text{bcg}^i}(V^i, t), \quad (1)$$

$$I^i_{\text{rec}}(V^i, t) = g^i_{\text{exc}}(E_{\text{e}} - V^i) + g^i_{\text{inh}}(E_{\text{i}} - V^i), \quad (2)$$

$$I^i_{\text{ext}}(V^i, t) = g^i_{\text{ext}}(E_{\text{e}} - V^i), \quad (3)$$

$$I^i_{\text{bcg}}(V^i, t) = g^i_{\text{bcg,exc}}(E_{\text{e}} - V^i) + g^i_{\text{bcg,inh}}(E_{\text{i}} - V^i), \quad (4)$$

$$\tau_{\text{exc}} \frac{\mathrm{d}g^i_{\text{ext}}}{\mathrm{d}t} = -g^i_{\text{ext}} + \sum_{j=1}^{n_{\text{ext}}} \sum_{t_s \in \mathcal{T}^j_{\text{ext}}} W^{ij}_{\text{ext}} \delta(t - t_s), \quad (5)$$

$$\tau_{\text{exc}} \frac{\mathrm{d}g^i_{\text{exc}}}{\mathrm{d}t} = -g^i_{\text{exc}} + \sum_{j=1}^{n_{\text{exc}}} \sum_{t_s \in \mathcal{T}^j_{\text{exc}}} W^{ij}_{\text{exc}} \delta(t - t_s), \quad (6)$$

$$\tau_{\text{inh}} \frac{\mathrm{d}g^i_{\text{ext}}}{\mathrm{d}t} = -g^i_{\text{inh}} + \sum_{j=1}^{n_{\text{inh}}} \sum_{t_s \in \mathcal{T}^j_{\text{inh}}} W^{ij}_{\text{inh}} \delta(t - t_s), \quad (7)$$

$$\tau_{\text{exc}} \frac{\mathrm{d}g^i_{\text{bcg,exc}}}{\mathrm{d}t} = (\mu_{\text{bcg,exc}} - g^i_{\text{bcg,exc}}) + \tau_{\text{exc}} \sigma_{\text{bcg,exc}} \sqrt{\frac{2}{\tau_{\text{exc}}}} \eta^i_{\text{exc}}(t), \quad (8)$$

$$\tau_{\text{inh}} \frac{\mathrm{d}g^i_{\text{bcg,inh}}}{\mathrm{d}t} = (\mu_{\text{bcg,inh}} - g^i_{\text{bcg,inh}}) + \tau_{\text{inh}} \sigma_{\text{bcg,inh}} \sqrt{\frac{2}{\tau_{\text{inh}}}} \eta^i_{\text{inh}}(t). \quad (9)$$

I_{rec} is the synaptic current arising from the recurrent connections (exc. to exc., exc. to inh., inh. to exc., inh. to inh.). I_{ext} is the excitatory current

Table 1: Parameters of the LIF model		
Membrane capacitance	C_m	$150\,\mathrm{pF}$
Leak conductance	g_L	$10\,\mathrm{nS}$
Resting potential	E_L	$-80\,\mathrm{mV}$
Exc. reversal potential	E_e	$0\,\mathrm{mV}$
Inh. reversal potential	E_i	$-80\,\mathrm{mV}$
Exc. synapse decay	τ_exc	$5\,\mathrm{ms}$
Inh. synapse decay	τ_inh	$5\,\mathrm{ms}$
Exc. threshold	θ_exc	$-55\,\mathrm{mV}$
Inh. threshold	θ_inh	$-60\,\mathrm{mV}$
Ext. synapse amplitude	a_ext	$1\,\mathrm{nS}$
Exc. synapse amplitude	a_exc	$0.01\text{–}1\,\mathrm{nS}$

Exc. inh. synapse amplitude	$a_\mathrm{bcg,exc}$	a_ext
Bcg. inh. synapse amplitude	$a_\mathrm{bcg,inh}$	$g \cdot a_\mathrm{ext}$
Inh. scaling factor	g	20

from external neurons. I_bcg is the current from synapses from neighboring cortex areas. $\mathcal{T}^j_\mathrm{ext}$, $\mathcal{T}^j_\mathrm{exc}$, $\mathcal{T}^j_\mathrm{inh}$ represent the spike times of the j-th external, excitatory, and inhibitory neuron respectively. The matrices $\mathbf{W}_\mathrm{ext}$, $\mathbf{W}_\mathrm{exc}$, $\mathbf{W}_\mathrm{inh}$ contain the synaptic connection strengths, $W_X^{ij} = a_X$ ($X \in \{\mathrm{ext}, \mathrm{exc}, \mathrm{inh}\}$) if the j-th neuron connects to the i-th neuron and 0 otherwise. The input from neighboring cortical areas is modeled as the Ornstein-Uhlenbeck process with means $\mu_\mathrm{bcg,exc}$ and $\mu_\mathrm{bcg,inh}$ and standard deviations of the limiting distributions $\sigma_\mathrm{bcg,exc}$ and $\sigma_\mathrm{bcg,inh}$ [20, 21]. We set the values of the background activity to match the moments of an exponential Poisson shot noise with rates $\lambda_\mathrm{bcg,exc} = 0.5\,\mathrm{kHz}$ and $\lambda_\mathrm{bcg,inh} = 0.125\,\mathrm{kHz}$ [22]:

$$\mu_X = a_X \tau_X \lambda_X, \tag{10}$$

$$\sigma_X = a_X \sqrt{\frac{\lambda_X \tau_X}{2}}, \tag{11}$$

where X represents the excitatory or inhibitory background activity.

When the membrane potential V crosses the firing threshold (θ_exc, θ_inh) a spike is fired and the membrane potential is reset to E_L.

The network consisted of $n_\mathrm{ext} = 1000$ neurons in the external population, $n_\mathrm{exc} = 800$ neurons in the excitatory population, and $n_\mathrm{inh} = 200$ neurons in the inhibitory population. The connections were set randomly with con-

nection probability for the recurrent connections (exc. to exc., exc. to inh., inh. to inh., inh. to exc.) set to $P_{\text{rec}} = 20\%$ and the connection probability from the external population (ext. to exc. and ext. to inh., P_{ext}) was varied from to 1% to 100% (Fig. 1A). We created the connection matrices $\mathbf{W}_X$ by generating a matrix of random uniformly distributed numbers $\mathbf{R}_X$ from the interval $[0, 1)$ and set $W_X^{ij} = a_X$ if $R_{\text{ext}}^{ij} < P_{\text{ext}}$ or $R_X^{ij} < P_X$ for $X \in \{\text{exc}, \text{inh}\}$. The random matrix $\mathbf{R}_{\text{ext}}$ was the same for all values of P_{ext}. In simulations where we controlled for the effects caused by a random number of connections from the external population, we fixed the number of connections by setting only the $k = n_{\text{ext}} P_{\text{ext}}$ elements in each row of W_{ext} non-zero, in the location of the k largest elements of the i-th row of $\mathbf{R}_{\text{ext}}$.

The simulations were carried out using the Brian 2 package [23] in Python with a 0.1 ms time step.

2.2. Obtaining the input-output relationship of the network

We considered the total number of action potentials n from the excitatory and inhibitory subpopulations in time window $\Delta T = 1\,\text{s}$ as the output of the network. We modeled the stimulus as the input from the thalamic neurons, parametrized by the mean input rate to a single neuron:

$$\lambda_{\text{ext}} = n_{\text{ext}} \lambda_{\text{ext}}^0 \frac{100\%}{P_{\text{ext}}}, \tag{12}$$

where λ_{ext}^0 is the firing rate of a single neuron in the external population and $n_{\text{ext}} \frac{100\%}{P_{\text{ext}}}$ is the mean number of pre-synaptic external neuron for each neuron in the excitatory and inhibitory populations. For each set of parameters (a_{rec} and P_{ext} pair) we determined the input $\lambda_{\text{ext}}^{\max}(a_{\text{rec}}, P_{\text{ext}})$ for which the output reached 30 kHz. In order to obtain the input-output relationship, we discretized the input space into 30 equidistant stimulus intensities: $\lambda_{\text{ext}}^i(a_{\text{rec}}, P_{\text{ext}}) = \frac{i}{30} \lambda_{\text{ext}}^{\max}(a_{\text{rec}}, P_{\text{ext}})$, where $i = 0, \ldots, 30$. With a fixed network connectivity, we simulated the network 1080 times for each $\lambda_{\text{ext}}^i(a_{\text{rec}}, P_{\text{ext}})$.

We then fitted 7th-degree polynomial functions to the mean output of the network as a function of the stimulus λ_{ext} and to the Fano factor as a function of the mean output, where Fano factor is defined as:

$$\text{FF} = \frac{\text{Var}[N]}{\text{E}[N]}, \tag{13}$$

where N is a random variable representing the number of output action potentials n. The weights of the polynomial fit were set as $\frac{1}{y^2}$, where y is the

independent variable. We then discretized the input space to 1000 equidistant stimulus intensities and estimated the mean output μ and Fano factor FF for each intensity from the polynomial functions. We then estimated the input-output relationship, defined by the conditional probability distribution $f(n|\lambda_{\text{ext}})$ as a lognormal distribution for each λ_{ext}, with corresponding parameters to match the estimated mean and Fano factor:

$$f(n|\lambda_{\text{ext}}) = \frac{1}{Z} \frac{1}{n\sigma_{\log}\sqrt{2\pi}} \exp\left(-\frac{(\ln n - \mu_{\log}^2)}{2\sigma_{\log}^2}\right), \tag{14}$$

$$\sigma_{\log} = \sqrt{\ln\left(\frac{\text{FF}}{\mu} + 1\right)}, \tag{15}$$

$$\mu_{\log} = \ln\mu - \frac{\sigma_{\log}^2}{2}, \tag{16}$$

$$Z = \sum_{n=0}^{+\infty} \frac{1}{n\sigma_{\log}\sqrt{2\pi}} \exp\left(-\frac{(\ln n - \mu_{\log}^2)}{2\sigma_{\log}^2}\right). \tag{17}$$

In this way, we avoided the sampling bias when calculating information measures from the data [24].

2.3. Metabolic cost of neural activity

In our calculations, we focus on the energy in the form of ATP molecules required to pump out Na^+ ions. We take into account the Na^+ influx due to excitatory post-synaptic currents, Na^+ influx during action potentials, and Na^+ influx to maintain the resting potential. To this end, we follow the calculations in [2] and [3], which we modify for our neuronal model.

We assume the standard membrane capacitance per area as $c_m = 1\,\mu\text{F/cm}^2$ and the cell diameter as $D = 69\,\mu\text{m}$, giving the total capacitance $C_m = \pi D^2 c_m = 150\,\text{pF}$. Therefore, to depolarize a neuron by $\Delta V = 100\,\text{mV}$ the minimum charge influx is $\Delta V C_m = 1.5 \times 10^{-11}\,\text{C}$ and the minimum number of Na^+ ions $\frac{\Delta V C_m}{e} \doteq 9.375 \times 10^7$, where $e \doteq 1.6 \times 10^{-19}\,\text{C}$ is the elementary charge. The minimal number of Na^+ ions is then quadrupled to get a more realistic estimate of the Na^+ influx due to the simultaneous opening of the K^+ channels [2]. The Na^+ influx must be then pumped out by the Na^+/K^+-ATPase, which requires one ATP molecule per 3 Na^+ ions. The cost of a single action potential can be then estimated as $\frac{4}{3} \times 9.375 \times 10^7\,\text{ATP} = 1.25 \times 10^8\,\text{ATP}$. However, about 80% of the metabolic

costs associated with an action potential are expected to come from the propagation of the action potential through the neuron's axons. Therefore, we estimate the total cost as 6.25×10^8 ATP.

Next, we assume that the excitatory synaptic current is mediated by the opening of Na$^+$ and K$^+$ channels with reversal potentials $E_{Na} = 90\,\mathrm{mV}$ and $E_K = -105\,\mathrm{mV}$. For the excitatory synaptic current, the following must hold

$$(g_{exc} + g_{ext})(V - E_e) = g_{Na}(V - E_{Na}) + g_K(V - E_K), \tag{18}$$

$$g_{Na} + g_K = g_{ext} + g_{exc}. \tag{19}$$

Therefore:

$$I_{Na} = \frac{g_K(V - E_K)}{(g_{exc} + g_{ext})(V - E_e)}. \tag{20}$$

The sodium entering with the sodium current I_{Na} must be pumped out by the Na$^+$/K$^+$-ATPase, and therefore we calculate the cost of the synaptic current as $\frac{1}{3e} I_{Na} \Delta T$ ATP, where ΔT is the time interval over which we are measuring the cost.

Each input to the network (parametrized by λ_{ext}) is then associated with a cost, which we express as

$$
\begin{aligned}
w(\lambda_{ext}) = &\left((N_{exc}\mu_{exc} + N_{inh}\mu_{inh} + N_{ext}\lambda_{ext}\frac{100\%}{P_{ext}})W_{AP} + \right. \\
&\left. + \frac{N_{exc}\langle I_{Na}^{exc}\rangle + N_{inh}\langle I_{Na}^{inh}\rangle}{3e} \right)\Delta T,
\end{aligned}
\tag{21}
$$

where $\mu_{exc} = \mu_{exc}(\lambda_{ext})$, $\mu_{inh} = \mu_{inh}(\lambda_{ext})$ are the mean firing rates of a single excitatory and inhibitory neuron (given the input λ_{ext}), $\langle I_{Na}^{exc}\rangle = \langle I_{Na}^{exc}\rangle(\lambda_{ext})$ and $\langle I_{Na}^{inh}\rangle = \langle I_{Na}^{inh}\rangle(\lambda_{ext})$ are the average excitatory synaptic currents in a single excitatory and inhibitory neuron.

2.4. Measuring the information content

We treat the neural network as a memoryless information channel [25, 26]. The firing rates of the external population λ_{ext} are the input to the channel, and the number of action potentials n that the excitatory population fires in the time window $\Delta T = 1\,\mathrm{s}$ is the output of the channel. The input is then described by a random variable Λ and the output by a random variable

N. The mutual information between the input and the output $I(\Lambda; N)$ is calculated as

$$I(\Lambda; N) = \int_{\lambda_{\text{ext}}^{\min}}^{\lambda_{\text{ext}}^{\max}} p(\lambda_{\text{ext}}) i(\lambda_{\text{ext}}; N) \, \mathrm{d}\lambda_{\text{ext}}, \tag{22}$$

$$i(\lambda_{\text{ext}}; N) = \sum_{n=0}^{+\infty} i(\lambda_{\text{ext}}; n) q_p(n), \tag{23}$$

$$i(\lambda_{\text{ext}}; n) = \log_2 \frac{f(n|\lambda_{\text{ext}})}{q_p(n)}, \tag{24}$$

$$q_p(n) = \int_{\lambda_{\text{ext}}^{\min}}^{\lambda_{\text{ext}}^{\max}} p(\lambda_{\text{ext}}) f(n|\lambda_{\text{ext}}) \, \mathrm{d}\lambda_{\text{ext}}, \tag{25}$$

where $f(n|\lambda_{\text{ext}})$ is the probability distribution of N given that $\Lambda = \lambda_{\text{ext}}$, $p(\lambda_{\text{ext}})$ is the input probability distribution, $i(\lambda_{\text{ext}}; n)$ is the amount of information that an observation of n spikes gives us about the stimulus λ_{ext}, $i(\lambda_{\text{ext}}; N)$ is then the average amount of information we get from the input λ_{ext}, $q_p(n)$ is the marginal output probability distribution.

Given the input probability distribution $p(\lambda_{\text{ext}})$, we can calculate the average metabolic cost as

$$W_p = \int_{\lambda_{\text{ext}}^{\min}}^{\lambda_{\text{ext}}^{\max}} p(\lambda_{\text{ext}}) w(\lambda_{\text{ext}}) \, \mathrm{d}\lambda_{\text{ext}}. \tag{26}$$

The capacity-cost function $C(W)$ is then the lowest upper bound on the amount of mutual information (in bits) achievable given the constraint that $W_p < W$:

$$C(W) = \sup_{p(\lambda_{\text{ext}}) : W_p < W} I(\Lambda; N). \tag{27}$$

The information-metabolic efficiency E is then the maximal amount of mutual information per molecule of ATP between the input and the output:

$$E = \frac{C(W^*)}{W^*}, \tag{28}$$

$$W^* = \arg\max_{W \in [0, +\infty)} \frac{C(W)}{W}. \tag{29}$$

The capacity-cost function can be obtained numerically with the Blahut-Arimoto algorithm [27], or the information-metabolic efficiency can be conveniently obtained directly with the Jimbo-Kunisawa algorithm [28, 29].

2.4.1. Low noise approximation of constrained information capacity

If the trial-to-trial variability is very low, a lower bound on the capacity-cost function can be found [30, 31]. We used this low-noise approximation to gain analytical insight into the importance of different properties of the neural system for information-metabolically efficient information transmission. In the low noise approximation, the optimal input distribution maximizing the mutual information constrained by metabolic expenses W is given by

$$p(\lambda_{\text{ext}}) = \sqrt{\frac{J(\lambda_{\text{ext}})}{2\pi e}} \exp\left[\lambda_1 - 1 - \lambda_W w(\lambda_{\text{ext}})\right]. \tag{30}$$

where $J(\lambda_{\text{ext}})$ is the Fisher information and λ_1 and λ_W are the Lagrange multipliers which can be obtained from the normalization condition:

$$\int_{\lambda_{\text{ext}}^{\min}}^{\lambda_{\text{ext}}^{\max}} p(\lambda_{\text{ext}}) w(\lambda_{\text{ext}}) \, \mathrm{d}\lambda_{\text{ext}} \tag{31}$$

and the average metabolic cost constraint (Eq. 26). In the Gaussian approximation, the Fisher information is given by

$$J(\lambda_{\text{ext}}) = \frac{\mu'_{\text{ext}}(\lambda_{\text{ext}})^2}{\sigma_{\text{exc}}(\lambda_{\text{ext}})^2}, \tag{32}$$

where $\sigma_{\text{exc}}(\lambda_{\text{ext}})$ is the standard deviation of the spike counts at input intensity λ_{ext}. The low noise estimate on the capacity-cost function is then

$$C_{\text{low}}(W) = 1 - \lambda_1 + \lambda_W W. \tag{33}$$

3. Results

3.1. Constrained information maximization in a simple linear model

In order to gain an insight into what affects the information-metabolic efficiency of a neural population, we first solve the problem for a simple linear system. The mean response of the system is given by $\gamma(\lambda_{\text{ext}}) = g\lambda_{\text{ext}}$, where λ_{ext} is the stimulus and g is the gain of the system. The Fano factor (Eq. 13) is constant, and we assume that the output is continuous and normally distributed. Therefore, the input-output relationship is described by

$$f(n|\lambda_{\text{ext}}) = \frac{1}{\sqrt{2g\lambda_{\text{ext}}\text{FF}}} \exp\left[-\frac{1}{2}\left(\frac{n - g\lambda_{\text{ext}}}{g\lambda_{\text{ext}}\text{FF}}\right)^2\right]. \tag{34}$$

and the Fisher information (Eq. 32) is

$$J(\lambda_{\text{ext}}) = \frac{g}{\lambda_{\text{ext}}\text{FF}} \tag{35}$$

Next, we assume that the cost of the activity $w(\lambda_{\text{ext}})$ depends linearly on the input:

$$w(\lambda_{\text{ext}}) = w_0\lambda_{\text{ext}} + W_0 = \frac{w_0}{g}\gamma(\lambda_{\text{ext}}) + W_0, \tag{36}$$

where W_0 is the cost of the resting state.

The probability distribution derived from the low-noise approximation (Eq. 30) is then

$$p(\lambda_{\text{ext}}) = \sqrt{\frac{1}{2\pi}\frac{g}{\lambda_{\text{ext}}\text{FF}}}\exp(\lambda_1 - 1 - \lambda_W w_0 \lambda_{\text{ext}}). \tag{37}$$

After applying the normalization conditions (Eqs. 26 and 31) and using Eq. (33) we obtain the lower bound on the capacity-cost function:

$$C_{\text{low}}(W) = \frac{1}{2}\log\left[(W - W_0)\frac{1}{w_{\text{AP}}}\frac{1}{\text{FF}}\right], \tag{38}$$

$$w_{\text{AP}} = \frac{w_0}{g}, \tag{39}$$

where w_{AP} is the cost of increasing the output intensity by one action potential.

The gain g, cost scaling w_0, and Fano factor FF cannot be considered constant for real neural populations. However, Eq. (38) provides an insight into the importance of these properties, which we will study numerically for a more realistic neural system.

In the following, we use

$$g = \mu'_{\text{ext}}(\lambda_{\text{ext}}), \tag{40}$$

$$w_0 = w'(\lambda_{\text{ext}}). \tag{41}$$

3.2. Inhibitory feedback decorrelates the neural activity

With the increasing probability of shared input (P_{ext}), the mean pairwise correlation between the firing output of neurons increases (feedforward network, Fig. 1B). These correlations could be removed by recurrent connections, as long as the synaptic currents from the recurrent connections were

inhibition dominated. We set the excitatory recurrent synaptic amplitude as $a_{\mathrm{exc}} = 0.01\,\mathrm{nS}$ to create a small perturbation from the feedforward network and varied the scaling g determining the amplitude of inhibitory synapses ($a_{\mathrm{inh}} = ga_{\mathrm{exc}}$) from 15 to 25. Correlations between neurons were decreased for $g \geq 20$ (Fig. 1C), which was also associated with stronger negative net current from the recurrent synapses (Fig. 1D). For the network considered further in our work, we set $g = 20$. Simultaneously increasing the strength of the recurrent synapses with fixed g led to a further decrease of the correlations among the neurons (Fig. 1E) while further decreasing the net current from the recurrent synapses (Fig. 1F).

3.3. Trial-to-trial variability of single neurons vs. a population

In an inhibition-dominated network, the input needed from the external population in order to evoke a given average firing rate has to be higher than in the case of the feedforward network. The resulting increase in synaptic noise leads to higher trial-to-trial variability in the LIF model (Fig. 2 A-C; see also [32]).

In the case of the total population activity, however, the pairwise correlations between the neurons have a significant effect on the trial-to-trial variability. By denoting the random variable representing the number of spikes of the i-th neuron observed during time window ΔT as N_i, we get for the Fano factor of the population activity:

$$\mathrm{FF} = \frac{\mathrm{Var}(\sum_i N_i)}{\mathrm{E}\left[\sum_i N_i\right]} \tag{42}$$

$$= \frac{\sum_i \mathrm{Var}(N_i)}{\sum_i \mathrm{E}\left[N_i\right]} + \frac{2\sum_{i<j} \mathrm{Cov}(N_i, N_j)}{\sum_i \mathrm{E}\left[N_i\right]} \tag{43}$$

$$= \frac{\sum_i \mathrm{Var}(N_i)}{\sum_i \mathrm{E}\left[N_i\right]} \left(1 + \frac{2\sum_{i<j} \mathrm{Cov}(N_i, N_j)}{\sum_i \mathrm{Var}(N_i)}\right) \tag{44}$$

$$= \frac{v}{\mu}\left(1 + (k-1)\frac{c}{v}\right) \tag{45}$$

$$\approx \mathrm{FF}_0\left(1 + kr\right) \tag{46}$$

where c is the mean pairwise covariance, v the mean variance of a neuron, μ is the mean number of spikes in ΔT, k is the number of neurons, and r is the Pearson correlation coefficient. The last approximation holds for neurons with identical variances and pairwise covariances [16]. It provides an insight

Figure 1: **Inhibitory feedback decreases noise correlations. A:** Schematic illustration of the simulated neural network. Poisson neurons in the external population make random connections to neurons in the excitatory and inhibitory subpopulations. The connection probability $P_{\mathrm{ext}} \in [0.01, 1]$ is varied to achieve different levels of shared external input to the neurons. The neurons in the inhibitory (inh.) and excitatory (exc.) subpopulations make recurrent connections (exc. to exc., exc. to inh., inh. to inh., inh. to exc.) with probability $P_{\mathrm{rec}} = 20\%$. The strength of those connections is parametrized by a_{rec} (Tab. 1). **B:** Mean pairwise correlations between any two neurons in the exc. and inh. subpopulations plotted against the mean output of the network for different values of P_{ext} in a feedforward network ($a_{\mathrm{rec}} = 0\,\mathrm{nS}$). **C:** Mean pairwise correlations as in **B**, for different values of g (ratio of inhibitory-to-excitatory synaptic strength), $a_{\mathrm{rec}} = 0.01\,\mathrm{nS}$. **D:** Total current from recurrent synapses for different values of g, as in C. **E-F:** Same as in **C-D**, but with fixed $g = 20$ and different values of a_{rec}.

into how the pairwise correlations and Fano factor of individual neurons affect the Fano factor of the total activity. If the correlations or number of neurons are small ($r \cdot k \ll 1$), the decorrelation by strengthening the recurrent

Figure 2: **Fano factor of single neurons and of populations.** **A-C:** Mean Fano factor of individual neurons for different values of P_{ext}: 0.01 (**A**), 0.2 (**B**), 1 (**C**). The strength of the recurrent synapses (a_{rec}) is colorcoded. The mean Fano factor increases with the strength of the recurrent synapses. **D-F:** Same as in **A-C** but for the Fano factor of the population activity. The points represent the population Fano factor obtained from the simulation, and the lines represent the fit with a 7th-degree polynomial. For $P_{ext} = 0.01$, the increase in trial-to-trial variability of individual neurons (**A**) can have a stronger effect on the population Fano factor than decreasing the pairwise correlations, resulting in an increase of the population Fano factor with high values of a_{rec} (**D**). For higher values of P_{ext}, the pairwise correlations greatly increase the population Fano factor, which then decreases with increasing a_{rec}.

synapses does not significantly decrease the population Fano factor. Instead, the population Fano factor may increase due to the increase of the Fano factor of individual neurons (Fig. 2D, $P_{ext} = 1\%$). If greater correlations are induced due to the shared input to the network, the correlations have a dominating effect on the population Fano factor, which can then be greatly decreased by strengthening the recurrent synapses and in turn decreasing the

pairwise correlations (Fig. 2E-F).

3.4. Inhibitory feedback is metabolically costly

3.4.1. Stronger recurrence strength increases the cost of the resting state

The cost of the resting state is an important factor for information-metabolic efficiency [10]. In our network, increasing the recurrence strength decreased the spontaneous activity of the neurons, due to inhibition dominating the recurrent currents. However, the simultaneous increase in the strength of the recurrent excitatory synapses increased the cost of the excitatory synaptic currents (Fig. 3A-C).

3.4.2. Inhibitory feedback decreases gain

Because the net current from recurrent synapses is hyperpolarizing, with stronger recurrent synapses, a stronger excitatory current is necessary to bring the neuron to a given post-synaptic firing rate, and higher pre-synaptic firing rates are necessary. Therefore, the gain g of the network decreases, and with increasing a_{rec} the cost of synaptic currents and the cost of external activity increase (Fig. 3D-E).

3.5. Shared input decreases gain

The number of synapses from the external population for each neuron in the excitatory and inhibitory subpopulations follows a binomial distribution:

$$p(k) = \binom{N_{\text{ext}}}{k} P_{\text{ext}}^k (1 - P_{\text{ext}})^{N_{\text{ext}}-k}, \tag{47}$$

with the mean number of synapses given by $N_{\text{ext}} \cdot P_{\text{ext}}$ and variance $N_{\text{ext}} \cdot P_{\text{ext}}(1 - P_{\text{ext}})$. We scaled the firing rate of the individual neurons in the external population as $\lambda_{\text{exc}}^0 = \frac{\lambda_{\text{exc}}}{N_{\text{ext}} \cdot P_{\text{ext}}}$. Therefore the mean output to a single neuron was always λ_{ext}, independently of P_{ext} and the variance of the input across neurons was $\lambda_{\text{ext}} N_{\text{ext}} \frac{1-P_{\text{ext}}}{P_{\text{ext}}}$.

Given the convexity of the single neuron tuning curve in the analyzed input range (Fig. S1) that out of two inputs with an identical mean λ_{ext}, but different variances across neurons, the input with the higher variance will lead to a higher average firing rate. Assuming that the input across neurons follows a normal distribution with mean λ_{ext} and variance σ^2 and that the single neuron tuning curve can be approximated by an exponential function

Figure 3: **Metabolic cost of the network activity. A-C:** Cost at resting state ($\lambda_{\mathrm{ext}} = 0$). **A:** Cost of the excitatory synaptic currents from the background activity and excitatory action potentials evoked by the background activity. **B:** Cost of the action potentials (both excitatory and inhibitory) evoked by the background activity. **C:** Total resting cost obtained by summing **A** and **B**. **D:** The total cost of the network activity is plotted against the output of the network (the total post-synaptic firing rate). *Caption continued on the next page.*

Figure 3: *Caption continued from the previous page.* Filled areas represent individual contributions of each cost component: cost of action potentials from the external population, cost of the excitatory synaptic currents, and cost of the post-synaptic (evoked) action potentials. As P_{ext} increases, the contribution of external action potentials to the overall cost decreases. With increasing a_{rec}, the contribution of excitatory synaptic currents increases. **E:** The cost of increasing the mean input by one action potential (w_{AP}, Eq. 39) is significantly lower for higher P_{ext}. However, although the difference between $P_{\text{ext}} = 1\%$ and $P_{\text{ext}} = 20\%$ is approximately 10-fold, the difference between $P_{\text{ext}} = 20\%$ and $P_{\text{ext}} = 100\%$ is only approximately 2-fold, as the cost of the external population starts to contribute less to the overall cost.

in the form of $c_1 \exp(c_2 x)$, where x is the input intensity to the single neuron, we obtain the mean firing rate:

$$\int_{-\infty}^{+\infty} \frac{1}{\sigma\sqrt{2\pi}} \exp\left[-\frac{(x - \lambda_{\text{ext}})^2}{\sigma^2}\right] c_1 \exp(-c_2 x) = \frac{c_1}{\sqrt{2}} \exp\left(\frac{c_2}{4}(c_2\sigma^2 - 4\lambda_{\text{ext}})\right),$$
(48)

which grows with the standard deviation of the input.

Accordingly, we observed that networks with higher P_{ext} needed higher λ_{ext} in order to produce the same mean PSFR as networks with lower P_{ext} (Fig. 4A-C). Moreover, the mean Fano factor of individual neurons increased with increasing P_{ext} (Fig. 4D-F). This effect could be mostly removed by fixing the number of connections from the external population to each neuron in the excitatory and inhibitory populations to $P_{\text{ext}}N_{\text{ext}}$ (Fig. S2).

3.6. Optimal regimes for metabolically efficient information transmission

We illustrated that the recurrence strength 1) increases the metabolic cost of the neural activity and 2) decreases the trial-to-trial variability of the population response by decreasing the correlations between the neurons. Similarly, the increased probability of a synapse from an external neuron to a neuron in the excitatory or inhibitory population decreases the cost of the neural activity but increases the trial-to-trial variability of the population response by increasing the noise correlations. To find the balance between the cost of the network activity (Eq. 26) and the mutual information between the input and the output (Eq. 22), we calculated the information-metabolic efficiency, which maximizes the ratio of the mutual information to the cost of the network activity (Eq. 28).

For low values of P_{ext} ($\leq 10\%$), increasing the strength of the recurrent input did not lead to an increase in the information-metabolic efficiency. For

Figure 4: **Shared input decreases the gain and increases the individual trial-to-trial variability. A-C:** The input intensity λ_{ext} needed to evoke a given firing rate (x-axis) with different connection probabilities P_{ext} relative to the input intensity for $P_{\text{ext}} = 1\%$. **A:** $a_{\text{rec}} = 0\,\text{nS}$, **B:** $a_{\text{rec}} = 0.2\,\text{nS}$, **C:** $a_{\text{rec}} = 1\,\text{nS}$. For higher P_{ext}, higher values of λ_{ext} are needed to achieve the same post-synaptic firing rates as with lower values of P_{ext}. This effect becomes more pronounced in stronger recurrent synapses (**E-F**). **D-F:** Gain of the network (Eq. 40). A higher P_{ext} leads to a lower gain of the population activity. **G-I:** Higher values of P_{ext} also increase the Fano factor of individual neurons.

higher values of P_{ext} the information-metabolic efficiency was maximized for a_{rec} between $0.1\,\text{nS}$ and $0.5\,\text{nS}$ (Fig. 5A-B), meaning that the strength of the

recurrent excitatory synapses was $2\times$ to $5\times$ lower that the strength of the synapses from the external population.

Moreover, varying P_{ext} had a significant effect on the information-metabolic efficiency across all values of a_{rec}. Namely, low values of P_{ext} resulted in lower values of information-metabolic efficiency across all values of a_{rec}, showing that shared input from the external population is beneficial for metabolically efficient information transmission. Overall, the highest values of information-metabolic efficiency ($E \geq 2\,\text{bit}/10^{12}\text{ATP}$) were reached for a_{rec} between $0.05\,\text{nS}$ and $0.5\,\text{nS}$ and P_{ext} between 20% and 100% (Fig. 5B).

We analyzed the effect of the resting cost (Fig. 3A-C) by setting the resting cost in all cases equal to W_0, the resting cost of the feedforward network. This did not have a significant effect on the information-metabolic efficiencies (Fig. S3).

Neural circuits might not necessarily maximize the ratio of information to cost. Instead, neurons and neural circuits could modulate their properties to maximize information transmission with the available energy resources [5]. For example, neurons in the mouse visual cortex have been shown to decrease the conductance of their synaptic channels after food restriction [34].

Accordingly, we studied how the optimal strength of recurrent synapses changes with the available resources. We calculated the optimal value of a_{rec} for different values of available resources (3, 4, 5, 6, 7, 8, 10, 12, 15, 20, 30, and 40×10^{12} ATP). In Fig. 5C-H, we plotted $C(W; a_{\text{rec}})$, the capacity-cost function (Eq. 27) extended by one dimension with a_{rec}. For each cost W, the optimal a_{rec} is highlighted, and the corresponding contour of $C(W)$ is shown (see Tab. 2 for the values of $C(W)$). With decreasing W, the optimal value of a_{rec} typically decreases. This effect is more robust with high values of P_{ext}, because the contours are more curved at the optimum.

We calculated the extended capacity-cost functions using input distributions obtained from the low-noise approximation. To verify that the low noise approximation applies in the case of the studied system, we compared these results to the information-metabolic efficiency obtained with the Jimbo-Kunisawa algorithm. The relative difference did not exceed 10% and did not have a significant impact on the information-metabolic efficiency heatmap structure (Fig. S4).

Figure 5: **Information transmission with cost constraints.** *Caption continued on the next page.*

Figure 5: *Caption continued from the previous page.* **A:** Information-metabolic efficiency E (Eq. 28) for different values of recurrence strength a_{rec}. P_{ext} is color-coded. **B:** Contour plot of the information-metabolic efficiency. Contours are at 0.6, 0.8, 1, 1.2, 1.4, 1.6, 1.8, and 2 bits/s. **C-H:** Contour plots showing the capacity-cost function $C(W)$ (Eq. 27) with dependence on the recurrence strength a_{rec} for different values of P_{ext}. The contours show the maximal capacities constraint at different values of W (see Tab. 2 for the costs and capacity values at the contours). The heatmaps in **B-H** were calculated using piece-wise cubic 2D interpolation (SciPy interpolator CloughTocher2DInterpolator [33]) from the grid calculated with P_{ext} values 1%, 2%, 3%, 5%, 10%, 20%, 50%, 80%, 100% and a_{rec} values 0, 0.01, 0.02, 0.03, 0.05, 0.1, 0.2, 0.3, 0.5, and 1 nS.

4. Discussion

Populations in the cortex that transmit information by their summed (or averaged) activity can be considered as a low noise information channel, due to the decrease in trial-to-trial variability [30]. The decrease in the trial-to-trial variability of the response will be lower in the presence of positive noise correlations [16]. Positive noise correlations can be reduced by inhibitory feedback, which, however, increases the cost of the neural activity [10].

In our work, we studied the balance between increasing the transmitted information by decreasing the noise correlations and the associated increase in the cost of the activity. We showed that in a linear system, if the Fano factor of the population activity and the ratio $\frac{g}{w_0\text{FF}}$ (g is the gain of the system, or slope of the stimulus-response curve, w_0 is the slope of the stimulus-cost curve) remain constant, the cost-constrained capacity will remain constant as well.

We proceeded to calculate the stimulus-response relationship and the metabolic cost for a more biologically realistic neural system. In the studied

system, the population Fano factor could not be considered constant. Instead, correlations between neurons increased with the mean output of the system, and the mean Fano factor of single neurons was also dependent on the mean output of the system, leading to complex dependence of the population Fano factor on the mean output of the system (Fig. 2D-F). We showed that reducing the noise correlations by strengthening the inhibitory feedback decreases the population Fano factor for large values of P_{ext} but may increase the population Fano factor for low values of P_{ext} due to an increase of the mean single neuron Fano factor FF_0.

We illustrated the effect of inhibition-dominated recurrence and shared input on the metabolic cost of neural activity. An increased strength of recurrence increased the cost of excitatory synaptic currents due to the stronger excitatory synapses and stronger input from the external population, as well as the cost of the activity of the external population. A higher connection probability from the external population (higher shared input probability) led to a decrease in the external population activity cost, as the overall activity of the external population could be lower to result in the same mean input to the post-synaptic neurons. On the other hand, due to less variable input to single neurons with high values of P_{ext}, a higher mean input was required across all neurons to evoke the same mean post-synaptic activity.

We found that high values of P_{ext} were beneficial for metabolically efficient information transmission, despite the increased noise correlations. For high values of P_{ext}, increasing the recurrence strength was also beneficial, suggesting that the two mechanisms - decreasing input cost by high connection probability from the external population P_{ext} and decreasing noise correlations by recurrent activity may act together to produce a metabolically efficient code.

Increasing the recurrence strength can lead to a 10% to 15% increase in the information-metabolic efficiency. The magnitude of the increase is dependent on the cost of the action potentials. If the cost of synaptic currents is negligible compared to the cost of the action potentials, there would be a higher benefit in increasing the inhibitory feedback since the increases in the cost of the synaptic current could also be neglected.

Although neurons in the cortex also connect to neighboring areas of the cortex and not only within the studied subpopulation, we did not consider the cost of synaptic currents evoked in neurons not involved in our simulation. We assume that such synaptic currents would be part of the background activity of a different area. Therefore, if we included these costs and considered

multiple cortical areas, we would have included the background activity cost multiple times.

In our model of the cortical area, we considered two neural subpopulations: excitatory and inhibitory. Each subpopulation was homogeneous, but we set the threshold of the inhibitory neurons lower to mimic the behavior of fast-spiking inhibitory neurons. The difference between excitatory, regular spiking neurons and inhibitory, fast-spiking neurons is often described not only by differences in the threshold but also in differences in the adaptation properties [35, 36, 37]. In our case, we did not consider adaptation for simplicity because estimating the information capacity of a neural system with adaptation is computationally considerably more difficult [10].

In our work, we assumed that the neural circuit maximizes the mutual information between the input and the output neurons while minimizing the cost of the neural activity. Such an approach does not provide any information about how the information is encoded. It only calculates the limit on the amount of information that can be reliably transmitted. Yet, the principles of mutual information maximization have proven very useful in explaining the properties of neural systems. For example, the tuning curves of blowfly's contrast-sensitive neurons are adapted to the distribution of contrasts encountered in the natural environment [38]; the power spectrum of distribution of odor in pheromone plumes follows the power spectrum predicted for an optimal input to olfactory receptor neurons [39]; distributions of post-synaptic firing rates of single neurons during *in-vivo* recordings follow distributions predicted from cost-constrained mutual information maximization [40, 41, 42].

By assuming a particular coding scheme, it is possible to place further constraints on the complexity of information encoding, with the assumption that complex codes are not an efficient way to transmit information [43, 44]. We did not attempt this in our study. However, it would be interesting to study whether inhibitory feedback decreases or increases the encoding complexity.

We have shown that a cortical area can adapt to the amount of available energy resources. When resources are scarce, information transmission can be adapted by weakening the synaptic weights, thus expending fewer resources to reduce the noise correlations. Such a mechanism is implemented in the mouse visual cortex [34]. (author?) showed that in food-restricted mice, the orientation tuning curves of individual orientation-sensitive neurons in the visual cortex become broader due to weakened synaptic conductances.

In our work, we studied the properties of a neuronal population instead of single neurons. In particular, we considered a population encoding the stimulus intensity instead of the stimulus identity, such as orientation. An extension this model to a situation in which stimulus identity is encoded and shared input is introduced due to the overlap of receptive fields would be interesting.

Neurons recorded *in-vivo* typically exhibit a Fano factor close to 1.0 and constant over a broad range of post-synaptic firing rates [45, 46, 18]. In the optimal regimes with stronger recurrent synapses, the Fano factor decreased only very slowly over the studied range of post-synaptic firing rates (up to 30 Hz in a single neuron). With weaker synaptic strengths, the Fano factor of a single neuron decreases rapidly with an increasing post-synaptic firing rate. Our model predicts that fewer available resources would lead to weaker recurrent synapses. This hypothesis is straightforward to test by calculating the Fano factors during stimulus presentation (both population and single neuron) in food-restricted animals and comparing them to controls. We expect that the population Fano factor will increase (alternatively, the noise correlations will increase) with food scarcity, and single neuron Fano factors will decrease.

Figure S1: **Input-output relationship of single neurons.** To exclude the network effects, we plotted the tuning curves for the feedforward network separately for the excitatory (blue) and inhibitory (yellow) neurons. The thick line represents the median response across the neurons, which shows that their tuning curves are convex in the studied range. The shaded area shows the spread of the tuning curves across neurons (2.5 to 97.5 percentile). With low values of P_{ext}, the tuning curves across neurons vary significantly and are skewed to the higher firing rates.

Figure S2: **Fixing the number of external connections to each neuron.** Same as Fig. 4, but exactly $k_{\text{ext}} \frac{P_{\text{ext}}}{100\%}$ external neurons connected to each excitatory and inhibitory neuron. This removed a large part of the dependence on P_{ext} seen in Fig. 4.

Figure S3: **Effect of equalizing the resting cost on the information-metabolic efficiency.** We observed that the cost of the resting state was different for different recurrence strengths a_{rec} (Fig. 3A-C). This could potentially explain the higher information-metabolic efficiency E (Eq. 28) for intermediate values of a_{rec} and its decrease for high values of a_{rec}. To quantify the effect of the resting cost, we set the resting cost in each case to the resting cost of the feedforward network $W_0(a_{\mathrm{rec}} = 0)$. The differences in the cost of the resting state did not have a qualitative effect on the conclusions. **A:** The same contour plot as in Fig. 5B. **B:** Contour plot with equalized resting costs (contours as in Fig. 5B: 0.6, 0.8, 1, 1.2, 1.4, 1.6, 1.8 and 2 bits/s). **C:** Heatmap of the relative differences.

Figure S4: **Accuracy of information-metabolic efficiency approximation.** To calculate the capacity-cost functions, we calculated the mutual information using Eq. (22) with the input probability distribution calculated from Eqs. (30) and (32). Here we compare the information-metabolic efficiencies calculated with the approximation and the Jimbo-Kunisawa algorithm. **A:** The same contour plot as in Fig. 5B with information-metabolic efficiencies calculated with the Jimbo-Kunisawa algorithm. **B:** Information-metabolic efficiencies calculated with the Fisher-information-based input distribution. **C:** Heatmap of the relative differences. Note that the approximation can only reach values lower than the actual information-metabolic efficiency.
