Abstract   We developed a 96-well plate assay which allows fast, reproducible and high-throughput generation of 3D cardiac rings around a deformable optically transparent hydrogel (PEG) pillar of known stiffness. Human induced pluripotent stem cell-derived cardiomyocytes, mixed with normal human adult dermal fibroblasts in an optimized 3:1 ratio, self-organized to form ring-shaped cardiac constructs. Immunostaining showed that the fibroblasts form a basal layer in contact with the glass, stabilizing the muscular fiber above. Tissues started contracting around the pillar at D1 and their fractional shortening increased until D7, reaching a plateau at 25±1%, that was maintained up to 14 days. The average stress, calculated from the compaction of the central pillar during contractions, was 1.4±0.4 mN/mm2. The cardiac constructs recapitulated expected inotropic responses to calcium and various drugs (isoproterenol, verapamil) as well as the arrhythmogenic effects of dofetilide. This versatile high-throughput assay allows multiple in situ mechanical and structural read-outs.

Introduction

Cardiac tissue engineering (CTE) aims to generate *in vitro* cell constructs that recapitulate the intricate structural and functional properties of the native myocardium (*van der Velden et al., 2022*). As the heart lacks regenerative capacities, CTE emerged in the field of regenerative medicine with the objective of producing cardiac grafts that can be implanted in patients with heart failure (*Madonna et al., 2019*; *Jabbour et al., 2021*; *Eschenhagen et al., 2022*). In parallel, the rapid development of biomaterials and microfabrication techniques, combined with progress in pluripotent stem cell biology have enabled the generation of miniature engineered heart tissues (EHTs) used as "hearts-on-chips" or cardiac organoids models. While these EHTs recapitulate a limited number of functions *in vitro*, they have provided essential platforms for cardiac disease modeling (*Filippo Buono et al.* (*2020*); *Cashman et al.* (*2016*); *Williams et al.* (*2021*); *Stillitano et al.* (*2016*); *Bliley et al.* (*2021*); *Goldfracht et al.* (*2019*); *Richards et al.* (*2020*)) and drug development (*Beauchamp et al.* (*2015*); *Polonchuk et al.* (*2017*); *Zhao et al.* (*2019*); *Mannhardt et al.* (*2020*)), reducing the need for animal studies.

Different combinations of cells, biomaterials, and scaffolds have successfully generated 3D EHTs (*Seguret et al.* (*2021*); *Zhuang et al.* (*2022*)) with various geometries including spheroids

41 (*Beauchamp et al.* (*2015*); *Polonchuk et al.* (*2017*); *Giacomelli et al.* (*2020*); *Richards et al.* (*2020*);
42 *Hofbauer et al.* (*2021*); *Lewis-Israeli et al.* (*2021*)), cardiac strips (*Hansen et al.* (*2010*); *Legant et al.*
43 (*2009*); *Turnbull et al.* (*2014*); *Mannhardt et al.* (*2016*); *Nunes et al.* (*2013*); *Zhao et al.* (*2019*)),
44 circular bundles (*Goldfracht et al.* (*2020*); *Tiburcy et al.* (*2017*); *Li et al.* (*2020*)), myocardium-like
45 sheets (*Shadrin et al.* (*2017*)) or ventricle-like chambers (*MacQueen et al.* (*2018*); *Li et al.* (*2018*);
46 *Lee et al.* (*2019*)). The EHTs are optimally formed by mixing human-induced pluripotent stem cells
47 (hiPSC)-derived cardiomyocytes, fibroblasts, and/or other cell types such as endothelial cells to
48 more closely mimic the structure and cellular complexity of native myocardium (*Giacomelli et al.*
49 (*2020*); *Saini et al.* (*2015*)). However, a major obstacle in the development of EHTs is the inevitable
50 trade-off between the need for miniaturization to increase throughput (i.e. several organoids in
51 each well of a 96- or 384-well plate) and the biological complexity of the tissues (*Cho et al.* (*2022*)).
52 The first EHTs were generated in small batches, using pre-designed molds, and having a millimet-
53 ric size (*Boudou et al.* (*2012*); *Turnbull et al.* (*2014*); *Legant et al.* (*2009*); *Mannhardt et al.* (*2016*)).
54 Since then, two different avenues of development have emerged. On the one hand, to optimize
55 throughput, more straightforward, low complexity assays such as spheroids were developed to
56 obtain smaller tissues (*Beauchamp et al., 2015*; *Polonchuk et al., 2017*). These multicellular con-
57 structs are valuable models to study drug responses and the human heart micro-environment but
58 they lack the geometric intricacy of a native cardiac tissue. On the other hand, the search for higher
59 tissue complexity and maturity led to the development of chambered organoids (*MacQueen et al.*
60 (*2018*); *Li et al.* (*2018*); *Lee et al.* (*2019*)). These constructs require the use of complex techniques
61 such as bioprinting or the use of bioreactors, and tissues are generated one at a time, making these
62 approaches time-consuming and impractical on a large scale. Therefore, the next step in tissue en-
63 gineering needs to be directed towards high-throughput physiologically-relevant assays that are
64 simple and straightforward for the end-user. Scaling down the tissue size to increase throughput,
65 while controlling their geometry represents a major engineering challenge. Moreover in actual de-
66 signs, many EHTs are attached on static posts that can impact tissue formation, result in isometric
67 contraction and can interfere with optical acquisitions when made with opaque material.

68   Here, we report the development of a novel assay which allows fast, reproducible and high-
69 throughput generation of 3D cardiac rings in a 96-well plate using hiPSC-derived cardiomyocytes.
70 The design allows the formation of multiple ring-shaped cardiac tissues in a well. The EHTs form
71 around a central pillar made from an optically-transparent and deformable polymer that enables
72 *in situ* monitoring of the tissue contraction with simultaneous measurements of force generation.

Results

Design and characterization of the molds

75 3D steel molds were designed to obtain a structure on which cells can be directed to ring-shaped
76 cavities during sedimentation (Figure 1A). The mold fits in the well of a 96-well plate, and consists
77 of 21 identical conical structures with a central hole (Figure 1A left). The molds obtained from
78 the manufacturer were imaged by scanning electron microscopy and found to correspond to the
79 intended design (Figure 1A, right). Casts of the mold were created in PEG to check the shape of the
80 inner cavities of the mold, but the resulting structures were too soft to maintain their shape in air,
81 and were transparent in water and therefore could not be imaged. More rigid polydimethylsiloxane
82 (PDMS) was cast from the mold to verify the shape of the resulting structures (Figure 1B). These
83 showed that the interior profile of the cavity was shaped in a reversed hourglass, as expected.

Generation and characterization of the gels

85 3D gel structures were obtained by adding a drop of PEG gel solution on top of the molds, in-
86 verting these onto a glass coverslip, polymerizing the gel and attaching the resulting sample on a
87 96-well plate. To determine the stiffness of the gels, a sample of the aqueous PEG solution was
88 polymerized. A capillary was placed perpendicularly to the edge of the gel and negative pressure
89 was applied to the gel through the capillary. The deformation of the gel into the capillary was mea-
90 sured and used to determine the Young's modulus of the gel (Figure 1 supplement 1). The values
91 obtained (11.4± 0.5 kPa) are within the physiological range for human cardiac tissue (*Gershlak*

92 *et al.* (*2013*)).

Generation of ring-shaped cardiac tissues

94 The efficiency of the differentiation of iPSCs into cardiomyocytes was in average of 96.9 $\pm$ 0.8 % (Fig-
95 ure 1 Supplement 2).Cardiomyocytes derived from iPSCs (iPSC-CMs) with fibroblasts were seeded
96 on the gels. After centrifugation, the cells sedimented into the ring-shaped cavities (Figure 1D),
97 and compacted around the pillars to rapidly form ring-shaped cardiac constructs (Figure 1D-E).
98 Initial tests with cardiomyocytes resulted in cell cluster formation and malformation of the rings
99 (Figure 2A). To stabilize the tissues, iPSC-CMs were mixed with fibroblasts and different ratios of
100 hiPSC-CMs to fibroblasts were tested in order to obtain the highest number of full stable cardiac
101 rings with time. Three ratios of hiPSC-CMs:fibroblasts were tested (Figure 2B) based on previous
102 reports (*Tiburcy et al.* (*2017*); *Saini et al.* (*2015*); *Giacomelli et al.* (*2020*); *Beauchamp et al.* (*2020*)).
103 The 3:1 hiPSC-CMs:fibroblasts ratio was determined to be optimal and was used for all of the fol-
104 lowing experiments. Tissues started beating within 24 hours after seeding (Video 1). The rings
105 compacted in time as shown in Figure 1E. In these optimization experiments, we obtained an av-
106 erage of 10.75$\pm$0.48 tissues per well which were stable over time for at least 20 days with the 3:1
107 hiPSC-CMs:fibroblasts ratio.

Structure and organization of the engineered cardiac tissues

109 The 3D organization of the tissues was assessed by 3D immunofluorescence imaging 14 days after
110 seeding. The fibroblasts are concentrated at the base of the ring in contact with the glass (Figure 2C
111 – bottom panel), whereas the cardiomyocytes form a compact ring above the fibroblasts around
112 the central pillar (Figure 2C – top panel). Troponin T staining evidenced the formation of striated
113 elongated fibers (Figure 2D), which are typical of cardiac tissue. The obtained cardiac tissues are
114 75.5$\pm$1.8 μm high and their shape is toric, as shown in the 3D reconstruction (Figure 2E and video
115 1).

Contractility analysis

117 Tissues started contracting less than 24 hours after seeding, which was visible through the defor-
118 mation of their central pillar (Supplemental video 1). Each tissue was recorded in brightfield imag-
119 ing, at a 10X magnification with a high-speed camera (Supplemental video 1). An in-house Matlab
120 code was developed to quantify the contraction and relaxation phases of the tissues by monitor-
121 ing the area of the central pillar over time (Figure 3A). The beat rate of the tissues first decreased
122 between day 1 and day 3 and increased again to reach 0.58$\pm$0.030 Hz on day 14 (Figure 3B). The
123 contraction stress developed by the tissues increased from day 1 until day 7 (Figure 3C). At day 7,
124 the contractility parameters stabilized with an average stress of 1.4$\pm$0.1 mN/mm^2 (Figure 3C.). The
125 corresponding developed strain ϵ_A was of 24.84$\pm$0.92 % (Figure 3 supplement 1). Consistently, the
126 relaxation and contraction speeds also increased during the first 7 days, then reaching a plateau
127 (Figure 3D and E).

Physiological testing on the engineered cardiac tissues

129 The response in contractility of the cardiac rings to an increase in the extracellular calcium concen-
130 tration was assessed by sequential addition of calcium in the medium, starting from a concentra-
131 tion of 0.5 mM up to 3.5 mM (Figure 4A). The changes in the contraction stress and the contraction
132 and relaxation speeds with calcium concentration were significant (p<0.0001 for each parameter,
133 non significant for the beat rate). We observed a stabilization of the beat rate around 0.5Hz at
134 2mM and a positive inotropic response as the contraction amplitude increased by 600 % with a
135 corresponding EC_{50} of 1.346 mM with a confidence interval (CI) of [1.159;1.535] mM.

Pharmacological testing on the engineered cardiac tissues

137 We next evaluated the dose-response to increasing concentrations of several cardiotropic drugs.
138 The changes in the beating parameters with verapamil concentration were found to be signifi-
139 cant (p=0.0053 for the beat rate and p<0.0001 for the other parameters). The addition of ve-
140 rapamil, an L-type calcium channel inhibitor, induced a negative inotropic effect until the com-

Figure 3—figure supplement 1. Strain ϵ_A developed by the rings at D14.

Figure 3—video 1. Contractility of a ring at day 14.

141 plete stop of contraction at 10µM, as expected (Figure 4B). The IC_{50} was estimated to be 0.677 µM,
142 CI=[4.278;12.81].10^7 M. The dose-response to the β-adrenergic receptor agonist, isoproterenol was
143 tested. We observed a trend towards increase of the contraction amplitude, as well as a significant
144 increase in the contraction and relaxation speeds (Figure 4C), without change in the beat rate. The
145 changes in the contraction stress and the contraction and relaxation speeds with isoproterenol
146 concentration are significant (p=0.0004 for the contraction stress; p<0.0001 for the contraction
147 and relaxation speeds). Finally, dofetilide, which is an inhibitor of the I_{Kr} current, was also tested
148 at different concentrations on the cardiac rings. This drug has been shown to be pro-arrhythmic
149 and to induce arrhythmic events such as Torsades-de-Pointes in patients. The changes in the beat
150 rate, the contraction stress and the contraction and relaxation speeds with dofetilide concentration
151 were found to be significant (p<0.0001 for all the parameters). As shown in Figure 4D, dofetilide
152 significantly reduced the contraction stress and speeds until the complete stop of the contraction
153 of the cardiac tissues for a concentration of 10 nM. Arrhythmic events were noted after adding
154 dofetilide at concentrations of 3 and 7 nM. Indeed, the Poincaré diagram for the different dofetilide
155 concentrations (Figure 4E) shows an increase in the contraction-to-contraction intervals (equivalent
156 to RR intervals) for some cells at 1 nM of dofetilide and an increasing number of erratic beats with
157 increasing dofetilide concentrations.

Discussion

159 The combination of pluripotent stem cells technologies, advanced cardiomyocyte differentiation
160 protocols and microfabrication methods have already resulted in the generation of engineered hu-
161 man cardiac muscle tissue-constructs, with different shapes and that can reproduce some cardiac
162 functions (*Seguret et al.* (*2021*); *Cho et al.* (*2022*)). However, until now, approaching the complex
163 geometry and structure of the human myocardium required complex techniques, which limits the
164 number of tissues produced, thus hampering their application for high-throughput experiments.
165 In this study, we aimed to address this challenge by developing a novel strategy to create ring-
166 shaped miniature cardiac tissues around a central pillar that is made from an optically-transparent
167 and deformable polymer. Our main findings are as follows : (1) this novel strategy enables the
168 fast and reproducible formation of an important number of cardiac tissues (up to 21 per well in
169 a 96-well format) with a limited number of hiPSC-cardiomyocytes (112,500 per well); (2) In this
170 assay, fibroblasts are essential to generate and maintain the tissue structure, with a 3:1 hiPSC-
171 CMs:fibroblast ratio providing with the best yield of tissue generation; (3) The self-organized ring-
172 shaped cardiac tissues contract and deform the optically-transparent central pillar, which can be
173 recorded and analyzed to estimate the contractile force developed by the tissue; (4) these EHTs
174 display concordant responses to positive or negative inotropes, and to arrhythmogenic drugs, as
175 required for drug testing applications.
176 The miniaturized cardiac constructs develop by self-organization of the hiPSC-derived cardiomy-
177 ocytes and fibroblasts, which are guided by a specific design to acquire a ring shape. The resulting
178 EHTs are in a convenient 96-well plate format and easy to use for a user familiar with cell biology
179 techniques. The 96-well plate format is adaptable to many plate readers and automated platforms.
180 In addition, the optical clarity of the gels and the absence of gel directly under the structures en-
181 sures optimal imaging conditions. We showed that the tissues can be fixed, stained by immunoflu-
182 orescence and imaged in situ at high resolution. Moreover, our EHTs would also be compatible
183 with live cell imaging experiments with fluorescent reporters, such as calcium transients studies
184 or conduction studies by optical mapping. While imaging the fluorescent reporter, the contraction
185 parameters could be monitored through the deformation of the pillar. The possibility to simul-
186 taneously record two parameters represents a significant asset. The current design of our EHTs
187 consists of up to 21 rings in a single well, thus providing many replicates within a single experi-
188 ment, even if some of the rings fail to form due to biological variability. This high throughput can
189 compensate for potential intra-batch effects. Moreover, the possibility to seed several wells at the
190 same time allows to easily study several differentiations, compensating for the variability which is
191 inherent to the differentiation of hiPSCs. The predictable circular shape of the tissues makes them
192 easy to recognize and track using software. Coupled with the known organization of the 21 rings
**Figure 4.** Physiological and drug testing on the cardiac tissues. Effect of the concentration in extracellular calcium (**A.**), verapamil (**B.**), isoproterenol (**C.**) or dofetilide (**D.**) on tissues contractility: beat rate, contraction stress and the maximum contraction and relaxation speeds. These parameters are expressed as a ratio between their value for each concentration and the value at basal state ($[Ca^{2+}]=0.5$ mM for calcium test and $[Drug]=0$M for drug testing). An ANOVA for repeated measures was carried out for each parameter. For each test, the value of each parameter at each concentration is compared to its value at the minimal concentration of the drug (respectively $[Ca2+]=0.5$mM, $[Verapamil]=10^{-9}$ M, $[Isoproterenol]=10^{-9}$ M and $[Dofetilide]=10^{-9}$ M). **E.** Poincaré plot for 0 nM, 1 nM, 3 nM and 7 nM of dofetilide. For each concentration of each drug, more than 20 tissues from 3 different concentrations could be analyzed. Data is presented as mean $\pm$ SEM. *: $p<0.05$; **: $p<0.01$; ***: $p<0.001$; ****: $p<0.0001$.

193 for easy automated imaging, a single well can quickly generate data on many tissues that is quickly
194 and automatically analyzed. The EHTs we described here are thus easy to use, image, manipulate
195 and obtain readouts from.

196 We found that the circular geometry of these self-organized cardiac tissues induces a homo-
197 geneous distribution of the cardiomyocytes and consequently of the contraction forces around
198 the pillar and in the tissue. Importantly, the presence of the central pillar not only allows resis-
199 tance to be felt by the tissue, but the control of its stiffness facilitates the calculation of the force
200 developed by the tissue. Our results showed that the tissues develop a fractional shortening (or
201 contraction strain) of about 25%, which is close to the contraction of a human heart (*Cheng et al.*
202 (*2010*)). The corresponding stress was 1.4 mN/mm^2 which is in a similar range to other previously
203 reported tissue-engineered cardiac muscle models with hiPSC-CMs in the literature (*Seguret et al.*
204 (*2021*); *Turnbull et al.* (*2014*); *Shadrin et al.* (*2017*); *Zhao et al.* (*2019*); *Ronaldson-Bouchard et al.*
205 (*2018*); *Goldfracht et al.* (*2020*); *Li et al.* (*2020*)). Some studies have reported higher force values
206 (*Ronaldson-Bouchard et al.* (*2018*)) but in tissues that have a much large size than the tissues pro-
207 posed here. The force generated by the adult human heart muscle, around 44 mM/mm^2 for a tissue
208 strip (*Hasenfuss et al.* (*1991*)), however remains significantly higher than the force developed by
209 the currently available platforms. Few cardiac assays can precisely monitor the force exerted by the
210 tissues. Indeed, cardiac cells seeded on micropillars (*Rodriguez et al.* (*2014*)) and gels containing
211 tracking beads (*Dou et al.* (*2021*); *Feyen et al.* (*2020*)) can provide information on local (subcellular)
212 force exertion. The force measurements do not result from the concerted effort of an organized
213 tissue composed of aligned cardiomyocytes, as proposed by ring-shaped tissues. Tissues attached
214 on two posts (*Turnbull et al.* (*2014*); *Mannhardt et al.* (*2016*); *Abilez et al.* (*2018*)) can also provide
215 some information on the force generated by a tissue but the force exertion is not radial as it is in
216 the native heart and the presence of the posts can impact the contraction by affecting the force
217 distribution in the tissue and creating potential edge effects in the vicinity of the posts, inducing the
218 formation of v-necks (*Abilez et al.* (*2018*)). Lastly, some other ring-shaped cardiac constructs have
219 to be transferred on posts or on a force transducer to measure their contraction force (*Goldfracht*
220 *et al.* (*2020*); *Tiburcy et al.* (*2017*)). Therefore, the easy *in situ* monitoring of the force generated by
221 our ring-shaped tissues with an image analysis routine represents a significant advantage, as less
222 manipulation improves the degree of standardization. Finally, the stiffness of the central pillar can
223 easily be adapted to model a pathological increase or decrease of the extracellular matrix stiffness.

224 The EHTs we developed are composed of cardiomyocytes that rely on fibroblasts for their as-
225 sembly and inter-cellular adhesion. Fibroblasts have been shown to play a prominent role in the
226 heart as they are crucial in the constitution of the supporting extracellular matrix and contribute to
227 cardiomyocyte electrical coupling, conduction system insulation, vascular maintenance, and stress-
228 sensing (*Ivey and Tallquist* (*2016*); *Baudino et al.* (*2006*)). Other studies have highlighted the im-
229 portance of a multi-cellular approach to generate EHTs (*Giacomelli et al.* (*2020*); *Saini et al.* (*2015*);
230 *Amano et al.* (*2016*); *Caspi et al.* (*2007*)). In our system, the fibroblasts additionally play a role
231 in providing a basement support under the cardiomyocytes, in contact with the glass support of
232 the EHTs. Immunofluorescence imaging showed an organization of the cardiomyocytes parallel
233 to each other, perpendicular to the direction of contraction, with an increased alignment of sar-
234 comeres. Our EHTs mimic the composition and organization of the native myocardial tissue, even
235 if only composed of cardiomyocytes and fibroblasts. Future experiments will determine whether
236 other, less abundant, cell types of the native myocardium, such as endothelial or smooth muscle
237 cells, can further improve heart tissue modeling.

238 The constructs showed a spontaneous beating in the day following seeding and this activity
239 was maintained over several weeks thus allowing contractile measurements and pharmacologi-
240 cal testing in the conditions of auto-pacing. As a proof-of-concept, we studied the effects of well-
241 established negative and positive inotropes and showed the ability of our platform to reproduce
242 the anticipated effects. We observed that our tissues presented a positive inotropic response to
243 increasing extracellular calcium concentration with a corresponding EC$_{50}$ which is in agreement
244 with the values reported in the literature for engineered heart tissues made of hiPSC-CM, which
245 are between 0.4 and 1.8mM for the EC$_{50}$ (*Feric and Radisic* (*2016*); *Schaaf et al.* (*2011*); *Streckfuss-*

246 *Bömeke et al.* (*2013*); *Mannhardt et al.* (*2016*); *Turnbull et al.* (*2014*); *Goldfracht et al.* (*2020*)). The
247 negative inotropic response to increasing concentrations of verapamil of our constructs was also
248 described in the literature and our IC_{50} value is also in the range of reported values in other EHTs:
249 Turnbull et al. *Turnbull et al.* (*2014*) found IC_{50}=0.61 μM and other papers range from 0.3 μM to
250 0.6 μM (*Mannhardt et al.* (*2016*); *Thavandiran* (*2019*)). The β-adrenergic stimulation of the tissues
251 with increasing concentrations of isoproterenol-induced a trend towards increase in the contrac-
252 tion force and significantly increased contraction and relaxation speeds without change in the beat
253 rate. This is in line with what has been shown by *Goldfracht et al.* (*2020*) and *Zhao et al.* (*2019*).
254 Last, applying increasing dofetilide concentrations on our constructs showed a decrease in the
255 contraction amplitude and contraction and relaxation speeds. This is in line with the literature as
256 Zhao et al. *Zhao et al.* (*2019*) depicted a significant reduction of the action potential amplitude of
257 the tissues above a concentration of dofetilide of 10 nM. By assessing the beating regularity by
258 plotting each period as a function of the previous one, we highlighted an increasing number of
259 erratic beats with the increase in dofetilide concentration. Other papers have also underlined the
260 pro-arrhythmic effect of dofetilide on cardiomyocytes derived from iPSCs (*Goldfracht et al.* (*2019*);
261 *Patel et al.* (*2019*); *Altrocchi et al.* (*2020*); *Blinova et al.* (*2017*)). Therefore, we demonstrated that
262 our platform recapitulated the expected cardiac responses to several inotropes and arrhythmo-
263 genic drugs.

264 While representing a significant improvement, our platform presents some limitations. First,
265 the size of the rings is very small compared to native tissue (400 μm). This size limitation is neces-
266 sary for the purposes of high throughput screening, but for applications requiring larger tissues,
267 wider rings can be considered in the future. Second, all measurements were performed under
268 spontaneous pacing as a specific technique should be developed to allow external pacing of the
269 tissues in the 96-well format. This includes electrical field stimulation or an optogenetics system
270 with light stimulation. The precise and regular organization of the rings in the well makes this
271 design very amenable to the introduction of microelectrodes for pacing, which could also allow
272 the measurement of the action potentials of individual micro-tissues. Nevertheless, our main re-
273 sults show that pharmacological responses, including the detection of the pro-arrhythmogenic
274 effects of dofetilide, were correctly measured under spontaneous beating conditions. Third, the
275 miniaturized format of our platform creates some limitations and challenges regarding some ex-
276 periments, including tissue stretching. Therefore, the length-tension relationships (Franck-Starling
277 mechanism) were not determined in our tissues.

278 Overall the novel platform we describe here is a versatile, easy-to-use and high-throughput
279 tool to generate cardiac rings in a reproducible way and analyze them *in situ*. This platform will be
280 useful in several cardiac research fields, including disease modeling and pharmacological testing.

281 ## Methods and Materials

282 ### Mold design and characterization
283 Micromachined stainless steel molds were obtained from high resolution CNC machining accord-
284 ing to our CAD designs. The designs consisted of a mold that would be slightly smaller than the
285 footprint of a well of a 96-well plate, composed of 21 structures (see Figure 1A). To check the shape
286 of the interior cavities of the mold, a cast of the mold was created out of polydimethylsiloxane
287 (PDMS) (Sylgard 184, Samaro), according to manufacturer's instructions.

288 ### 3D hydrogel substrate preparation
289 A solution of 5% w/w photopolymerizable polyethylene glycol (PEG) was prepared in distilled water.
290 Circular coverslips (16 mm, Paul Marienfeld GmbH, Germany) were silanized to ensure adequate
291 bonding between the PEG and glass. A drop of 10-15 μL of gel was placed on the stainless steel
292 mold, which was then placed in contact with a silanized coverslip. The gel solution was briefly
293 exposed to light of the appropriate wavelength to polymerize the hydrogel. The resulting 3D struc-
294 tured hydrogel, bound to the coverslip, was unmolded and immediately placed in distilled water.
295 The hydrogel was rinsed at least three times with distilled water and incubated in water overnight.
296 For cell experiments, the coverslip coated in a 3D hydrogel was briefly dried and attached to a

297 commercial black polystyrene 96-well plate with an adhesive backing (Grace Bio-labs, USA). The
298 resulting well was filled with distilled water. Prior cell seeding, the plate was sterilized by UV irradi-
299 ation for at least 20 minutes.

Young's modulus measurements of the molds

301 The PEG-based hydrogel solutions were prepared and 100μL of solution was deposited into a ring-
302 shaped mold with an inner diameter of 1cm positioned on a 16mm glass coverslip. The solution
303 was polymerized using 365nm UV light for 1 minute at a power of 70 mW/cm^2, after which the
304 mold was removed. The coverslip containing the gel was then transferred to the microscope (Leica
305 camera AG, Germany). A hollow glass capillary with an inner diameter 0.75mm (World Precision
306 Instruments, USA) was attached to a platform movable in the xy-plane which was used to position
307 the capillary right next to the edge of the circular polymerized hydrogel. Once the capillary and the
308 hydrogel made contact, a negative pressure was applied, using the Cobalt autonomous pressure
309 pump (Elvesys, France), creating a small convexity in the surface of the hydrogel. Images of this
310 convexity were taken (5X magnification) for a pressure ranging from -100mbar to -200mbar, with
311 10 mbar increments (Figure 1A.). Two measurements were done on two separate gels, resulting in
312 4 measurements per gel with 10 datapoints each. The images (and thus the size of the convexities)
313 were analyzed using ImageJ (version 1.53c). The Young's modulus was calculated with the formula
314 $E = \frac{P}{0.872\frac{l}{a}+0.748(\frac{l}{a})^2}$ according to literature (*Gandin et al.* (*2021*)).

Cardiomyocyte differentiation and culture

316 The SKiPSC-31.3 hiPSC cell line, from a healthy control subject, has been used here and was previ-
317 ously reported (*Galende et al.* (*2010*)). Induced pluripotent stem cells were seeded on Matrigel and
318 cultivated in mTESR Plus medium (Stemcell Technologies). At 80 % confluency, cells were passaged
319 with ReleSR reagent (StemCell Technologies). When hiPSCs reached a 90 % confluency, differenti-
320 ation was carried out according to a protocol adapted from *Garg et al.* (*2018*). Briefly, on day 0
321 of differentiation, mTESR Plus was changed to RPMI-1640 (Life Technologies) supplemented with
322 B27 without insulin (RPMI-B27 minus insulin) and 6 μM CHIR-99021 (Abcam). After 48 hours, the
323 medium was changed to RPMI-B27 minus insulin and then to RPMI-B27 minus insulin with 5μM
324 IWR-1 (Sigma) for 48 hours. On day 5, the medium was replaced by RPMI-B27 minus insulin, and
325 switched to RPMI-B27 with insulin on day 7. At day 11 a glucose starvation was carried out by
326 replacing the medium with RPMI 1640 without glucose (Life Technologies), supplemented by B27
327 with insulin for 3 days. Cells were then dissociated with 0.05% trypsin (Life Technologies) and re-
328 plated in a 12-well plate at a density of 0.3 10^6 cells/cm^2 in RPMI-B27 with insulin. The following day,
329 the medium was switched back to RPMI 1640 without glucose (Life Technologies), supplemented
330 by B27 with insulin for 3 days again. These two rounds of glucose starvation have been shown to
331 increase dramatically the percentage of cardiomyocytes obtained *Sharma et al.* (*2015*). After day
332 18, the cells were cultured in RPMI-B27 with insulin and the medium was changed every two days.

Cardiomyocyte characterization

334 The efficiency of the differentiation was assessed by cardiac troponin T flow cytometry at D21.
335 On day 21 of differentiation, hiPSC-CMs were dissociated by enzymatic digestion (Miltenyi Multi
336 Tissue dissociation kit 3) and stained with the Zombie NIR™ Fixable Viability Kit (BioLegend). Then,
337 collected cell pellets were fixed and permeabilized using Inside Stain kit (Miltenyi Biotech, 130-
338 090-477) at room temperature for 10 minutes. Cells were incubated with either APC anti-cardiac
339 troponin T (CTNT) antibody (Miltenyi Biotech; 130-106-689 1:100) or APC isotype control (Miltenyi
340 Biotech, 130-104-615 1:100) for 10 min at room temperature. Cells were analyzed using the BD
341 Biosciences FACS LSR Fortessa X-20 instrument with at least 30,000 cells. Results were processed
342 using FlowJo v10 (FlowJo, LLC).

Human fibroblasts culture

344 Commercially available normal adult human dermal fibroblasts (NHDF-Ad Lonza CC-2511, Lot 545147)
345 were used up to passage 6 to generate the tissues. They were cultured in T75 flasks, in DMEM high
346 glucose, supplemented with 10% FBS, 1% NEAA and 1% penicillin-streptomycin.

Tissues generation and culture

The wells of the assay were first rinsed twice with PBS and incubated at 37°C in DMEM high glucose, 2.3 mM CaCl2, 10%FBS, 0.1% penicillin-streptomycin. To generate the tissues, cardiomyocytes were dissociated by enzymatic digestion (Miltenyi Multi Tissue dissociation kit 3) on day 22 after differentiation. Fibroblasts were dissociated with TrypLE Express Enzyme (12605010 Thermofischer). Three ratios of hiPSC-CMs:fibroblasts were tested: 4:1, 3:1 and 2:1. For the following experiments the tissues are generated with a ratio of 3:1 hiPSC-CMs:fibroblasts as this ratio allowed the best preservation of tissues in time. A total of 150k cells were seeded in each well. The required numbers of fibroblasts and cardiomyocytes were then mixed and resuspended in 200µL per well of DMEM high glucose, 2.3 mM CaCl2, 10%FBS, 0.1% penicillin-streptomycin. The plate was then incubated at 37°C for 5 minutes and centrifuged 3 times in "short" mode to ensure that the cells fall into the circular molds. The plate was then kept at 37°C and the medium was changed every two days.

Tissues recording and analysis

The cardiac rings were recorded for 10 seconds in brightfield imaging with a high speed CCD camera (PL-D672MU, Pixelink) mounted on a microscope (Primovert, Zeiss), at a 10X magnification. The videos were then analyzed with a custom Matlab script. Briefly, the area of the central pillar is monitored in time and allows to recover the contraction amplitude in time Amplitude(t)= Max(Area)-Area(t) and therefore the contraction strain in time (in terms of area) ϵ_A calculated as $\epsilon_A(t) = (Max(Area) - Area(t))/Max(Area)$ as well as the derivative of this strain in time. $\epsilon_A(t)$ is linked to the linear strain ϵ with the formula $\epsilon = \frac{\Delta r}{r_{max}} = \frac{\epsilon_A}{1+\sqrt{1-\epsilon_A}}$. As we measured the Young's Modulus of the gel, we can recover the stress developed by the cardiac rings $\sigma = E.\epsilon(t)$. From these traces we also derive the contraction frequency by Fourier transform. It was considered that below a contraction of 0.5 %, the signal to noise ratio was not sufficient enough to detect the contraction of the tissue and the beating frequency was therefore set to 0 Hz. Finally, the maximum contraction and relaxation speeds of the tissue were also calculated respectively from the maxima and minima of the derivative of this strain in time.

Response to increasing extracellular calcium concentration and drug tests

Tissues response to different drugs and increasing calcium concentrations was assessed after day 14. For the increasing extracellular calcium concentrations, tissues were first changed to Tyrode solution 0.5 mM in calcium (NaCl 140 mM, KCl 5 mM, 10 mM Hepes, Glucose 10 mM, MgCl$_2$ 1 mM, CaCl$_2$ 0.5 mM, pH 7.4) and let to equilibrate for 30 minutes at 37°C, 5 % CO2. Calcium concentration was then increased by sequential addition of a Tyrode solution at 10mM in calcium. After each addition, the tissues were incubated for 5 minutes before recording. For drug tests, tissues were changed to Tyrode solution at 1.8mM in calcium (NaCl 14 mM, KCl 5 mM, 10 mM Hepes, Glucose 10 mM, MgCl$_2$ 1 mM, CaCl$_2$ 1.8 mM, pH 7.4) and let to equilibrate for 30 minutes at 37°C, 5% CO2. To evaluate the dose-response of the cardiac rings to the different drugs (Verapamil- sigma v0100000, isoproterenol - sigma 1351005, dofetilide - sigma PZ0016), the contractility was first recorded for 30 seconds in basal state and the drug was then added sequentially. Between each addition of drug, the tissues were incubated for 5 minutes at 37°C before being recorded for 30 seconds.

Immunofluorescence staining and confocal microscopy

Tissues were fixed at day 15 with 4% paraformaldehyde for 15 minutes and rinsed 3 times in PBS for 5 minutes. They were then blocked and permeabilized with blocking solution(BSA 2%, Triton 0.5%) at 4°C overnight. Primary antibodies Vimentin diluted at 1:250 (MA5-11883, ThermoFischer Scientific) and Troponin T diluted at 1:500 (ab45932, Abcam) were added the next day and incubated at 4°C overnight. Tissues were rinsed 3 times in PBS for 5 minutes and secondary antibodies (Alexa Fluor secondary antibodies, LifeTechnologies, at 1:1000) and DAPI diluted at 1:1000 were added and incubated at 4°C overnight. Immunostaining pictures were taken with a Leica SP8 confocal system.

Statistical analysis

All numerical results are expressed as mean $\pm$ standard error mean (SEM) of three independent experiments. Differences between experimental groups were analyzed with the appropriate statistical tests, specified each time. P values < 0.05 were considered significant for all statistical tests. Statistical analyses were performed with GraphPad Prism software.

A.

1 UV-Curing the PEG-based hydrogel and removing the ring-shaped mold.

2 Positioning the hollow glass capillary to be in contact with the cured hydrogel.

3 Applying a pressure p to the hollow glass capillary, creating a convexity of the surface of the hydrogel.

4
$$E = \frac{p}{0.872\frac{l}{a} + 0.748(\frac{l}{a})^2}$$

Imaging and analyzing using Image J. Calculation of the Young's Modulus E.

574

B.

PEG gels measurements
Figure 1—figure supplement 1. A. Procedure to measure the Young's Modulus of a PEG-gel disk by pipette aspiration. **B.** Young's modulus of 5% PEG gels (n=44).

Quantification of differentiation efficiency

575
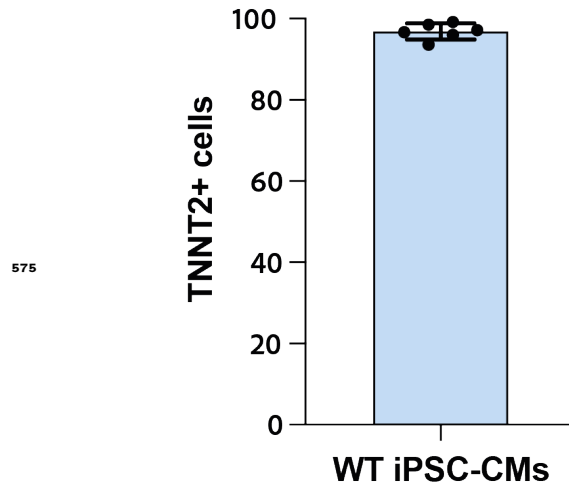

Figure 1—figure supplement 2. Percentage of positive cells for Troponin T2 (TNNT2) determined by flow cytometry in the 6 different differentiations of wild-type (WT) iPSCs, used for these experiments.

576
Figure 2—figure supplement 1. Larger scale confocal pictures of immunostained tissues at different heights basal layer(left) and cardiac ring (right) at 40X magnification: vimentin is stained in green, troponin in red, and DAPI in blue. Scale bars: 50 μm.

Contraction strain ε_A
**Figure 3—figure supplement 1.** Evolution of contraction strain ϵ_A through time after seeding at days 1, 3, 7, 10 and 14. Contraction strain changes through time are significant (p<0.0001 - ANOVA for repeated measures - D1: n=57, D3: n=59 D7: n=47, D10: n=43, D14: n=36 tissues, from 3 differentiations). Contraction strain for each concentration is compared to contraction strain at day 1 (****: p<0.0001).
