1   **ABSTRACT**
2   Efficient metabolic engineering and the development of mitochondrial therapeutics often rely upon
3   the specific and strong import of foreign proteins into mitochondria. Fusing a protein to a
4   mitochondria-bound signal peptide is a common method to localize proteins to mitochondria, but
5   this strategy is not universally effective with particular proteins empirically failing to localize. To
6   help overcome this barrier, this work develops a generalizable and open-source framework to
7   design proteins for mitochondrial import and quantify their specific localization. By using a
8   Python-based pipeline to quantitatively assess the colocalization of different proteins previously
9   used for precise genome editing in a high-throughput manner, we reveal signal peptide-protein
10   combinations that localize well in mitochondria and, more broadly, general trends about the overall
11   reliability of commonly used mitochondrial targeting signals.

14   image analysis, Python

INTRODUCTION

Synthetic biologists increasingly leverage natural mitochondrial protein import pathways for compartmentalized metabolic engineering[1,2] and the development of molecular therapeutics[3,4]. For metabolic engineering, sequestering enzymes within yeast mitochondria has resulted in a ~300-fold increase in production of high-value biosynthetic compounds[5,6]. In human health, emerging mitochondrial therapeutics address a major unmet need since mutations to mitochondrial DNA (mtDNA) are at the root of numerous incurable diseases that affect over 1 in 5000 individuals[7,8]. In search of cures, researchers are exploring both allotopic expression, where corrected mitochondrial genes are expressed from the nuclear genome and sent to the mitochondria[9], and gene editing, where mutated mtDNA is either depleted by nucleases or corrected by base editors[10–18].

All of these approaches require efficient targeting of proteins of interest (POIs) to the mitochondria. The most common strategy to achieve such localization is by fusing a mitochondrial targeting sequence (MTS), typically a short and positively charged signal peptide, to the N-terminus of the POI. MTSs are recognized by translocases on the outer and inner mitochondrial membrane (TOM/TIM23 complex) that unfold the POI, import it through both mitochondrial membranes, and release the protein into the mitochondrial matrix following cleavage of the N-terminus MTS from the POI[19,20]. Hundreds of putative MTSs have been identified from natural proteins using computational tools[21–24].

However, attachment of an individual MTS to a given POI does not always guarantee efficient import into mitochondria[25,3]. In fact, allotopic expression and gene editing approaches in mammalian mitochondria have been hindered by low or non-specific POI localization. For instance, only a small sub-selection of protein subunits typically encoded in mtDNA are able to be allotopically expressed in mammalian cells[26,27]. Moreover, even when proteins are imported to mammalian mitochondria, they can also accumulate in other organelles[28]. For mitochondrial gene editing, such imprecise localization poses danger; for example, the mitochondrial base editor DdCBE[16] has substantial off-target editing in nuclear DNA[29], highlighting the need for more specific import of genome editing-related proteins to mitochondria.

Previous studies in yeast suggest that length, hydrophobicity, charge, and folding of the MTS or POI can all affect the efficiency of mitochondrial import[30–32,19]. However, research in mammalian cells is much sparser and at present a given MTS-POI combination cannot be assumed to result in reliable mitochondrial import. Instead, researchers often empirically test multiple MTSs before finding one that results in their specific POI localizing in mitochondria[33,15].

To address a relative lack of broad experimental data and help establish a quantitative assessment of mitochondrial localization in mammalian cells, we developed a quantitative and high-throughput imaging-based pipeline to measure POI import into mitochondria. Using this platform, we screened combinations of three commonly used N-terminus MTSs and POIs from five protein families relevant to mitochondrial gene editing to reveal the most reliable MTS-POI combinations.

RESULTS

High-throughput Localization Workflow

To investigate the effect of MTS on mitochondrial import across different POIs, we generated 66 protein cassettes containing a combination of localization signal and POI, followed by a HA tag on the C-terminus (**Fig 1a**). Localization signals included three commonly used MTSs—COX8 (29 amino acid-long peptide derived from human cytochrome c oxidase subunit VIII)[34], Su9 (69 amino acid-long peptide derived from *Neurospora crassa* ATPase subunit 9)[35], and ATG4D (42 amino acid-long peptide derived from a Atg4 cysteine protease)[36]—that were previously used to probe the import of CRISPR nucleases into mammalian mitochondria[15]. The use of no localization signal or a nuclear localization signal (NLS) served as negative controls. Nineteen POIs were chosen across five different protein classes that have been used as components of precise gene editing technologies: Class I CRISPR systems (Cas3/CASCADE)[37], Class II CRISPR/Cas nucleases, RecTs, single-stranded binding proteins (SSBs), and retron reverse transcriptases (RTs). Both Class I and II CRISPR systems can cut DNA at programmable sites to induce editing using double-stranded break (DSB) repair pathways[38]. In contrast, RecTs and SSBs have been used to integrate donor DNA into bacterial and yeast genomes through recombineering[39–42]. Finally, retron RTs allow *in vivo* production of DNA donor editing templates in both prokaryotes and eukaryotes that mediate precise editing using either DSB repair pathways or recombineering[43–46]. As a positive control, we used the construct mito-APEX2, a protein that contains an MTS derived from the mitochondrially imported COX4 fused to APEX2, which has been shown to localize to the mammalian mitochondrial matrix using immunocytochemistry and proteomic mapping that found mito-APEX2 in close proximity to mitochondrial matrix proteins[47].

To engineer mammalian cell lines expressing a given protein cassette, each construct was cloned into a PiggyBac vector under the control of a doxycycline-inducible promoter adjacent to a constitutive puromycin resistance gene. These cassettes were randomly integrated into the genome of HEK293T cells using the PiggyBac transposase system and selected with puromycin (**Fig 1b**). Biological replicates of a given construct were defined as either individual clones derived from a single bulk transposase integration or multiple parallel transposase integrations. We screened the localization of each cassette by seeding cells into 96-well plates, expressed each protein for 24 hours under an inducible promoter, performed immunocytochemistry, and imaged each well using a high-throughput confocal microscope (ImageXpress Micro Confocal High-Content Imaging System). Specifically, each cell line was imaged for nuclei using Hoescht, POI using an antibody against HA, and mitochondria using an antibody against the mitochondrial marker TIM23 (**Fig 1c**). Using this high-throughput method, we found that localization of some cassettes varied qualitatively depending on localization signal. For instance, while the mito-APEX2 and Su9-LbCas12a showed punctate expression that colocalizes with mitochondria, NLS-LbCas12a showed clear nuclear colocalization and LbCas12a with no localization signal showed a diffuse, cytoplasmic phenotype. While these particular lines illustrate the expected localization based on signal, the localization of many other cassettes, such as of ATG4D-LbCas12a, were less predictable or more ambiguous. Thus, we next developed an analytical pipeline to quantify localization within mitochondria or nuclei.
Figure 1. High-throughput localization workflow. **(a)** 66 genetic cassettes containing a combination of localization signal and POI, followed by a C-terminus HA tag, were synthesized. Localization signals include three N-terminus MTSs (Su9, COX8, and ATG4D), a nuclear localization signal (NLS), or no localization tag (None). POIs were chosen from five different protein families—Class I CRISPR/Cas proteins, Class II CRISPR nucleases, retron RTs, RecTs, and SSBs. A positive control of mito-APEX2 was also included. **(b)** Each cassette was randomly integrated into the genome of HEK293T cells using a piggyBac transposase system. Following co-transfection of the cassette in a piggyBac vector and a plasmid constitutively expressing piggyBac transposase, cells were selected for at least one week using the antibiotic puromycin. To image each cell line, expression of a given cassette was induced for 24 hours using doxycycline before being fixed and stained prior

110   to imaging using a high-throughput confocal microscope (ImageXpress Micro Confocal High-Content Imaging
111   System). **(c)** Engineered cell lines were stained with Hoescht (blue), an antibody against HA (green), and an
112   antibody against the mitochondrial marker TIM23 (red). Shown are representative images from the positive
113   control (red background) and LbCas12a fused to one of three MTSs (purple), NLS (blue), or no localization tag
114   (white).

115

116

117   **Automated, quantitative, and open-source analysis pipeline**
118   To better compare localization differences exhibited by MTS-POI combinations, we developed an
119   unbiased Python-based analysis pipeline to quantify the mitochondrial and nuclear import between
120   our dozens of cassettes. Crucially, we found that expression and localization were variable between
121   individual cells of a given condition so our analysis pipeline is built to quantify colocalization at
122   the level of single cells. Images corresponding to the nuclei and mitochondria for each biological
123   replicate cell line from each condition were fed into a Cellpose-based machine learning model[48,49]
124   to label individual cells (**Fig 2a,b**). Next, cells were filtered using Otsu thresholding to remove
125   any cells with no detectable protein expression (**Fig 2c**). Specifically, Otsu thresholding was
126   applied on each image to determine the pixel intensity threshold separating POI signal from
127   background fluorescence. This analysis also revealed that some images had such low fluorescence
128   that signal was effectively indistinguishable from noise. To ensure these specific images did not
129   bias the final colocalization scores, any images in which Otsu thresholding did not separate signal
130   from noise in each cell, as defined by the majority of filtered cells in an image failing to show a
131   non-Gaussian intensity distribution typical of true fluorescent signal, were discarded (**Fig S1**). In
132   some cases, only a few images for a cell line were eliminated, although—in cases where a clonal
133   or transfected line suffered from minimal cassette expression—the entire biological replicate was
134   removed from analysis.
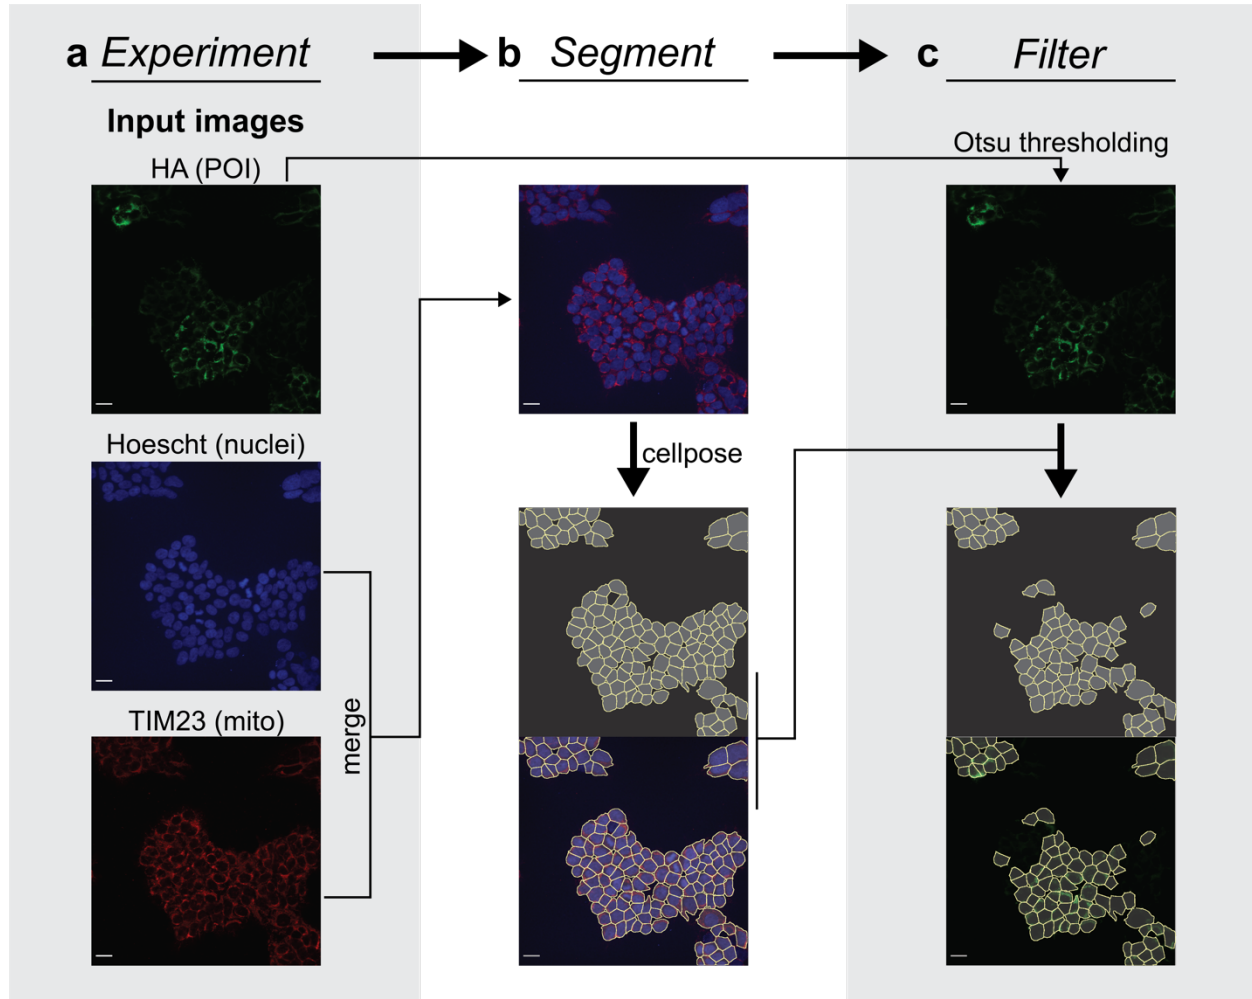

Figure 2. Machine learning algorithm enables automated labeling of cells containing cassette protein. Scale bar = 25 μm. **(a)** Unprocessed images from each fluorescent channel are fed into a Python-based analysis pipeline to segment individual cells. Shown are representative images from the cell line Su9-LbCas12a (top, HA; middle; Hoescht, bottom; TIM23). **(b)** The Hoescht and TIM23 channels are merged (top) prior to being fed into a custom, retrained neural network (arrow), resulting in automated labeling of each cell found within the image. Images below arrow; top image shows Cellpose-generated mask of segmented cells, where each yellow line indicates a cell boundary. Bottom image shows mask overlaid atop merged Hoescht/TIM23 channels. **(c)** Cellpose-segmented cells are filtered to keep only cells which express the cassette protein. Otsu thresholding is applied to the HA channel (top) to determine a threshold separating true fluorescent signal from background noise. Segmented cells containing at least 50 pixels with signal are kept to perform further colocalization measurements. Images below arrow; top image shows segmented cells following filtering. Bottom image shows filtered mask overlaid atop HA channel.

After selecting a population of filtered cells to further analyze for a given protein cassette, colocalization between the cassette protein and either mitochondria (**Fig 3a,b**) or nuclei (**Fig 3d,e**) was measured on a per cell basis using Pearson's correlation coefficient (PCC)[50]. Using this method, PCC scores vary between -1 (anti-correlated) to +1 (highly correlated). High colocalization scores indicate that a protein is collocated with a given organelle while low colocalization scores suggest little to no specific colocalization between a POI and a given organelle occurred.

157   For our analysis, we considered individual cells that survived quality filters from a single
158   transfection or clone as technical replicates and summarized the overall colocalization score for a
159   single biological replicate of each protein cassette by taking the median of all the individual cell
160   colocalization scores for mitochondria (**Fig 3c**) or nuclei (**Fig 3f**). We replicated our experiments
161   using at least three different transfections or five clonal lines as biological replicates.
162

163   We generally found low variability within our biological replicates, suggesting that protein import
164   is a fairly reliable phenomenon. The positive control mito-APEX2 obtained an average score of
165   0.63 +/- 0.03 (mean +/- std. dev), a high PCC value that strongly implies mito-APEX2 is imported
166   into the mitochondrial matrix. Similar to our previous qualitative assessments (**Fig 1c**), we found
167   that colocalization scores, even across a single POI, vary depending on localization signals. The
168   colocalization scores of LbCas12a fused to the Su9 or COX8 MTSs were not statistically different
169   from mito-APEX2, suggesting mitochondrial import had occurred. In comparison, when
170   LbCas12a was instead fused to ATG4D, no localization signal, or NLS, colocalization scores
171   dropped significantly, indicating less mitochondrial import occurred (**Fig 3g**). Moreover, when
172   comparing nuclear colocalization scores (**Fig 3h**), all cell lines except NLS-LbCas12a showed a
173   consistent, low nuclear colocalization score, suggesting little to no nuclear import. As expected,
174   only the cell line fused to a NLS had a high colocalization score indicating high nuclear import.
175   These findings suggest that our workflow is able to compare import efficiencies across different
176   combinations of MTS and POI for multiple organelles.
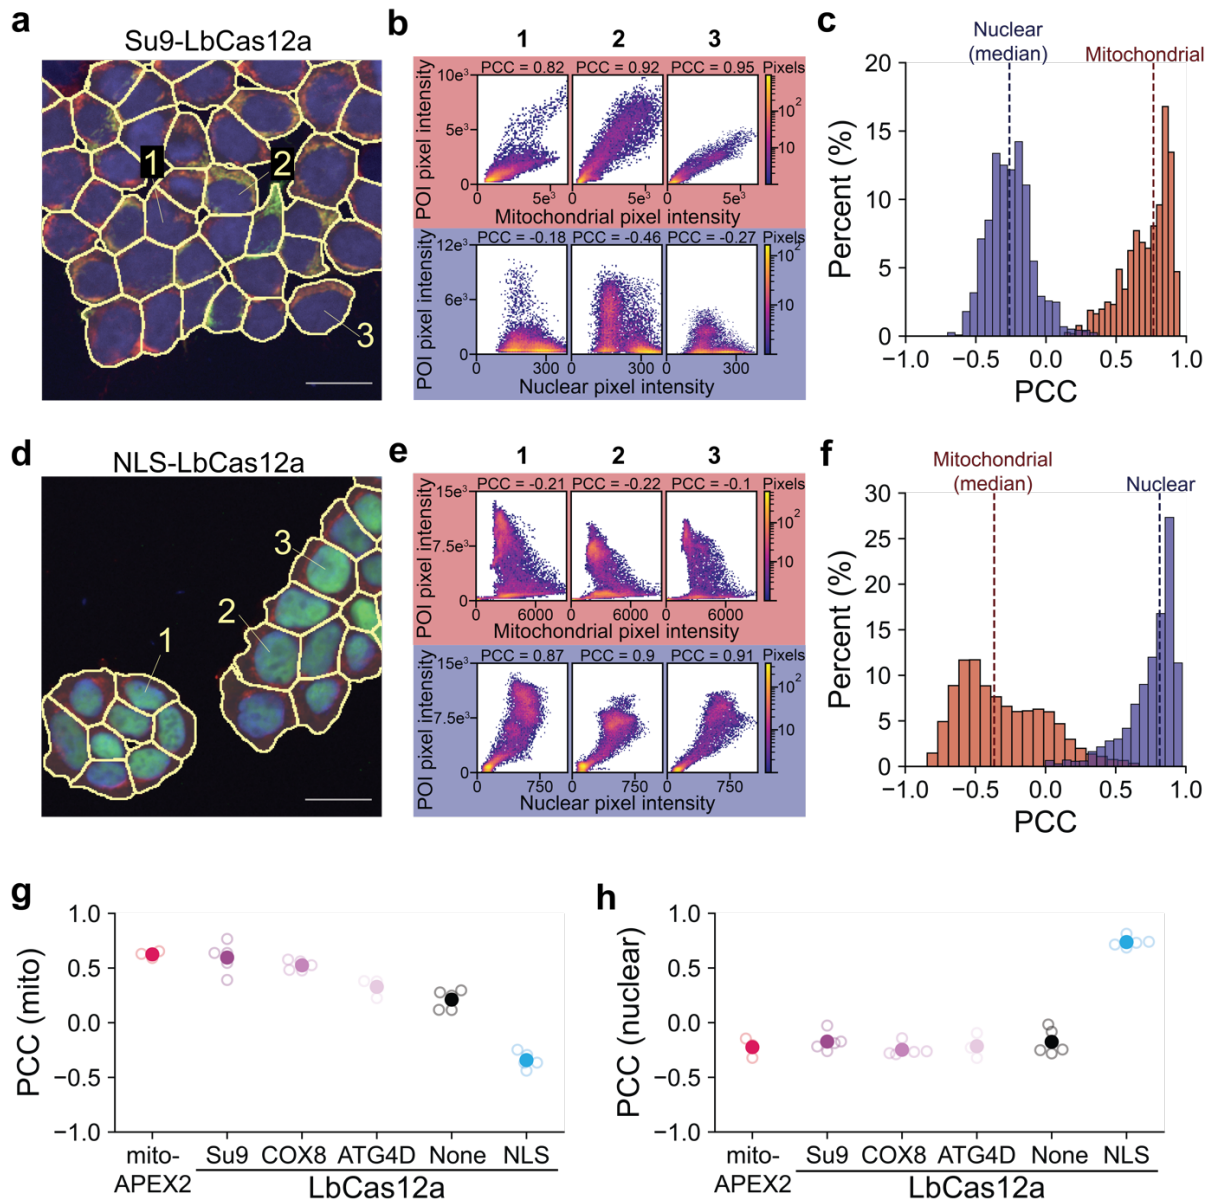

Figure 3. Computational workflow quantifies the colocalization of cassette proteins with mitochondria or nuclei. **(a)** Representative image of a cell line (Su9-LbCas12a) with clear mitochondrial expression of its cassette protein, with mask in yellow overlaid on top. Numbers refer to three representative cells for which data is shown in (b). Scale bar = 25 μm. **(b)** Heatmaps depicting the relationship between Su9-LbCas12a pixel intensity and organellar pixel intensity (mitochondria on top in red; nuclei on bottom in blue) for each pixel within a representative cell from (a) (left; cell #1, middle; cell #2, right; cell #3). Color depicts the number of pixels. The strength of the linear relationship between pixel intensities, or colocalization, within each cell is calculated using PCC, and the result depicted on top its respective heatmap. **(c)** Histogram depicting the all the colocalization scores for all the cells for one clonal line expressing Su9-LbCas12a. Mitochondrial PCC scores are shown in red, while nuclear PCC scores are shown in blue. Dotted lines depict the median colocalization score for mitochondria (red) and nuclei (blue). **(d)** Representative image of a cell line (NLS-LbCas12a) with clear nuclear expression of its cassette protein, with mask in yellow overlaid on top. Numbers refer to three representative cells. Scale bar = 25 μm. **(e)** Heatmaps depicting the relationship between NKS-LbCas12a pixel intensity and organellar pixel intensity (mitochondria on top in red; nuclei on bottom in blue) for each pixel within a representative cell from (d) (left; cell #1, middle; cell #2, right; cell #3). Color depicts the number of pixels. The

193 strength of the linear relationship between pixel intensities, or colocalization, within each cell is calculated using
194 PCC, whose result is on top its respective heatmap. **(f)** Histogram depicting the all the colocalization scores for
195 all the cells for one clonal line expressing NLS-LbCas12a. Mitochondrial PCC scores are shown in red, while
196 nuclear PCC scores are shown in blue. Dotted lines depict the median colocalization score for mitochondria (red)
197 and nuclei (blue). **(g)** Mitochondrial colocalization of positive control mito-APEX2 (red) and LbCas12a fused
198 to different localization tags, as measured using the described experimental and analytic workflow. There is a
199 significant effect of localization signal (one-way ANOVA, $P<0.0001$), where ATG4D ($P=0.0021$), no signal
200 ($P<0.0001$), and NLS ($P<0.0001$) are all significantly different from mito-APEX2, but Su9 ($P=0.9831$) and
201 COX8 ($P=0.376$) are not (Dunnett's corrected). Open circles are biological replicates; closed circles are average
202 of all biological replicates. **(h)** Nuclear colocalization of mito-APEX2 (red) and LbCas12a fused to different
203 localization tags measured using the described experimental and analytical workflow. There is a significant
204 effect of localization signal (one-way ANOVA, $P<0.0001$), where NLS ($P<0.0001$) is significantly different
205 from mito-APEX2, but Su9 ($P=0.8587$), COX8 ($P=0.9930$), ATG4D ($P=0.9998$), and no signal ($P=0.0.8825$)
206 are not (Dunnett's corrected). Open circles are biological replicates; closed circles are average of all biological
207 replicates. Additional statistical details in Supplementary Table 1.

208
MTS selection strongly influences mitochondrial import
210 After validating the analytical pipeline, we used this workflow to quantify the mitochondrial and
211 nuclear import of all 66 different protein cassettes (**Fig 4a; S2a,b**). Interestingly, mitochondrial
212 colocalization scores did not cluster bimodally into high and low scores. Instead, scores were
213 distributed continuously, suggesting that different cassettes have varying capabilities to drive POIs
214 to the mitochondria.

215
216 Previous studies have found that both the specific MTS and hydrophobicity of individual POIs can
217 influence the probability that a MTS-POI will localize in the mitochondria [31,19,33]. To determine if
218 localization signal influences mitochondrial import across the four protein families tested, we
219 investigated how the mitochondrial import rank of cassettes clustered based on localization signal
220 (**Fig 4b**). We fit a linear mixed effects model with a fixed effect of localization signal and a random
221 intercept within each protein family, to specifically test the statistical significance of each
222 localization signal while accounting for the variability inherent within each protein of interest. As
223 expected, we found that cassettes clustered based on specific localization signals; while fusion to
224 an MTS resulted in higher rankings across the board, having a NLS led to clear clustering at the
225 bottom of the rankings. However, there was a clear ranking priority to how well each MTS
226 performed compared to each other, with Su9 and COX8 driving high mitochondrial import, while
227 ATG4D performed significantly worse.

228
229 Given ATG4D's uneven performance across different POIs, we next further analyzed how
230 colocalization scores varied based on localization scores within different protein families (**Fig 4c-
231 g**). Interestingly, all three MTSs were able to drive high mitochondrial import of Class I CRISPR-
232 related proteins (**Fig 4c**), whereas both COX8 and ATG4D appeared less capable than Su9 of
233 importing the larger Class II CRISPR nucleases (**Fig 4d**). Of the two retron RTs tested, only Su9
234 led to mitochondrial localization of retron-Eco1 RT, whereas COX8 and ATG4D were able to
235 localize retron Eco2 RT (**Fig 4e**). Finally, while both COX8 and Su9 were able to import all RecTs
236 and SSBs tested into the mitochondria (**Fig 4f,g**), ATG4D instead appeared to misdirect these
237 proteins to a different location, based on an unusual punctate pattern which did not colocalize with
238 mitochondria (**Fig S2c**).
239

240
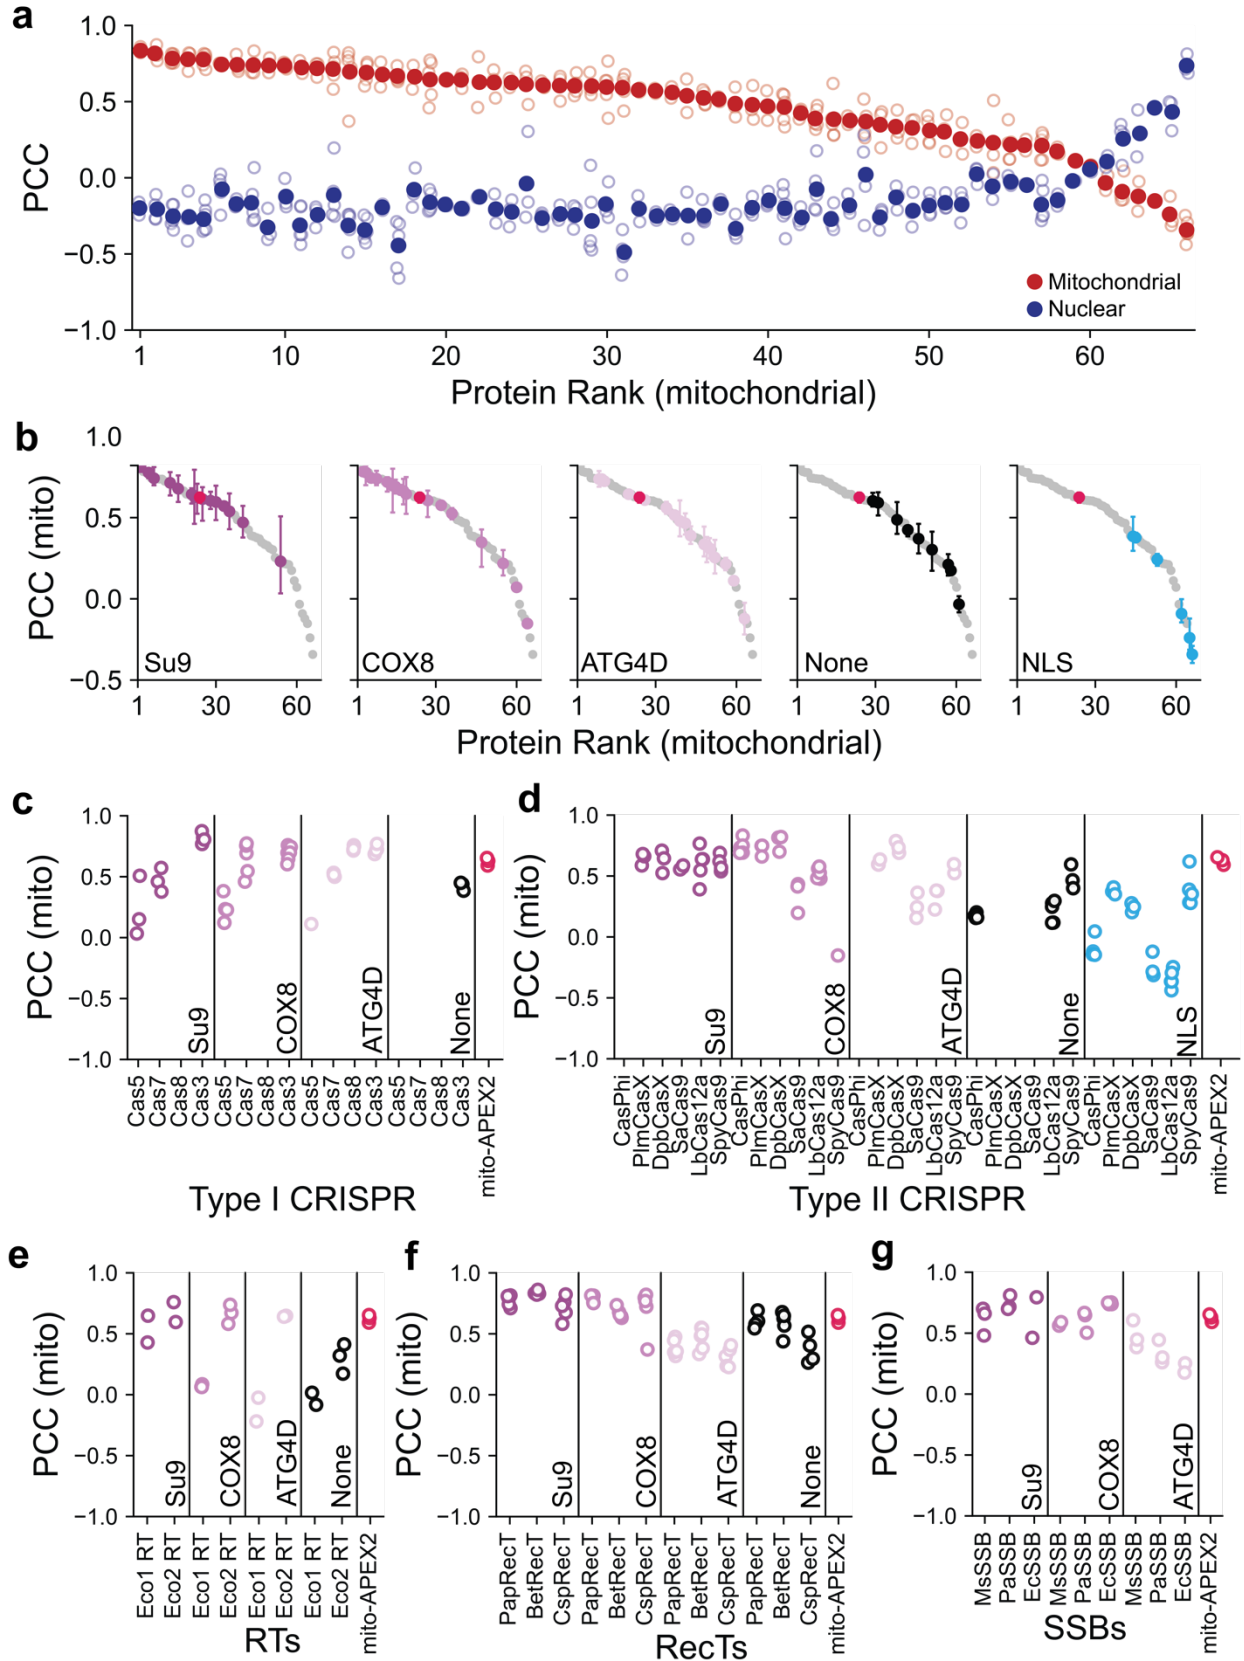

241 **Figure 4.** MTS selection strongly influences mitochondrial import. **(a)** Mitochondrial (red) and nuclear (blue)
242 colocalization scores of 66 different protein cassettes. Proteins were ranked based on average mitochondrial
243 colocalization score, from highest mitochondrial PCC to lowest. Open circles are biological replicates; closed
244 circles are average of all biological replicates. **(b)** Clustering of cassettes based on specific localization signal.
245 The entire continuum of all mitochondrial colocalization scores from (a) is shown in each subplot in gray, while
246 the positive control mito-APEX2 is shown in each subplot in red. The clustering of cassettes with a specific
247 localization signal is shown in another color on top (from left to right subplots: Su9, COX8, ATG4D, none, and
248 NLS). There is a significant effect of localization signal (linear mixed effects model, $P<0.0001$), where ATG4D
249 is significantly different from both Su9 ($P<0.0001$) and COX8 ($P<0.0001$) but not None (0.092559) during
250 follow-up (Kenward-Roger corrected). Meanwhile, there is no significant difference between Su9 and COX8
251 ($P=0.88139$). Closed circles indicate average of all biological replicates; error bars indicate standard deviation.
252 **(c)-(g)** Mitochondrial colocalization scores broken down by localization signal within a given protein family (**c**;
253 Class I CRISPR Cas3/CASCADE, **d**; Class II CRISPR nucleases, **e**; retron RTs, **f**; RecTs, **g**; SSBs). Specific
254 proteins are listed in order of amino acid length, from shortest on the left to longest on the right. As a reference
255 for mitochondrial PCC scores suggestive of mitochondrial import, scores for positive control mito-APEX2 are
256 shown to the right of each figure (red). Open circles are individual biological replicates.

257
258

259 **DISCUSSION**
260 Importing non-canonical proteins into mammalian mitochondria is a critical step to overcome
261 particular challenges in metabolic engineering and for developing therapeutics to treat genetic
262 diseases of the mtDNA. Here, we design a high-throughput imaging-based workflow to quickly
263 screen the subcellular localization of a tagged protein. This method enabled us to determine the
264 best MTS-POI combination across three commonly used MTSs and five different protein classes
265 that are components of gene editing technologies. The results from these screens should help drive
266 more robust mitochondrial gene editing by enabling researchers to test mitochondrial gene editing
267 using other nucleases or proteins beyond SpyCas9, which has been reported to cause mitochondrial
268 dysfunction when imported to mitochondria[15], or testing MTSs that yield more specific
269 mitochondria import to prevent off-target effects in nuclear DNA[29].

270

271 This work also reveals broader trends about which MTS to use across multiple protein types. By
272 testing three common MTSs on a diverse set of POIs, we find that Su9 and COX8 consistently
273 performed the best while ATG4D performed the most unevenly and misdirected several POIs to
274 an alternate location. In addition, unlike COX8 and ATG4D, Su9 was able to import specific
275 proteins, such as large Class II nucleases and Eco1 RT, into the mitochondria.

276

277 As a tool for the field, our Python-based workflow implemented in an annotated Jupyter notebook
278 can be reused for future experiments, including more generally to other screens using different
279 proteins, organelles of interest, or cell lines. Although we used a high-throughput confocal
280 microscope in our own workflow, other confocal microscopes could easily be used, depending on
281 the necessary throughput or number of samples. Computationally, the analytic pipeline uses
282 Python, an open-source programming language, and relies on pixel-based colocalization analyses
283 and quality check steps to eliminate cells not expressing a protein of interest that can be universally
284 applied regardless of cell line or differing expression levels or phenotypes[50]. The only experiment-
285 specific alteration to the pipeline would be to apply a different neural network to segment
286 individual cells, depending on the cell line and seeding density used. However, Cellpose already
287 offers a collection of ready-to-use neural networks or—if further refinement is necessary—an
288 intuitive GUI that enables users to retrain and create their own neural network in fewer than 30

289　minutes[49]. Therefore, others should be able to easily apply this analytical framework to quantify
290　colocalization within their own fluorescent images.
291
292　**Methods**
293　*Constructs and strains*
294　Protein cassettes were constructed by amplifying localization signals and POI nucleotide
295　sequences using PCR from synthesized gBlocks (IDT) or existing plasmids. Complete protein
296　cassettes were cloned into a PiggyBac integrating plasmid for doxycycline-inducible human
297　protein expression (TetOn-3G promoter) using Gibson assembly. Alternatively, some cassettes
298　were synthesized into the same custom PiggyBac integrating plasmid by Twist Bioscience (see
299　Supplementary Table 2).
300
301　Stable mammalian cells for imaging were generated using the standard Lipofectamine 3000
302　transfection protocol (Invitrogen) and a PiggyBac transposase system. T12.5 flasks with 50-70%
303　confluent HEK293T cells were transfected using 1.6 µg POI cassette expression plasmid and 0.8
304　µg PiggyBac transposase plasmid (pCMV-hyPBase). Stable cell lines were selected using
305　puromycin for at least one week.
306
307　Clonal lines were generated by growing individual cells into separate cell populations.
308　Specifically, stable cell lines were serially diluted to a final concentration of 2.5 cells per mL media
309　then seeded into a 96-well plate using 100 µL/well. Wells that received a single cell had media
310　refreshed weekly until a clonal line proliferated to ~40% confluency, at which point a clonal line
311　was passaged to a larger flask for further experiments.
312
313　*Immunocytochemistry*
314　96-well glass bottom plates with #1 cover glass (Cellvis, catalog # P96-1-N) were coated with a
315　mixture of 50% poly-D-lysine (ThermoFisher Scientific, catalog #A3890401) and DPBS
316　(ThermoFisher Scientific, catalog #14040133) for 30 minutes at room temperature. Wells were
317　washed three times with distilled water and left out to dry for at least 2 hours prior to seeding.
318
319　Cells were seeded at a density of 10,000 cells per well. The following day, doxycycline was added
320　at a final concentration of 1 µg/mL to induce expression of the protein cassette. At 24 hours post-
321　induction, cell nuclei were stained using a final concentration of 10 µM Hoescht for at least 5
322　minutes prior to fixation.
323
324　For fixation, media was aspirated from each well and replaced with a solution of 4%
325　paraformaldehyde (PFA) created fresh by fixing a 1 mL 16% (w/v) PFA ampule (ThermoFisher
326　Scientific, catalog #28906) with 3 mL PBS. Cells were fixed for 30 minutes at room temperature
327　prior to three 5-minute washes with PBS. Following fixation, cells were permeabilized and blocked
328　for an hour at room temperature using blocking buffer made fresh with the following ingredients:
329　PBS containing 10% donkey serum (Sigma-Aldrich, catalog #D9663), 10% Triton X-100 (Sigma-
330　Aldrich, catalog #X100), and 100 mg BSA (Sigma-Aldrich, catalog #A9418) per 10 mL solution.
331　Next, cells were incubated overnight at 4°C in blocking buffer with the antibodies anti-HA tag
332　conjugated to DyLight 550 (ThermoFisher Scientific, catalog #26183-D550) and anti-TIM23
333　(Abcam, catalog #ab230253) each added at a 1:100 dilution. After performing three more 5-minute
334　washes, cells were incubated with a secondary antibody goat anti-rabbit conjugated to DyLight

335   650 (ThermoFisher Scientific, catalog #84546) at a 1:500 dilution in blocking buffer for 3 hours.
336   Following secondary antibody incubation, three more 5-minute washes were performed prior to
337   the addition of 30 uL antifade mountant (ThermoFisher Scientific, catalog #S36967) per well.
338
339   Plates were wrapped in aluminum foil to avoid light and either stored temporarily at 4°C or at -
340   20°C for longer-term storage prior to imaging.
341

342   *Imaging*
343   Stained cells were imaged using an ImageXpress Micro Confocal High-Content Imaging System
344   (Molecular Devices) using a 40X water immersion objective by taking a 7-layer Z-stack, with each
345   layer spaced 0.3 μm apart, at four different sites per well.
346

347   *Colocalization Image Analysis Pipeline*
348   A colocalization image analysis pipeline was made using jupyter-notebook in Python 3[51,52], and
349   uses the following packages: numpy, pandas, scipy, skimage, tdqm, and tifffile. Additionally, the
350   pipeline requires the Cellpose code library[48,49] along with these additional packages: numba,
351   opencv, and pytorch. Using the Cellpose GUI also requires PyQt and pyqtgraph[53].
352

353   TIFF files consisting of merged nuclear and mitochondrial channels were created using a custom
354   function and fed into a neural network retrained according to the instructions for the Cellpose
355   GUI[49]. Briefly, the "CP" model from the Cellpose model zoo was initially used to segment all
356   images. Afterwards, about five images with poor initial segmentation were chosen for manual
357   annotation. The CP model was then retrained using the corrected labels and the new model was
358   re-run on all images.
359

360   To remove segmented cells that did not contain expression of the cassette protein, Otsu
361   thresholding was performed on the HA channel to determine a pixel intensity threshold separating
362   signal from background for each image. Only segmented cells containing at least 50 pixels of
363   cassette protein signal, referred to as filtered cells, were kept for further analysis.
364

365   Two additional functions to ensure quality-check steps were also implemented. First, any image
366   containing fewer than six filtered cells was automatically removed from further analysis. Second,
367   since the overall expression of a cassette protein can vary between different cell lines, a function
368   was written to ensure that the filtering step effectively distinguished between cells that did or did
369   not express a cassette protein. Individual cells containing noise, rather than signal, exhibit a
370   Gaussian distribution of protein cassette pixel intensities. In contrast, cells with signal tend to
371   exhibit non-normal or skewed pixel intensity distributions. Thus, for every image, a "non-
372   Gaussian" test was performed on each filtered cell by testing for normality. If over 60% of filtered
373   cells failed the "non-Gaussian" test, then this result suggests that the majority of filtered cells
374   within the image do not contain true expression of the cassette protein, thus that specific image
375   would be removed from further analysis.
376

377   Afterwards, a custom function was built to calculate PCC between the HA channel pixel intensities
378   and either the mitochondrial or nuclear channel pixel intensities for every filtered cell related to a
379   given biological replicate. Due to the skew present in most PCC distribution, these results were
380   summarized by taking the median of all the filtered cells for a given biological replicate.

381
382 *Statistics*
383   ANOVA and post-hoc analyses were performed using GraphPad Prism v9.4.1 For linear mixed
384   effects modeling, we used *R* v4.2.3 using the *lme4* and *lmerTest* packages (post-hoc analyses used
385   the Kenward-Roger degrees of freedom correction method implemented in the package *pbkrtest*).
386
387   **ABBREVIATIONS**
388   MTS: mitochondrial targeting sequence
389   POI: protein of interest
390   mtDNA: mitochondrial DNA
391   CRISPR: clustered regularly interspaced short palindromic repeats
