Abstract

In *Streptococcus pyogenes*, the fatty acid (FA) synthesis pathway FASII is feedback-controlled by the FabT repressor bound to an acyl-Acyl carrier protein. Despite FabT defects being linked to reduced virulence in animal models, spontaneous *fabT* mutants arise *in vivo*. To resolve this paradox, we characterized the conditions and mechanisms that require FabT activity, and those that promote *fabT* mutant emergence. The primary *fabT* mutant defect is energy dissipation: specific nutrients are consumed, but the mutant fails to grow on human tissue, cells, or cell filtrates where nutrients are limited. These features explain the FabT requirement during infection. Conversely, *fabT* mutants exhibited a marked growth advantage over the wild-type in biotopes rich in saturated FAs. *fabT* mutants emerge in this context, where continued FASII activity prevented environmental FA incorporation. An *ex vivo* muscle model demonstrated that wild-type *S. pyogenes* was inhibited, while *fabT* mutant growth was stimulated, but conditional to FASII activity. Our findings elucidate the rationale for emerging *fabT* mutants that improve survival in lipid-rich biotopes, but lead to a genetic impasse for infection.

Introduction

Bacterial membranes form a mutable permeable barrier that facilitates adaptation to a changing environment. They usually comprise a phospholipid bilayer composed of a polar head and apolar fatty acid (FA) chains. The FA synthesis pathway (FASII), which is widespread among bacteria, synthesizes saturated and/or unsaturated FAs joined to an acyl carrier protein (ACP; forming acyl-ACP) (Supplementary Fig. 1a). Unsaturated FAs are produced *via* a FASII shunt catalyzed by an acyl-ACP-isomerase named FabM in streptococci. While FASII is conserved (with some enzyme variation), its regulators differ among Firmicutes. In streptococcaceae and enterococcaccae, FASII gene expression is controlled by a unique MarR-family feedback-type regulator named FabT encoded in the main FASII locus (Supplementary Fig. 1 b-c). FabT uses acyl-ACP as corepressor [1,2, for review 3]. The affinity of FabT-(acyl-ACP) binding to a specific DNA palindromic sequence increases with the length of the acyl carbon chain and the presence of an unsaturation [4]. FabT regulons were characterized in various streptococcaceae species and in conditions that affect membrane FA composition, including growth temperature, pH or growth phase [5-9]. FabT exerts greater repression of genes encoding elongation steps, mainly the *trans*-2-enoyl-ACP reductase II FabK, and less repression of *fabM*. In *Streptococcus pneumoniae fabM* expression is not repressed by FabT [6]. Accordingly, an *S. pneumoniae* strain lacking a functional FabT produced longer and more saturated FAs [6]. FabT regulons reportedly also comprise non-FASII genes involved in transport, DNA and carbohydrate metabolism, protein, purine and pyrimidine synthesis; however, their identities vary according to reports and the species under study [3]. To date, FabT regulons were not analyzed in the presence of exogeneous FAs (eFAs), which enhance FabT transcriptional repression [4]. This missing information is particularly relevant as numerous host infection sites are FA-rich.

Streptococcus pyogenes, also known as Group A *Streptococcus*, GAS, is a major human

pathogen responsible for a large variety of clinical manifestations ranging from superficial

infections to life-threatening invasive infections. GAS infections rank among the top ten causes

of death due to bacterial infections worldwide [10]. GAS isolates mutated in *fabT* were recovered

in non-human primates at the point of intramuscular inoculation, raising the possibility of such

populations forming in the human host [5]. In a murine model, strains harboring *fabT* point

mutations display smaller size lesions, no loss of body weight and a lower mortality than their

wild-type counterparts [11]. In a non-human primate model, a *fabT* deleted strain shows decreased

colonization and dissemination capacities compared to the parental strain [5]. Its survival is also

decreased in human blood or in the presence of human polymorphonuclear leukocytes [5].

These reported properties indicate that the *fabT* mutant variants are poorly adapted for

infection, which led us to question the rationale for their emergence. We solve this question

here by performing in-depth analyses of the features of WT and a representative *fabT* mutant

in different conditions relevant to host infection. We report that the *fabT* mutant is metabolically

wasteful, by consuming sugars and amino acids, yet failing to grow, which accounts for its

failure to cause infection. Conversely, saturated FA-rich environments impose a counter-

selective pressure against WT bacteria expressing active FabT. We show that *fabT* mutant

growth is stimulated around lipid-rich muscle sources in a FASII-dependent manner, while WT

growth is inhibited. These findings solve the apparent contradiction between the *in vivo*

emergence of attenuated *fabT* variants and the need for an active FabT repressor during

infection.

Results

WT and *fabT* mutant growth properties

Multiple independent FabT point mutants were harvested from the infection site of nonhuman

primates, some of which mapped to His105 [5]. We chose the FabT[H105Y] point mutation as being

representative of mutations that arose *in vivo*, which was established in the *emm28* reference

strain M28PF1 (respectively mFabT and WT) [12,13](Supplementary Fig. 1b-c) [14]. A Δ*fabT*

deletion strain was constructed for comparison. mFabT and WT strains grow similarly in

laboratory medium (THY), and in THY supplemented with a C18:1Δ9 (oleic acid) source,

0.1 % Tween 80 (THY-Tween) [2]. Survival of WT and mFabT strains in mid-exponential phase

was also comparable, as assessed by live-dead staining (Supplementary Fig. 2a-b). Unlike

mFabT, the Δ*fabT* mutant grew slowly in both THY and THY-Tween media (Supplementary

Fig. 2c-d; also see [11]). As *fabT* deletions were not reported to arise *in vivo,* we chose to study

the mFabT mutant strain as being representative of *in vivo* mutations.

FabT[H105Y] impacts membrane lipid production and species

The GAS mFabT strain produced greater proportions of longer length saturated FA (C18:0)

than the WT strain (26.1 % *versus* 6.8 % respectively; Supplementary Table 1), as first reported

in *S. pneumoniae* [6]. In THY-Tween, which supplies C18:1Δ9, the native FabT in the WT strain

represses FASII, and contains 1.7 times more C18:1Δ9 than did mFabT. In this condition, the

proportion of C18:0 remained higher in mFabT than in the WT (12.4 % and 0.2 % respectively;

Supplementary Table 1) [2].

The effects of the FabT mutation on membrane FA composition should also alter

phospholipid metabolism. Lipid analyses of WT and mFabT strains cultured in THY and THY-

Tween media identified notable differences in membrane lipid features: i, the primary

differences between WT and mFabT FA composition were reflected in all identified lipid species (Supplementary Fig. 3, Supplementary Table 2); ii, THY grown mFabT has ~60 % overall lipid yield compared to that of the WT, extracted from equivalent bacterial OD_{600} (N=4); these differences were narrowed to ~5 % in cultures grown in THY-Tween (Fig. 1a-b, Supplementary Table 3). Among the detected lipids, diglucosyldiacylglycerol (DGDG) and cardiolipin (CL) amounts were proportionately lower in mFabT compared to WT in THY medium. In THY Tween, WT levels of both CL and DGDG decreased. iii, CL species in mFabT were 2-fold enriched in deoxidized cardiolipin (deoxy-CL) species compared to CL in the WT strain, regardless of the growth medium (Fig. 1c-e). CL but not deoxy-CL reportedly facilitates oxidative phosphorylation activity by binding protons [15]. In conclusion, the greater proportions of saturated and longer FAs in the *fabT* mutant appear to cause a reduced overall membrane lipid content and alterations in lipid distribution and composition as compared to the WT.

  fabT mutants are reportedly more resistant to the cationic cyclic peptide polymyxin B [5,16]. Polymyxin B binds negatively charged lipids such as CL [17]. Putting together these reports and the CL changes noted above, we examined polymyxin B resistance of mFabT and WT strains in conditions where CL amounts varied (Fig. 1f). Features that decreased CL pools, *i.e.*, *fabT* mutation or FA availability during WT growth, correlated with greater polymyxin B resistance. These data support the idea that greater polymyxin B resistance in *fabT* mutants is due to lower CL pools, and show that availability of environmental FAs can lead to polymyxin B resistance. They give a rationale for *fabT* mutant emergence upon polymyxin B selection [16]. However, they do not explain the *in vivo* emergence of mFabT mutants at an early stage of GAS infection.

Effects of *fabT* on virulence factor expression

In FA-free medium, streptococcal *fabT* truncation or point mutants exhibit an increased *fabK*:*fabM* ratio. FabK and FabM compete for the same substrate to respectively synthesize saturated and unsaturated FAs (Supplementary Fig. 1a). Higher *fabK* expression is thus consistent with the higher proportion of saturated FAs in *fabT* mutants [2,6]. Differential *fabK* and *fabM* expression also suggests that these genes may not belong to the same transcriptional unit. Organization of the FASII locus was analyzed by RT-PCR (Supplementary Fig. 4). All genes from *fabM* to *accD* were shown to be cotranscribed. However, transcription start sites are also present within this operon (Fig. 2a) [18]. All transcriptional start sites except that of *fabH* are preceded by a FabT consensus DNA binding motif (5'-ANTTTGATTATCAAATT). This transcriptional organization explains the differential regulation of *fabK* and *fabM*.

We performed transcriptomic analyses to identify how the *fabT* mutant and accompanying membrane FA changes might impact and explain the virulence defect during host infection. WT and mFabT expression was compared in THY, and in THY-Tween (as C18:1Δ9 source), which activates WT FabT repression ([3] for Review; Supplementary Table 4, Fig 2b-e). Several differences, some corresponding to multi-gene operons, distinguished the two strains (Supplementary Table 4). Notably, purine synthesis operon genes (M28_Spy0022 to M28_Spy0026) were upregulated in mFabT, suggestive of increased metabolic activity. An operon encoding adhesins (M28_Spy0107 to M28_Spy0111) was also upregulated; however, expression of virulence genes of the Mga regulon, i.e., C5 peptidase ScpA, and other adhesins, M protein, Sof and SfbX, were down-regulated (Supplementary Table 4). Decreased expression of adhesins and other virulence factors such as SLO (*slo*) and NADase (*nga*) could contribute to the reported poor virulence of *fabT* mutants in infection [19].

Addition of C18:1Δ9 activates FabT-mediated repression, which, as reported, turns off FASII gene expression in the WT strain (Fig. 2c, Supplementary Table 4) [4]. In contrast, FASII genes, and a non-FASII gene within the FabT regulon (M28_Spy1638, encoding a putative

fatty acid kinase binding protein; [13]), remain transcriptionally active in the mFabT mutant,

showing that FabT^{H105Y} is defective for repression (Fig. 2e, Supplementary Table 4). This

transcriptional analysis confirms that the single FabT^{H105Y} point mutation loses control of FASII

and does not act as a repressor when eFAs are available, and leads to deregulation of virulence

genes.

The WT strain has a fitness advantage over mFabT during growth on human decidua

To understand the role of *fabT* and emergence of *fabT* mutants, we designed *ex vivo* assays to

study infection with WT and *fabT* variants. mFabT strain capacity to colonize human tissue *ex*

vivo was assessed by measuring its growth on human tissue. As *emm28* strains are associated

to puerperal fever [20,21], we compared *ex vivo* growth of WT and mFabT on human decidua [22].

In control experiments, both strains failed to grow in RPMI, as assessed by growth ratios

between cfus after 8 h incubation and the inocula (Supplementary Fig. 2e). In static conditions,

growth of mFabT was 63 % lower than that of the WT strain (Fig. 3a). Growth kinetics of

WT$^{eryR\text{-}igfp}$ and mFabT$^{eryR\text{-}igfp}$ GFP-marked strains were then followed in flow conditions at the

tissue surface by time-lapse microscopy (Fig. 3b-c). The surface colonized by the WT strain

increased throughout the 4 h growth period (Fig. 3b). In contrast, mFabT strain growth only

increased during the first half-hour of image acquisition. The thickness of bacterial

microcolonies increased for the WT, but decreased for the mFabT strain (Fig. 3c). Altogether,

the WT strain grew with a doubling time of roughly 200 min whereas the mFabT strain did not

grow. Thus, in contrast to normal growth in THY medium, the mFabT strain has a major growth

defect in the presence of human decidua. These results provide insight into the nature of the

colonization defect and virulence attenuation of *fabT* mutant strains [5,11].

Impaired mFabT fitness is due to defective adhesion and poor growth on human cells and in cell supernatants

Bacterial colonization of host tissue comprises an initial adhesion step, followed by bacterial multiplication [22]. As GAS has tropism for endometrial and skin tissues, we compared WT and mFabT adhesion capacities on human endometrial cells, and on differentiated (as present in upper skin layers), and undifferentiated skin keratinocytes (Fig. 3d). The mFabT mutant displayed an adhesion defect on endometrial cells as reported [2] and undifferentiated keratinocytes compared to the WT. In contrast, the strains adhered similarly on differentiated keratinocytes. The adhesion defect, as also suggested by transcriptome analyses (Supplementary Table 4, Fig. 3d), may contribute to the virulence defect observed in the non-human primate animal models [5].

GAS replicates mainly extracellularly during infection of endometrium and skin [23]. Growth comparisons of WT and mFabT strains on these biotopes, namely endometrial cells, undifferentiated keratinocytes, and differentiated keratinocytes, showed that the mFabT strain was decreased (90 %, 53 % and 56 % respectively) compared to the WT strain. The FabT^{H105Y} mutation thus leads to impaired growth in the presence of human cells. To determine whether adhesion is required for the growth differences between WT and *fabT* strains, we assayed bacterial growth in uninfected cell supernatant, termed "conditioned supernatant" (Fig. 3f). The mFabT strain displayed a similar growth defect in endometrial, undifferentiated and differentiated keratinocyte conditioned supernatants (72 %, 50 % and 50 % respectively) compared to the WT. This indicates that cell-secreted products differentially affect growth of WT and mFabT strains. Adhesins differentially produced in WT (Supplementary Table 4, Fig. 3d) could also contribute to promoting higher bacterial densities during infection.

The differences in WT and mFabT growth were visible when grown on endometrial cells or their conditioned supernatants. It is therefore likely that secreted endometrial cell compounds

affecting GAS growth are produced independently of infection. Higher bacterial growth densities on differentiated keratinocytes than on conditioned supernatants (compare Fig. 3e and 3f) may be due to greater nutrient availability after infection. Altogether, these data implicate both adhesion and growth defects in poor survival of mFabT in cell infection environments.

Poor mFabT growth suggests that mFabT makes inefficient use of nutrients secreted by eukaryotic cells and/or is more susceptible than WT to secreted bactericidal molecules. We investigated growth kinetics of WT and mFabT strains in endometrial cell conditioned supernatant in time course experiments (Fig. 3g left). Cfu ratios were similar for both strains at 4 h, indicating no difference in the lag time. However, at 8 h, cfu ratios were higher for the WT strain (Fig. 3f-g left). In addition, mFabT mortality was ~1.5-fold greater than WT at 8 h post-inoculation in conditioned supernatant (Fig. 3g right); these differences are accentuated at 16 h and 24 h (Fig. 3g left). We noted that GAS dies rapidly when growth stops, as seen in RPMI (Supplementary Fig. 2e). We conclude that mFabT grows more slowly and dies more rapidly than the WT strain, and suggest that GAS death is triggered by slow growth.

Faster metabolic turnover in mFabT generates a growth defect during infection

We investigated a possible metabolic basis for the mFabT growth defect, which could reflect an incapacity to use cell-secreted products for growth, and/or higher mortality (Fig. 3g). We used a metabolomics approach to assess metabolites that are differentially consumed by mFabT compared to the WT strain, as performed on conditioned supernatants. Hexoses and amino acids, Asn, Gly, Ile and Lys were the main metabolites overproduced by uninfected cells (Supplementary Fig. 5, Supplementary Table 5). The mFabT strain consumed more hexoses and amino acids Asn, Ile, Lys, and Ser, as seen at 16 h (Fig. 4, Supplementary Table 5). This overconsumption is not linked to a higher bacterial yield, but rather the opposite. These data give evidence that the mFabT mutant has a greater metabolic consumption at the GAS site of

infection. Thus, the mFabT strain wastes energy during growth: it over-uses amino acids and

hexoses compared to the WT strain, but without growth benefits. Futile energy loss, and

expression changes in the absence of eFAs, can account for the diminished capacity of *fabT*

mutants to cause infection.

mFabT is defective for eFA incorporation

C18:1Δ9 incorporation is reduced in the mFabT strain (Supplementary Table 1). In *S.*

pneumoniae, a *fabT* mutant reportedly incorporated only traces of C16:1 [6]; in an *Enterococcus*

faecalis fabT deletion mutant, incorporation of unsaturated FAs, and to a lesser extent, saturated

FAs, was defective [4]. We evaluated FA incorporation by GAS in medium supplemented with

C17:1, which is not synthesized by GAS; incorporation of this FA generates a discrete peak by

gas chromatography (Fig. 5a left). The proportion of C17:1 was 52 % in the WT strain, and 17

% in mFabT.

Continued FASII synthesis in the mFabT mutant might create competition between

endogenously synthesized and eFAs for incorporation into membrane phospholipids. To test

this, we performed the same experiments in the presence of platensimycin (Fig. 5a right), a

FabF inhibitor that blocks FASII synthesis independently of FabT [24]. WT and mFabT strains

grew similarly in the presence of C17:1 and platensimycin (Supplementary Table 6), and C17:1

was the major membrane FA in both strains (Fig. 5a). In conclusion, the FabT[H105Y] mutant is

less responsive to environmental FAs than the WT strain. Poor eFA incorporation in mFabT

phospholipids is thus due to continued expression of FASII genes.

De novo **emergence of *fabT* mutants in saturated FA environments**

We hypothesized that the defect in eFA incorporation could actually confer a growth advantage

to the mFabT strain in toxic lipid environments, and thereby point to conditions of *fabT* mutant

emergence. Indeed, FA incorporation can negatively affect bacterial integrity, and free FAs are considered part of the first line of host defense against skin infections [25]. Notably, increased C18:0 levels in the mFabT mutant compared to WT ([2]; Supplementary Table 1) led us to examine saturated FAs as potential selective pressure for *fabT* emergence. WT and mFabT growth and eFA incorporation were then compared in the presence of C14:0 and C16:0, both of which are found among host lipids [26]. Both FAs inhibited WT growth, and were nonetheless efficiently incorporated in WT membranes; in striking contrast, mFabT failed to incorporate C14:0, and incorporated >2-fold less C16:0, while strain growth was robust (Fig. 5b-c). This growth advantage incited us to consider that spontaneous *fabT* mutants could emerge in the presence of saturated FAs.

As proof of concept, we grew the WT strain in THY liquid medium without or with C14:0, and then streaked cultures on solid medium containing C14:0. Single colonies appeared on this medium, and *fabT* genes were sequenced. Mutations in *fabT* were obtained in both selection procedures, and encoded FabT variants FabT^{T65M} and FabT^{G99S} (Supplementary Fig. 1b-c). Both variants were also identified in a primate infection study [5]. These results provide a rationale for emergence of *fabT* mutants, by generating a growth advantage in lipid-containing biotopes as likely present at the infection locus.

Evidence that eFA exclusion by mFabT confers a growth advantage in a simulated muscle biotope

We hypothesized that *fabT* mutations could provide a transient advantage in lipid-rich biotopes, which would explain their emergence in muscle [5]. An *ex vivo* model was devised to assess effects of muscle on GAS growth. For this, commercial organic 15 % fat meat, *i.e.*, muscle from cattle, was placed on lawns of WT$^{eryR\text{-}igfp}$ and mFabT$^{eryR\text{-}igfp}$. Remarkably, WT strains

developed a weak inhibitory halo surrounding the muscle samples. In strong contrast, the mFabT strain grew directly and vigorously around muscle sources (Fig. 5d).

This result is consistent with growth inhibition of WT but not mFabT GAS, notably by saturated eFAs (Fig. 5b). To confirm that vigorous growth of mFabT around muscle relates to its lower incorporation of FAs from muscle lipids, we tested the effects of adding the FASII inhibitor platensimycin to growth medium and plates. All media contained C17:1, which is incorporated and allows mFabT growth in the presence of the FASII inhibitor (Fig. 5a, Supplementary Table 6). As in Fig. 5d, mFabT growth was robust around muscle sources in the absence of FASII inhibitor (Fig. 5e, upper). In contrast, growth was strongly inhibited around the muscle source when platensimycin was present (Fig 5e lower). The marked inhibitory effect of the muscle sample on the *fabT* mutant when FASII is blocked gives strong evidence that incorporation of muscle lipids negatively affects GAS growth. We conclude that continued FASII activity in mFabT mutants reduces eFA incorporation and thus protects bacteria from toxicity of host lipids as present in muscle biotopes.

Discussion

Our work establishes the causal origin for *fabT* mutation emergence and provides an explanation for its disappearance during invasion (Fig. 6): GAS is genetically designed to incorporate eFA from lipid-containing environments, and repress FASII. We showed that WT GAS growth is inhibited by saturated FAs in such environments. Counter-selection can lead to emergence and outgrowth of *fabT* mutants, which explains their detection at a non-invasive step of infection [5]. At this step, the *fabT* mutation would confer a transient advantage over non-mutant strains. We first showed the *fabT* growth advantage, and mutant emergence, using C14:0 selection. We then demonstrated that the lipid-rich muscle environment promotes *fabT* mutant growth in a FASII-dependent manner, while inhibiting the WT strain. However, the *fabT*

mutation has a cost for virulence: it results in higher mortality and a multiplication defect in the

presence of human cells, which is confirmed on human decidua tissue. Continued FASII

activity in *fabT* mutant strains provokes a state of futile bacterial metabolism where increased

metabolite uptake does not lead to improved growth.

Our findings indicate that futile FASII synthesis by mFabT is detrimental for GAS

virulence. We showed previously that blocking FASII with antibiotic inhibitors, mutation, or

deletion did not prevent infection by *Streptococcus agalactiae*, nor by other Firmicute

pathogens [27-29]. FASII inhibition and eFA incorporation in phospholipids corresponds to the

natural feedback inhibition in response to eFAs [3,27]. The contrary, *i.e.*, making FASII synthesis

constitutive by inhibiting FabT, is detrimental for *in vivo* infection. FabT is thus a promising

target for new therapeutics against specific Gram-positive pathogens including GAS, *S.*

agalactiae, *S. pneumoniae*, and *E. faecalis*.

Methods

Bacterial strains and culture conditions

The strains used in this study are described in Supplementary Table 7. GAS strains were grown under static condition at 37 °C in Todd Hewitt broth supplemented with 0.2 % Yeast Extract (THY) or on THY agar (THYA) plates, or in brain heart infusion (BHI) liquid or agar medium when specified. Medium was supplemented with 0.1 % Tween 80 (THY-Tween; Sigma-Aldrich, Ref. P1754) as indicated, as a source of C18:1Δ9. THY was also supplemented with the saturated FAs, C14:0 and C16:0, in the presence of FA-free bovine serum albumin, 1 mg.ml^{-1} (Sigma-Aldrich, Ref. A6003) Where indicated, the FASII inhibitor platensimycin (Tebubio, France) was added at (1 µg/ml). For WT$^{eryR\text{-}igfp}$ and mFabT$^{eryR\text{-}igfp}$ (Supplementary Table 7) strains, medium was supplemented with 5 or 10 µg.ml^{-1} of erythromycin as specified. Strains were prepared as follows, unless specified otherwise: overnight cultures were diluted to an $OD_{600} = 0.05$ and grown in THY to the exponential phase (OD_{600} comprised between 0.4 and 0.5). For GFP expression, exponential-phase bacteria were further diluted to $OD_{600} = 0.1$ in THY supplemented with 10 µg.ml^{-1} erythromycin, and 20 ng.ml^{-1} anhydrotetracycline to induce GFP expression, grown for 90 min at 37 °C, and diluted in RPMI as indicated below. For growth in saturated FAs, WT and mFabT THY precultures were diluted in THY or THY-C14:0 or THY-C16:0 to $OD_{600} = 0.05$, transferred to 50 mL falcon tubes, and incubated at 37 °C. Growth was determined by OD_{600} readings at designated time points.

Strain construction

Primers used for cloning and strain verification are described in Supplementary Table 8. The ΔFabT strain corresponds to a *fabT* deleted mutant. It was obtained by homologous recombination of the plasmid pG1-ΔFabT following a published protocol [30,31]. The DNA fragments encompassing *fabT* were cloned in BamHI – EcoRI digested pG1 using the In Fusion

cloning kit® (Clonetech). This led to the deletion of *fabT* from nucleotides 49 to 389, as confirmed by PCR. The mFabT[eryR-igfp] strain harboring an integrated inducible *gfp* gene was constructed as described for the WT[eryR-igfp] strain [22]. Whole genome sequencing was performed on the mFabT and mFabT[eryR-igfp] constructed strains, and no surreptitious mutations were found (Bioproject PRJNA926803, accession number SAMN34247893 for mFabT, SAMN34247911 for mFabT[eryR-igfp]).

Fatty acid analysis

Strains were grown until OD_{600} = 0.4 - 0.5. Fatty acids were extracted and analyzed as described [2,13,27-29]. Briefly, analyses were performed in a split-splitless injection mode on an AutoSystem XL Gas Chromatograph (Perkin-Elmer) equipped with a ZB-Wax capillary column (30 m x 0.25 mm x 0.25 mm; Phenomenex, France). Data were recorded and analyzed by TotalChrom Workstation (Perkin-Elmer). FA peaks were detected between 12 and 40 min of elution, and identified by comparing to retention times of purified esterified FA standards (Mixture ME100, Larodan, Sweden). Results are shown as percent of the specific FA compared to total peak areas (TotalChrom Workstation; Perkin Elmer).

Lipid analysis

Strains were grown as 200 ml cultures in THY or THY-Tween until OD_{600} = 0.4 - 0.5. Lipid extractions and identifications were performed as described [28,32-34]. Lipid separation was realized by normal phase HPLC (U3000 ThermoFisher Scientific) using a Inertsil Si 5μm column (150 x 2.1 mm I.D.) from GL Sciences Inc (Tokyo, Japan). Lipids were quantified using a Corona-CAD Ultra and identified by mass-spectrometry negative ionization and MS^2/MS^3 fragmentations (LTQ-Orbitrap Velos Pro). The concentration of each lipid class was determined as described using as standards DGDG, 840524P-5MG; MGDG, 840523P-5MG;

CL (heart CA), 840012P-25MG; PG (egg), 841138P-25MG [35]. Lipid spectra were analyzed on

Xcalibur^{TM} software (ThermoFisher Scientific, version 4.2.47). Lipid concentrations are

presented as milligrams per $OD_{600} = 100$ for all samples.

Polymyxin B assay

Polymyxin B sensitivity was assayed as described [5]. Bacteria were grown to $OD_{600} = 0.4 - 0.5$

in THY or THY-Tween. Serial dilutions were prepared in PBS, and 2.5 µl of each dilution was

inoculated onto THY or THY-Tween plates containing or not 20 µg.ml^{-1} polymyxin B (Sigma-

Aldrich, Ref. 81271). Plates were incubated at 37 °C for approximately 24 h and photographed.

Experiments were done in biological triplicates.

In silico analysis

Geneious prime Biomatters development, www.geneious.com was used to identify 5'-

ANTTTGATTATCAAATT-3', the putative FabT binding sequence, on the M28PF1 genome,

accepting up to 2 mismatches.

RNA isolation and Illumina RNA-seq sequencing

GAS strains were cultured at 37°C in THY or THY-Tween, and cells were harvested during

exponential growth (OD_{600} between 0.4 and 0.5). Independent triplicate cultures were prepared

for each condition. For RNA preparation, 2 volumes of RNA protect* (Qiagen) was added to

cultures prior centrifugation (10 min 12,000 g) and total RNA was extracted after lysing

bacteria by a 30 min 15 mg.ml^{-1} lysozyme, 300 U.ml^{-1} mutanolysin treatment at 20°C followed

by two cycles of Fast-prep (power 6, 30 s) at 4 °C. RNA extraction (Macherey-Nagel RNA

extraction kit; Germany) was done according to supplier instructions. RNA integrity was

analyzed using an Agilent Bioanalyzer (Agilent Biotechnologies, Ca., USA). 23S and 16S

rRNA were depleted from the samples using the MICROBExpress Bacterial mRNA enrichment

kit (Invitrogen, France); depletion was controlled on Agilent Bioanalyzer (Agilent

Biotechnologies). Libraries were prepared using an Illumina TS kit. Libraries were sequenced

generating 10,000,000 to 20,000,000 75-bp-long reads per sample.

RNA-Seq data analysis

The MGAS6180 strain sequence (NCBI), which is nearly identical to M28PF1 [12,20], was used

as a reference sequence to map sequencing reads using the STAR software (2.5.2b)

BIOCONDA (Anaconda Inc). RNA-seq data were analyzed using the *hclust* function and a

principal component analysis in R 3.5.1 (version 2018-07-02). For differential expression

analysis, normalization and statistical analyses were performed using the SARTools package

and DESeq2 [36,37] *p*-values were calculated and adjusted for multiple testing using the false

discovery rate controlling procedure [38]. We used UpsetR to visualize set intersections in a

matrix layout comprising the mFabT *versus* the WT strain grown in THY and in THY-Tween,

and growth in THY-Tween *versus* THY for each strain [39,40].

Ex vivo **GAS growth capacity analysis**

Human placentas with attached maternal-fetal membranes were collected and processed as

described [22] with the following modifications. Tissues were obtained after vaginal delivery, and

the samples used were from regions located far from the cervix, known as zone of intact

morphology [41]. Human decidual explants were infected within hours of their reception.

Ex vivo bacterial growth capacity in the presence of decidua human tissue was done as

follows: exponentially growing GFP-expressing bacteria were washed twice in PBS and diluted

in RPMI at a final concentration of 10^4 bacteria per ml. Decidua tissue were washed twice in

PBS. One ml of bacteria were then added to tissue, followed by incubation at 37°C + 5 % CO_2.

After 8 h, the tissues were shredded using Precellys Evolution (Bertin Technologies) (6 x 20 s

at 5500 rpm with a 20 s pause between shaking). Serial dilutions of shredded material were

plated on THYA plates. The number of cfus was determined after 24 h of growth at 37 °C and

normalized to the inoculum for each experiment.

Live bacterial multiplication on human tissue: infection of maternal-fetal explants, image

acquisition and treatments were realized as described [22].

Study approval

425 The study of the human maternal-fetal membranes was approved by the local ethics committee

426 (Comité de Protection des Personnes Ile de France III, no. Am5724-1-COL2991, 05/02/2013).

427 All participants provided written informed consent prior to inclusion in the study at the

428 Department of Obstetrics, Port Royal Maternity, Cochin University Hospital, Paris, France.

Cell culture

HEC-1-A (ATCC_ HTB-112TM) endometrial epithelial cells were cultured as recommended,

in McCoy's 5A medium (Gibco, Ref. 26600080) supplemented with 10 % fetal bovine serum

at 37 °C, 5 % of CO_2. HaCaT (Addex-Bio T0020001) keratinocytes were cultivated as

recommended, in DMEM high glucose medium (Gibco, Ref. 31966) supplemented with 10 %

fetal bovine serum at 37 °C, 5 % of CO_2. HaCaT cells were maintained in the undifferentiated

state by cultivation in poor DMEM medium (Gibco, Ref. 21068-028) supplemented with 1X

glutaMax (Gibco, Ref. 35050-038), 1X sodium pyruvate (Gibco, Ref. 11360-039), 2 % fetal

bovine serum and 8 % chelated fetal bovine serum using Chelex® 100 Resin (BioRad, Ref. 142-

1253). To differentiate HaCaT cells, 2.8 mM $CaCl_2$ (Sigma-Aldrich, Ref. 21115) was added to

the medium. Cells were differentiated after seven days as previously described and checked by

microscopy [42].

Bacterial adhesion capacity

GAS adhesion capacity was evaluated as described after growing bacteria in THY to an OD_{600} of 0.4 to 0.5 [30]. Values were normalized to the inoculum for each experiment.

Bacterial growth capacity in the presence of eukaryotic cells or culture supernatants

GAS were cultured in THY to $OD_{600} = 0.4 - 0.5$. Bacteria were washed twice in PBS and diluted in RPMI medium without glutamine (Gibco, Ref. 32404-014) to infect cell cultures or inoculate filtered cell culture supernatants (conditioned supernatants) at a final concentration of 10^3 and 10^4 bacteria per ml, respectively. Confluent cells in 24-well plates were starved 24 h before the experiment, *i.e.* incubated in RPMI medium without glutamine, and washed twice in PBS. Cells were infected with 1 ml of bacteria and incubated at 37 °C + 5 % CO_2. After 8 h, supernatants were recovered and cells were lysed with 1 ml distilled water. The fractions were pooled and serial dilutions plated on THYA plates. Conditioned supernatants were prepared by incubating cells in 1 ml RPMI at 37°C + 5 % CO_2 for 8 h. The conditioned supernatant was recovered, inoculated with 10^3 bacteria, and incubated for another 4, 8, 16 or 24 h. Serial dilutions were plated on THYA plates. The number of cfus was determined after 24 h of growth at 37 °C and normalized to the inoculum for each experiment.

Live / dead analysis

After bacterial growth in the HEC-1-A conditioned supernatant during 8 h, bacterial Bacterial mortality was determined using the LIVE/DEAD® BacLightTM Bacterial Viability Kit (ThermoFischer Scientific, Ref. L7012) as described for flow cytometry utilization using an ACCURI C6 cytometer (BD Biosciences, Le pont de Claix,France) from the CYBIO Core

Facility. Bacteria were grown in HEC-1-A conditioned supernatant for 8 h for testing. Results

of three independent experiments were analyzed using the BD Accuri C6 software.

Metabolomic analysis

HEC-1-A conditioned supernatants were inoculated or not with WT or mFabT strains during 8

or 16 h and prepared as described above (see 'Bacterial growth capacity in the presence of

eukaryotic cells or culture supernatants'). The metabolite composition of these supernatants

was analyzed by Proteigene (https://proteigene.com) using MxP® Quant 500 kit (Biocrates) by

two analytical methods, LC-MS/MS for small molecules and FIA-MS/MS for lipids. This

analysis was repeated on 3 independent series of supernatants and on RPMI. These analyses

have a defined detection threshold (LOD) for each family of metabolite.

Spontaneous *fabT* mutant isolation

WT strain overnight precultures were diluted either in THY or in THY-C14:0 supplemented

with BSA 0.025 %. When the THY culture reached mid-exponential phase, (OD$_{600}$ = 0.4 - 0.5),

both cultures were streaked on THYA supplemented with C14:0 (THYA-C14:0). Plates were

incubated 60 h at 37°C. Colonies were isolated on THYA-C14:0, and isolated colonies were

subsequently grown on THYA. Six and eight clones originating from the THY and the THY-

C14:0 liquid media, respectively, were used for *fabT* sequencing PCR was performed directly

on patched colonies. The oligonucleotides used were FabT-222, and FabTavComp,

(Supplementary Table 8) binding 221 bp 5' from the T of the TTG translation start site and 565

bp downstream of it, respectively. The *fabT* gene and surrounding sequences were amplified

by PCR using the Green Taq DNA Polymerase, GenScript, according to the manufacturer's

instruction, with 30 cycles with a hybridizing temperature of 50°C and an elongation time of 1

min. The Sanger sequencing was carried out by Eurofin Genomics

(https://eurofinsgenomics.eu/en/custom-dna-sequencing/portfolio-overview/)   on   PCR

products.

***Ex vivo* assessment of GAS WT and mFabT growth on muscle (meat) lipids**

WT$^{eryR\text{-}igfp}$ and mFabT$^{eryR\text{-}igfp}$ strains (Supplementary Table 7) [22] were grown overnight in BHI

(Ery 5), and then diluted to $OD_{600} = 0.05$ in FA-free bovine serum albumin (referred to as BSA;

0.025%) plus C17:1 100 µM in 1 ml, without or with platensimycin 1 µg/ml, with Ery 5 for

selection. After 4 h growth, culture densities were adjusted to $OD_{600} = 1$ in BHI, and 35 µl were

spread on 5 cm diameter plates containing 5 ml BHI agar plus BSA 0.025% and C17:1 100 µM,

without or with platensimycin 0.5 µg/ml, with Ery 5 for selection. The muscle samples used

were from organic cattle meat bought frozen and pre-ground, containing 15% fat (Picard,

France). Absence of contaminants was checked by plating without bacteria. Samples were

placed directly on the lawns, and plates were incubated 48 h at 37°C, and photographed. N=4

for experiments without platensimycin, and N=2 for those with platensimycin.

Statistical analysis

Data were analyzed with GraphPad Prism version 9.4.1. The tests used are indicated in figure

legends. Statistical significance is indicated by: ns (not significant, $p > 0.05$); *, $p < 0.05$; **, p

< 0.01; ***, $p < 0.001$; ****, $p < 0.0001$.

Acknowledgments

Expert assistance of Benjamin Saint-Pierre (Genom'IC facility of the Institut Cochin) with transcriptomic experiments is gratefully acknowledged. We thank Alice d'Orfani, Lauryn Moali, Iman Nasr and Laure Detheve, undergraduates in the laboratory for technical help, the Imag'IC and Cybio core facilities of the Institut Cochin, and Cédric Broussard, Virginie Salnot and François Guillonneau for helpful discussions. Jamila Anba-Mondoloni (Micalis Institute) provided valuable comments and suggestions on this work. We also thank the personnel of the CIC Mère-Enfant Cochin-Necker for the human decidua. We acknowledge the use of Alphafold and ChimeraX for FabT *in silico* design, and BioRender for computer-generated models.

Funding

CL was supported by Université Paris Cité (BioSPC, n°51809666), FRM (FDT202106012831) and FEMS (FEMS Congress Attendance Grant for poster n° 7875 in 2021 and FEMS grant - LISSSD 2022 n° LISS-213065). Figure legends

Fig. 1 │FA differences in WT and mFabT strains impact lipid content and composition.
a, b, HPLC-MS profiles represent the main lipid classes in WT and mFabT grown in indicated media; lipid profiles and quantifications by class. Lipid concentrations correspond to mg extracted from $OD_{600}=100$ culture. MGDG, monoglucosyldiacylglycerol; DGDG, diglucosyldiacylglycerol ; PG, phosphatidylglycerol; CL, cardiolipin (Supplementary Table 3). **c, d, e** CL species in WT and mFabT, showing deoxidized cardiolipin (deoxy-CL) species (indicated by a 'd' preceding the identification name; see Supplementary Table 2); **a-b,** N=4; **c-d,** N=3. **a, b, e,** 2-way ANOVA, Bonferroni post-test, **p<0.01; ***p<0.001. **f,** Polymyxin B sensitivity. WT and mFabT were precultured to $OD_{600} = 0.5$ in THY or THY-Tween and dilutions were spotted on the same respective solid medium supplemented or not with polymyxin B (PB). Plates are representative of 3 independent experiments. **a-d**, NL, normalization level; WT, white bars; mFabT, green bars.

Fig. 2 │FabT regulon in the presence of eFAs and genetic organization of the GAS FASII genes. a-Schematic representation of the GAS FabT regulon, comprising FASII locus and *fakB4* genes. Gene positions with names below are represented. Red asterisks, putative FabT binding sites; bent arrows, transcription start sites; solid arrow, transcript defined by RT-PCRs; dotted arrows, transcripts [18]. **b-e**, Volcano plots of differentially expressed genes, compared as indicated. Volcano plots were constructed using GraphPad Prism, by plotting the negative base 10 logarithm of the p value on the y axis, and the log of the fold change (base 2) on the x axis. P-values for comparisons of peak intensities were calculated by t-tests. Padj: calculated p-values were adjusted for multiple testing using the false discovery rate controlling procedure (see Methods section). Gene expression was considered modified in a given condition when the absolute value of log2-Foldchange (FC) was greater than or equal to 1, with an adjusted p-value ≤ 0.05. Data points with low p-values (highly significant) appear at the top of the plot.

Growth experiments were started with 10^3 bacteria per ml. Determinations were based on N=5 for **a**, N=3 for **b, c, g,** N=9, 7, 7 for d (left to right), N=11, 9, 6 for e (left to right) and N=8, 7, 9 for f (left to right). Analyses were done by T test and Wilcoxon test for **a, d-f** and

2-way ANOVA, Bonferroni post-test for **b**, **c**, **g**; *p<0.05; **p<0.01; ***p<0.001; ****p<0.0001. **d-g:** WT, white bars; mFabT, green bars.

Fig. 4 │ The mFabT strain is more energy-consuming than the WT strain. Metabolomic analysis of conditioned supernatants and conditioned supernatants inoculated with WT or mFabT after 8 or 16 h incubation. Carbohydrate and amino acid consumption by the mFabT strain (also see Supplementary Table 5). N=3, 2-way ANOVA, Bonferroni post-test; *p<0.05; **p<0.01; ***p<0.005; p-values just above the p=0.05 threshold are indicated. Strains and growth times are at right.

Fig. 5 │ The eFA incorporation defect of mFabT confers a selective advantage in saturated eFA environments, and in a simulated muscle biotope. a, FA membrane composition of WT and mFabT strains grown in THY-C17:1 (100 μM), containing or not the FASII-inhibitor platensimycin (1 μg/mL^{-1}). Left, FA profiles; right, quantified proportions of major FAs. Both strains grew in the presence of C17:1 regardless of the presence of platensimycin (Supplementary Table 6). **b,** Growth of WT (left), and mFabT (right) in THY supplemented with 100 μM saturated FAs, C14:0 or C16:0. **c, Left,** Incorporation of exogenous C14:0 and C16:0 from cultures described in '**b**'. **Right**, Percent C14:0 and C16:0 incorporation from growth experiments at left. For these analyses, N=3, 2-way ANOVA, Bonferroni post-test, *p<0.05; **p<0.01; ***p<0.001. WT (black lines, white bars) and mFabT (green lines and bars). **d-e,** The indicated strains were spread on solid agar. Pellets of organic ground bovine meat (~15 % fat) were used as muscle source, and were placed on the bacterial lawns. Plates were photographed 36 h after incubation at 37°C. Arrowheads indicate zones of inhibition (black) or growth (white) around muscle sources. N=4. **d, Upper,**WT*eryR-igfp* and mFabT*eryR-igfp* strains were grown in BHI ery5, and plated on the same solid medium. **Lower**, schematic representation of GAS strain growth inhibition and stimulation by muscle. **e,** mFabT*eryR-igfp* was grown in BHI ery5 medium containing C17:1 as FA source, without or with platensimycin to turn off FASII. Cultures were then plated on respectively the same solid medium. N =2.

Fig. 6 │ Model for emergence of *fabT* mutants that are attenuated for virulence. a, Saturated FAs (SFAs) in a lipid environment favor mFabT emergence. Toxic FAs may be present in initial GAS contacts with the host. Counter-selection would lead to emergence of FA-insensitive *fabT* mutants, conferring a growth advantage. In a proof of concept, we show that *fabT* mutants are selected in an SFA environment. **b, Host cell environment during invasion hinders mFabT growth**. Compared to the WT, *fabT* mutant bacteria fail to develop and die more rapidly when exposed to human cells; they are also impaired for adhesion. Continued FASII activity in *fabT* mutants provokes a state of futile bacterial metabolism where metabolite uptake is stimulated, but does not lead to improved growth. Thus, *fabT* mutants in GAS populations may confer a survival advantage at the inoculation site, but do not withstand host cell infection conditions. Mauve and green circles, WT and mFabT cocci; zoom is on phospholipids. Small yellow circles and lines, lipids and eFA hydrolysis products respectively, small red, blue, pink circles, sugars and amino acid residues. Figure was drawn using BioRender (BioRender.com).

Supplementary Figures

Supplementary Fig. 1│FabT regulator and FASII pathway in GAS. a, The FASII synthesis pathway comprises a first initiation phase for precursor synthesis, followed by the recursive elongation cycle. The final product, acyl-ACP (acyl-Acyl Carrier Protein), supplies FAs for phospholipid synthesis. FabM (orange) leads to unsaturated FAs; FabK products are saturated. Initiation phase and elongation cycle enzymes are represented in green and red, respectively. **b,** FabT sequence; amino acids involved in DNA binding are in red, and those interacting with acyl-ACP are in blue. Arrow indicates the His105Tyr mutation studied in this work. Magenta star highlights amino acids spontaneously mutated *in vivo* and in a saturated-FA environment (this work). **c,** Overall structure of FabT dimer predicted by Alphafold and adapted with ChimeraX (see references 1-2 in Supplementary Methods); one monomer is represented as multicolored (each color designates a separate domain), and the other is beige. Residues Thr64, Gly99 and His105, in magenta, correspond to mutants obtained in this study.

Supplementary Fig. 2│Impact of FabT mutations on GAS growth. a-b, Live/Dead bacteria, tests, using the LIVE/DEAD® BacLightTM Bacterial Viability Kit, performed on WT and mFabT cultures after growth in the indicated media to $OD_{600} = 0.4 - 0.5$. **c-d,** Growth curves of WT and Δ*fabT* strains in the indicated media. **e,** Ratios of OD_{600} of WT or mFabT strains after 8 h over respective initial inocula (10^3/ml for each) in RPMI medium; ratio below 1 indicates that bacteria die. **a-d** N=3; **e** N=10; differences in **a, b,** and **e** were not statistically significant using T-test. WT, white bars; mFabT, green bars.

Supplementary Fig. 3│ Phospholipid membrane composition. Identification of **a,** monoglucosyldiacylglycerol (MGDG), **b,** diglucosyldiacylglycerol (DGDG), **c,** phosphatidylglycerol (PG), **d,** cardiolipin (CL) and **e,** deoxidized cardiolipin (Deoxy-CL). Lipids are presented as the percentage of each class to the total lipids, and are quantified in Supplementary Table 2. Statistical values were determined using 2-way ANOVA, Bonferroni post-test. *$p<0.05$; **$p<0.01$; ***$p<0.001$; ****$p<0.0001$. Strains were grown in THY (open bars) and THY-Tween (hatched bars). WT, black lines and white bars; mFabT, green lines and bars.

Supplementary Fig. 4│mRNA transcript analysis of FASII locus genes. Agarose gel of PCR amplification products on cDNA using primer pairs from neighboring genes. MW, molecular weight reference (Generuler 100 bp, ThermoFisher Scientific). Lane 1, *fabM-fabT* (234 bp); 2, *fabH-acpA* (221 bp); 3, *acpA-fabK* (302 bp); 4, *fabZ-accC* (105 bp); 5, *accD-serS* (288 bp). Results confirm the FASII transcriptional units indicated in Fig. 2a.

Supplementary Fig. 5│ Carbohydrates and amino acid residues produced by human endometrial cells. Metabolomic analysis of RPMI and HEC-1-A conditioned supernatants, as per legend at right on figure. (see Supplementary Table 5 for complete data). N=3, 2-way ANOVA, Bonferroni post-test; *$p<0.05$; ***$p<0.005$; ****$p<0.001$.

Supplementary Methods

FabT modelling. Overall structure of FabT dimer (supplementary Figure 1) was predicted by Alphafold [1]. We used UCSF ChimeraX [2] for molecular graphics and further analyses. ChimeraX was developed by the Resource for Biocomputing, Visualization, and Informatics at the University of California, San Francisco, with support from NIH R01-GM129325 and the Office of Cyber Infrastructure and Computational Biology, NIAID.

Live - dead analysis. Bacterial mortality was determined using the LIVE/DEAD® BacLightTM Bacterial Viability Kit (ThermoFisher Scientific, Ref. L7012) as described for flow cytometry utilization using an ACCURI C6 cytometer (BD Biosciences, Le pont de Claix, France) from the CYBIO Core Facility. Bacteria were grown in HEC-1-A conditioned supernatant for 8 h for testing. Results of three independent experiments were analyzed using the BD Accuri C6 software.

Growth curves. GAS stationary precultures were diluted in THY or THY-Tween to an OD_{600} = 0.05, and transferred to 96-well plates, which were incubated at 37 °C in a Thermo Scientific Multiskan GO (ThermoFischer Scientific). Growth was determined by shaking plates immediately before measuring absorbance at OD_{600} every 10 min.

GAS growth capacity analysis in RPMI. GAS bacteria were grown in THY to an $OD_{600} =$ 0.4 to 0.5. Cultures were washed twice in PBS and diluted in RPMI medium without glutamine (Gibco, Ref. 32404-014) to a final concentration of 10^3 bacteria per ml, and then incubated at 37°C + 5 % CO_2 for 8 h. Serial dilutions were plated on THYA solid medium. Cfus were determined after 24 h growth at 37 °C and normalized to the inoculum for each experiment.

Screening for FA sensitivity on solid medium. Overnight WT and mFabT cultures were grown starting from single colonies on solid medium containing 0.5% bovine serum albumin. Cultures were then adjusted to $OD_{600} = 0.1$, and 100 µl was spread as a lawn on plates. Four µl (0.1 µm) of each FA (25 mM stocks) were deposited. Plates were incubated 24 h at 37°C and photographed.
