Abstract

Two different models have been proposed to explain how the endpoints of chromatin looped domains ("TADs") in eukaryotic chromosomes are determined. In the first, a cohesin complex extrudes a loop until it encounters a boundary element roadblock, generating a stem-loop. In this model, boundaries are functionally autonomous: they have an intrinsic ability to halt the movement of incoming cohesin complexes that is independent of the properties of neighboring boundaries. In the second, loops are generated by boundary:boundary pairing. In this model, boundaries are functionally non-autonomous, and their ability to form a loop depends upon how well they match with their neighbors. Moreover, unlike the loop-extrusion model, pairing interactions can generate both stem-loops and circle-loops. We have used a combination of MicroC to analyze how TADs are organized, and experimental manipulations of the *even skipped* TAD boundary, *homie*, to test the predictions of the "loop-extrusion" and the "boundary-pairing" models. Our findings are incompatible with the loop-extrusion model and instead suggest that the endpoints of TADs in flies are determined by a mechanism in which boundary elements physically pair with their partners, either head-to-head or head-to-tail, with varying degrees of specificity. Although our experiments do not address how partners find each other, the mechanism is unlikely to require loop extrusion.

Introduction

The chromosomes of multicellular animals have a regular and inheritable physical organization. This was first recognized in studies on the lampbrush chromosomes in amphibian oocytes and the polytene chromosomes of insects (Callan 1963; Nora et al. 2020; Zhimulev and Belyaeva 1991; Zhimulev et al. 1983). Subsequent research has shown that the architectural features inferred from analysis of lampbrush and polytene chromosomes are present in chromosomes throughout much of the animal kingdom. The key organizational principle is the subdivision of the chromatin fiber into a series of independent looped domains, commonly called "TADs" (Cavalheiro et al. 2021; Chetverina et al. 2017; Jerković et al. 2020; Matthews and White 2019; Rowley and Corces 2018). With important exceptions, the arrangement of TADs along a given chromosome tend to be invariant and are largely independent of the cell type or developmental stage. This regular and inheritable organization is a reflection of the underlying mechanism of TAD formation. TADs are separated from each other by special elements called boundaries or insulators. While these elements have been found in many different species, they have been most fully characterized in *Drosophila* (Cavalheiro et al. 2021; Chetverina et al. 2017). Fly boundaries span DNA sequences of 150 bp to 1.5 kb in length and contain one or more nucleosome-free nuclease-hypersensitive regions. These nuclease-hypersensitive regions are targets for a large collection of DNA binding proteins that have been implicated in boundary function. Some of the fly boundary factors are widely conserved (CTCF, BEN family proteins, GAF), while others appear to be restricted to insect linages (Su(Hw), Pita, Zw5, Zipic, Mod(mdg4), BEAF) (Heger et al. 2013; Heger and Wiehe 2014; Schoborg and Labrador 2010).

Boundary elements in flies are not only responsible for organizing the chromatin fiber, they also have genetic activities. When interposed between enhancers or silencers and target promoters, boundary elements block regulatory interactions (Bell et al. 2001; Chetverina et al.

2014; Chetverina et al. 2017). This insulating activity provides a mechanism for delimiting units of independent gene activity: genes located between a pair of compatible boundaries are subject to regulatory interactions with enhancers/silencers present in the same chromosomal interval, while they are insulated from the effects of enhancers/silencers located beyond either boundary in adjacent neighborhoods. Genetic studies suggest that the insulating activity of boundary elements is a consequence of subdividing the chromosome into a series of topologically independent domains (Cai and Shen 2001; Gohl et al. 2011; Muravyova et al. 2001). Organizing the chromatin fiber into looped domains enhances contacts between sequences within the loop, while it suppresses contacts with sequences outside of the loop. While it is not known whether a similar insulation mechanism is at play in mammals, the fact that mammalian chromosomes are also subdivided into TADs by boundary-like elements suggests that it might be.

A critical question in chromosome biology is the mechanism(s) responsible for determining the endpoints of the loop domains, the TADs. In mammals, a novel loop-extrusion model has been proposed to not only generate chromosomal loops but also determine the endpoints of those loops (Alipour and Marko 2012; Fudenberg et al. 2016; Guo et al. 2012; Guo et al. 2015; Nuebler et al. 2018; Sanborn et al. 2015). In this model, a cohesin complex initiates loop formation at a loading site within the "loop-to-be" and then extrudes a chromatin loop until it bumps into CTCF-dependent roadblocks, one on each side of the extruding loop. The location of these roadblocks combined with the processive action of the cohesin complex determines the endpoints of each TAD (Davidson and Peters 2021; Ghosh and Meyer 2021; Mirny and Dekker 2022; Perea-Resa et al. 2021). A key assumption of the loop-extrusion model is that mammalian boundaries are fully autonomous: they are roadblocks, and their physical presence in and of itself is sufficient to define the loop endpoint, independent of the functional properties of neighboring boundaries. In a more specific variant of this model, the relative orientation of the paired CTCF

roadblocks is also important—in order to halt cohesin-mediated extrusion, the CTCF sites on each side of the loop must have a convergent orientation. In this model the CTCF roadblocks are able to block an oncoming cohesin complex in only one direction; however, their intrinsic blocking activity is independent of the orientation of other CTCF sites in their neighborhood.

While this loop extrusion mechanism is widely thought to be operative in mammals, the evidence regarding TAD formation and function in flies is seemingly inconsistent with this mechanism. Genetics studies have shown that fly boundaries are functionally non-autonomous and that their activities in both loop formation and gene regulation depend upon their ability to engage in direct physical interactions with other boundaries (Chetverina et al. 2014; Chetverina et al. 2017). That fly boundaries might function by physical pairing was first suggested by studies which showed that the *gypsy* transposon *su(Hw)* boundary and the bithorax complex (BX-C) *Mcp* boundary can mediate regulatory interactions (enhancer/silencer: reporter) between transgenes inserted at sites separated by 15-32 MB or more (Muller et al. 1999; Sigrist and Pirrotta 1997; Vazquez et al. 1993). Consistent with direct physical interactions, these distant transgenes co-localize *in vivo*, and in living tissue remain in contact for extended periods of time (Chen et al. 2018; Li et al. 2011; Vazquez et al. 2006).

Some of the parameters that govern pairing interactions have been defined in two different transgene assays, insulator bypass and boundary competition. In one version of the bypass assay, a set of enhancers are placed upstream of two different reporters (Cai and Shen 2001; Kyrchanova et al. 2008a; Muravyova et al. 2001). When a single boundary is introduced between the enhancers and the closest reporter, the enhancers are unable to activate either reporter. However, if the same boundary is placed downstream of the closest reporter, bypass is observed. In this case the closest reporter, which is bracketed by the two boundaries, is still insulated from the enhancers; however, the downstream reporter is activated (Muravyova et al.

2001). Kyrchanova et al. (Kyrchanova et al. 2008a) showed that bypass activity is, in most cases, orientation-dependent. When the same boundary is placed in the upstream and downstream position, they typically need to be introduced in the opposite orientation. The reason for this is that self-pairing is head-to-head, and this configuration generates a stem-loop topology, bringing the upstream enhancers into close proximity to the downstream reporter. When the two boundaries are introduced in the same orientation, the enhancers do not activate the downstream reporter because a circle-loop rather than a stem-loop is formed (Chetverina et al. 2017; Kyrchanova et al. 2008a). Head-to-head pairing seems to be a common feature of self-pairing interactions between fly boundaries and was observed for *scs*, *scs'*, *iA2* and *wari* (Kyrchanova et al. 2008a). A preference for head-to-head interactions is also observed for heterologous pairing interactions between different boundaries in the *Abdominal-B* (*Abd-B*) region of the BX-C (Kyrchanova et al. 2011; Kyrchanova et al. 2008b). There are some exceptions. The BX-C *Fab-7* boundary pairs with itself and with its neighbor *Fab-8* in both orientations (Kyrchanova et al. 2011; Kyrchanova et al. 2008b). Bypass activity also seems to depend upon finding the proper match. For example, when multimerized dCTCF or Zw5 binding sites are placed both upstream and downstream of the closest reporter, bypass is observed. However, there is no bypass when multimerized dCTCF sites are tested with multimerized Zw5 sites (Kyrchanova et al. 2008a). Similar results have been reported for the Zipic and Pita factors (Zolotarev et al. 2016). Boundary:boundary pairing preferences are also observed in competition assays in which different boundaries are introduced into the same transgene (Gohl et al. 2011). In these assays, the insulating activity of a boundary in the blocking position (between an enhancer and a reporter that is flanked by a 3' boundary) is challenged by placing a heterologous boundary upstream of the enhancer. If the boundary upstream of the enhancer is a better match for the boundary located downstream of the reporter,

then the insulating activity of the boundary in the blocking position can be compromised or lost altogether. These and other experiments argue that fly boundaries are functionally non-autonomous—that is, their activities depend upon their ability to physically interact with other boundaries.

However, the differences between the two models are not limited to the mechanisms for determining the endpoints of TADs. The models also differ in the possible topologies of the chromatin loops that form TADs. Only two loop topologies can be generated by the cohesin-extrusion mechanism. One is a stem-loop while the other is an unanchored loop. Depending upon the location of the road-blocks that halt cohesin extrusion and the cohesin loading sites, the chromatin fiber would be organized into a series of stem-loops. These stem-loops will be separated from each other by unanchored loops (see Fig. 1B). This is the configuration that is often illustrated in articles discussing the loop-extrusion model. If the relevant road-blocks are very closely juxtaposed, then the unanchored connecting loops will disappear and be replaced by a series of stem-loops which point in opposite orientations, as illustrated in Fig. 1C. Stem-loops are also possible in the boundary-pairing model, and they will be formed when two heterologous boundaries pair with each other head-to-tail in *cis* (see Fig. 1D). Like loop-extrusion, the stem-loops could be separated from each other by unanchored loops (Fig. 1E). If the boundaries in the neighborhood pair with each other head-to-tail, a series of connected stem-loops pointing in opposite orientations will be generated. In this case, the main axis of the chromosome would be a series of paired boundaries (Fig. 1F).

Stem-loops are not, however, the only loop topology that can be generated in the boundary-pairing model. If the neighboring boundaries pair with each other head-to-head instead of head-to-tail, a circle-loop structure will be generated (Fig. 1G). Like stem-loops, the circle-loops could be connected by unanchored loops (Fig. 1H). Alternatively, if boundaries pair

with both neighbors head-to-head this will generate a series of linked circle-loops oriented in (more or less) the same direction (see Fig. 1I).

In the studies reported here, we have critically evaluated these two models. We have used a combination of MicroC to analyze how TADs are organized and experimental manipulations to test the predictions of the "loop-extrusion" and the "boundary-pairing" models. For these experimental manipulations, we have used the well-characterized *homie* boundary from the *even skipped* (*eve*) locus. *homie* together with *nhomie* flank the 16 kb *eve* locus, and these two elements share many of the properties of other fly boundaries (Fujioka et al. 2013; Fujioka et al. 2009). Like the *gypsy* and *Mcp* boundaries, *nhomie* and *homie* can mediate long-distance regulatory interactions. For example, a *lacZ* reporter transgene containing *homie* (or *nhomie*) inserted on one homolog can be activated by an *eve* enhancer in a *homie*- (or *nhomie*-) containing transgene inserted on the other homolog over a distance of 2 Mb (Fujioka et al. 2016). Long-distance activation is also observed in heterologous combinations of *nhomie* and *homie*, but not in combinations with phage *lambda* DNA. Similarly, regulatory interactions are observed when a *homie*- or *nhomie*-containing reporter is inserted at an attP landing site in the *hebe* gene, 142 kb upstream of the *eve* locus (Chen et al. 2018; Fujioka et al. 2016; Fujioka et al. 2009). In this case, the *eve* enhancers drive reporter expression during development in a pattern that mimics the stage- and tissue-specific expression of the endogenous *eve* gene. Activation also depends upon the orientation of the boundary (5'→3') relative to the reporter in the transgene. For *homie*, the reporter must be located "upstream" of the boundary (5'→3'), just like the *eve* enhancers (and *eve* gene) are "upstream" of endogenous *homie* (see Fig. 2B). Little or no activation is observed when the relative orientation is reversed so that the reporter is located "downstream" of *homie*. For *nhomie*, the reporter must be located "downstream", in the

same relative position as that in which the *eve* enhancers and *eve* gene are located with respect to endogenous *nhomie* (5'→3': Fig. 2B).

Results

The eve TAD

We used MicroC to probe the TAD organization of the *eve* locus and the genomic region that extends from *eve* to just beyond the attP site at –142 kb. For this purpose, we chose nuclear cycle 14 embryos. DNA replication commences soon after nuclei exit the previous mitosis and continues for nearly an hour until the nuclei arrest in G2, and the process of cellularization is completed. As sister chromosomes in flies pair with each other in register, there will be two juxtaposed copies of this region of the chromosome in most nuclei. The sister chromosomes should be linked to each other by cohesin in preparation for the asynchronous cellular divisions at the end of NC14 (Collier and Nasmyth 2022; Gligoris et al. 2014). While homolog pairing is limited in pre-cellular blastoderm embryos, there are regions of the chromosome that already show evidence of pairing (Erceg et al. 2019; Fung et al. 1998). In fact, transvection mediated by transgenes containing the *gypsy* insulator and the *homie* and *Fab-8* boundaries has been observed in live imaging studies of nuclear cycle 14 embryos (Lim et al. 2018). Since the NC14 nuclei are just emerging from an earlier mitosis and are undergoing DNA synthesis, one would imagine that other key features of chromosome organization might also be in the process of being established. Thus, it should be possible to capture evidence of intermediates like those expected to be generated by extruding cohesin complexes as they move through the *eve* TAD and other nearby loci at this stage of development.

Shown in Fig. 2A is a blow-up of the TAD organization of the *eve* locus. As expected, the left and right boundaries of the *eve* TAD correspond to *nhomie* and *homie*, respectively, and sequences containing these two boundaries converge at the apex of the *eve* interaction triangle. All of the sequences within the TAD appear to come into contact with each other and define a high density of internal contact domain (HDIC). These contacts are expected to be generated, at

least in part, by the sliding of the chromatin fiber within the TAD against itself, much like

sequences in circular/supercoiled DNA can interact with each other (Fig. 1E). There are also

sequences within the *eve* TAD that show enhanced interactions. For example, there is a darker

interaction triangle connecting *nhomie* and the promoter region, while another triangle connects

homie and the PRE adjacent to *homie* to the promoter region. These enhanced internal contacts

would be expected to help insulate the *eve* gene from external regulatory elements and at the

same time facilitate interactions between *eve* and its upstream and downstream enhancers.

As predicted by both the loop-extrusion and boundary-pairing models, the *eve* TAD is a

stem-loop, not a circle-loop (Fig. 2B). This is evident from the prominent "volcano plume" at

the apex of the *eve* TAD (volcano triangle). A volcano plume is observed because sequences

flanking *eve* are brought into close proximity when *homie* and *nhomie* are linked to each other by

either cohesin or by head-to-tail pairing (see Fig.1: see also Ke et al., 2024). Fig. Supplemental 1

shows the hierarchy of interactions between TADs to either side of *eve* (L-M, K-M and J-M in

Fig. Supplemental 1). This conclusion is supported by previous transgene studies. As first

described in the boundary bypass experiments of Cai and Shen (Cai and Shen 2001) and

Muravyova et al. (Muravyova et al. 2001), the formation of a stem-loop structure when two

boundaries are linked together brings sequences immediately beyond the linked boundaries into

close proximity with each other. In this assay, a stem-loop structure is required, as it enables

enhancers flanking the "upstream" boundary to interact with reporters flanking the downstream

boundary (Kyrchanova et al. 2008a). In contrast, a circle-loop configuration does not bring the

neighbors to either side of *eve* into close proximity.

While a stem-loop is the topology expected for the *eve* TAD in both models, one feature

of the TAD is inconsistent with the loop-extrusion model. According to this model, loops

(TADs) are generated by a cohesin complex that forms a small bubble at a loading site

somewhere in the TAD-to-be and then extrudes both strands of the growing loop at an equal rate until it bumps into the boundary road-blocks (Davidson and Peters 2021; Ghosh and Meyer 2021; Mirny and Dekker 2022; Perea-Resa et al. 2021). If the loading site were located in the middle of the TAD-to-be, and the extrusion intermediates in a population of nuclei were captured by crosslinking, one should observe a crosslink-generated stripe that begins at the loading site and extends perpendicular to the chromosomal DNA until it reaches the apex that links the two TAD boundaries with imaginary lines of 45° (Fig. Supplemental 2B). This is the pattern that would be generated by a "broken zipper" when it transiently links the zipper teeth equidistant from the initial "loading site". If the loading site is off center to the left, the crosslinking of the passing cohesin complex in a population of nuclei will generate a perpendicular stripe until cohesin come to a halt when it encounters the roadblock on the left (Fig. Supplemental 2C). Assuming that the complex continues to extrude the right strand, it will then generate a stripe at 45° degrees that extends to the apex of the TAD. If the loading site corresponds to one of the CTCF roadblocks or is located close to the roadblock, the cohesin complex will generate a 45° stripe that comes to a halt at the apex of the triangle when it encounters the neighboring CTCF roadblock (Fig. Supplemental 2D and E). If there are multiple loading sites within the TAD, there should be a series of perpendicular stripes that generate and sequentially reinforce the stripe(s) at 45° (Fig. Supplemental 2F). However, in spite of the fact that NC14 fly embryos should provide by far the best prospect of actually capturing loop extrusion intermediates, there are no vertical stripes in the *eve* TAD, nor are there stripes at 45° that extend to the apex of the *eve* TAD. Nor do we observe a population of perpendicular stripes that convert into a series of reinforced 45° stripes. There is also no evidence of stripes that are initially tilted to the left or right of a "loading site", as might be observed if the rate of extrusion were unequal on the two

strands, and then subsequently convert to a 45° stripe as cohesin comes to a halt at the first boundary encountered.

TADs in the eve environs

The attP insertion site at –142 kb is near the end of the first exon of the *hebe* transcription unit (Fig. 2C). It is located just within a ~14 kb TAD, TB, that has a high density of internal contacts, and extends from the *hebe* promoter to the 3' end of the neighboring *dila* gene. In between *hebe* and the *eve* locus there are at least ten distinct TADs, TC-TL (Fig. 2C). The endpoints of most of these TADs correspond to sequences that are associated with one or more known chromosomal architectural factors (dots along the horizontal axis in Fig. 2C).

These TADs correspond to the fundamental building blocks for organizing the 3D architecture of this chromosomal segment. Superimposed upon these TADs are regions that exhibit lower density of contacts (LDC). For example, the *mef2* gene spans two TADs, TJ and TK. TK contains the *mef2* distal promoter region and extends to the internal *mef2* promoter, while TJ extends to near the promoter of the divergently transcribed *Etf-QO* gene (blue arrow). Both of these TADs are linked together by a rectangular LDC domain, J-K (see Fig. Supplemental 1). Likewise, TJ is linked to its immediate neighbor TI by the LDC domain I-J. In the next level, TADs separated by a single TAD are linked together. In the region immediately above TJ, the LDC domain I-K links TI to TK (Fig. Supplemental 1). Similarly, TJ is linked to TL by J-L while TJ is also linked to the large TAD TM (which contains *TER94* and the neighboring gene, *pka-R2*) on the other side of *eve* by J-M. The same pattern of a hierarchical series of LDC domains linking TAD neighbors, TAD next-door neighbors and next-next-door neighbors is observed in the DNA segment that includes the *hebe* gene.

--cohesin-mediated loop extrusion: Like *eve*, the TADs in the region between *eve* and the attP site in the *hebe* locus are defined by right-angle triangles (volcanos) with a high density of

internal contacts. However, unlike *eve,* these volcano triangles do not have a plume, and instead are surrounded by a series of LDC rectangular "clouds". This is not the contact pattern that one might expect for either a series of stem-loops connected by unanchored loops or a series of stem-loops connected to each other. Moreover, there are no perpendicular or angled crosslinking stripes (broken zippers) emanating from the base of these triangles, nor are their stripes along their 45º legs. Thus, in spite of the fact that the NC14 nuclei used in this analysis are just emerging from an earlier mitosis and a round of DNA synthesis and should be in the process of assembling TADs, the crosslinking signatures that should be generated by the embrace of passing cohesin complexes are completely absent.

In the loop-extrusion model, the LDC domains would arise in a subset of nuclei because the extruding cohesin complex breaks through one or more boundary roadblocks before its progression is halted (Fig. Supplemental 3A versus B, C and D) (Hsieh et al. 2020; Krietenstein et al. 2020). Breakthroughs could occur at only one roadblock on one side of the extruding loop (Fig. Supplemental 3B and C), or at multiple roadblocks on one or both sides (Fig. Supplemental 3D), giving rise to a set of overlying LDC domains like that evident in the region between *hebe* and *eve*. However, while there would have to be multiple breakthrough events to account for the hierarchical array of LDC domains observed in these NC14 embryos, there is no evidence of the 45º crosslinking stripes that would be expected to mark the legs of the LDC domains following the breakthrough. For example, the I-J LDC domain (Fig. Supplemental 1) could be generated by cohesin complexes that initiated extrusion in either TI or TJ and then failed to halt at the TI:TJ boundary (green arrowhead). In either case, there should be a 45º stripe of crosslinking that marks (at least part of) the left (TI) and/or the right (TJ) leg of the I-J LDC domain and extends to the apex of the TI-TJ LDC triangle; however, there is no evidence of such stripes.

Nor is there evidence of crosslinking stripes marking one or both legs of the J-K or I-K LDC domains (Fig. Supplemental 1).

While the LDC domains associated with the TADs located between *eve* and the *hebe* locus could potentially be explained by cohesin breaking through one or more boundaries (even though we do not observe the expected stripe intermediates), it is important to note that the *eve* boundaries, *nhomie* and *homie,* do not appear to be subject to as frequent break-through events. This is because, unlike the other TADs in the neighborhood, the LDC domains that link *eve* to TA and TL are much more lightly populated compared to the LDC domain that links TA to TL. *--boundary:boundary pairing:* At least two different mechanisms are expected to account for the TADs and LDC domains in the region between *eve* and the attP insertion site at -142 kb. First, since none of the TADs in this DNA segment (with the possible exception of TA) are topped by volcano plumes, they could correspond to circle-loops. As circle-loops are generated by head-to-head pairing, the boundaries in the region between *nhomie* and *hebe* would be expected to pair with each other head-to-head. (The TAD to TAD contact maps generated by circle-loops and stem-loops are considered further in the accompanying paper (Ke et al. 2024).)

As illustrated in Fig. Supplemental 3E-G, the coiled circle-loop TADs, though topologically independent, are expected to be in relatively close proximity to each other. This means that in addition to crosslinking events within the TADs, there will be crosslinking events between neighboring TADs. These crosslinking events could generate the LDCs seen in Fig. 2C and Fig. Supplemental 1. Since TADs next to each other (Fig. Supplemental 3E and F; Fig. Supplemental 1, I-J or J-K) would typically be expected to interact more frequently than TADs separated by one, two or more TADs (Fig. Supplemental 3G; Fig. Supplemental 1, I-K or J-L), there should be a progressive reduction in contact frequency at each step. This is generally what is seen (see Fig. Supplemental 1). While connected stem-loops generated by cohesin extrusion

should also bump into one another, contacts between next-door neighbors might be expected to be less frequent than contacts between next-next-door neighbors (Fig. 1B, C and Fig. Supplemental 3A). (TAD-to-TAD crosslinking and the impact of loop topology is further examined in Ke et al. (Ke et al. 2024).

The second mechanism for generating LDC domains would be switching and/or combining pairing partners (Fig. Supplemental 3H-J). Though imaging studies suggest that pairing interactions can be of relatively long duration (>30 min: Chen et al. 2018; Vazquez et al. 2006), they are not permanent, and other nearby boundaries can compete for pairing interactions (Gohl et al. 2011). If switching/combining occurs in NC14 embryos (see Fig. Supplemental 3H-J), then the precise pattern of TADs and LDC domains could also be impacted by the relative avidity of potential pairing partners in the neighborhood and also the distances separating potential partners. For example, the rectangle linking TH and TI (H-I in Fig. Supplemental 1) could represent partner switching, so that the boundary between TI and TJ (green arrowhead in Fig. Supplemental 1) sometimes pairs with the boundary separating TH and TI (blue arrowhead in Fig. Supplemental 1) and sometimes with the boundary separating TG and TH (red arrowhead in Fig. Supplemental 1). Distant boundary elements could also occasionally interact with each other, generating a supra-TAD that contains multiple TAD domains. For example, at the apex of the LDC domain B-I there is an interaction dot (small black arrow, Fig. Supplemental 1) that links the TA-TB boundary to the TI-TJ boundary (green arrowhead).

Activation of a distant reporter by the eve enhancers

In previous studies we found that a minimal 367 bp *homie* fragment can orchestrate regulatory interactions between the *eve* enhancers and reporters inserted at an attP site in the first intron of the *hebe* transcription unit, 142 kb upstream of the *eve* gene (Fujioka et al. 2016). This minimal fragment lacks the one potential *homie* CTCF site, but has sites for several other generic

boundary proteins including BEAF, Zipic, Su(Hw), Pita and Ibf2. In blastoderm stage embryos, *lacZ* reporter expression was observed in a 7-stripe pattern that coincided with the stripes of the endogenous gene. However, at this stage only a subset of *eve*-expressing nuclei also expressed the reporter. Later in development, during mid-embryogenesis, reporter expression was observed in cells in the dorsal mesoderm, the ventral CNS, and in the anal plate region, in a pattern that recapitulated *eve* gene expression (Fujioka et al. 2016). At these later stages, most of the *eve*-expressing cells also appear to express the reporter. The *eve*-dependent activation of the reporter in a stripe pattern has also been visualized in live imaging of pre-cellular blastoderm-stage embryos (Chen et al. 2018). Within the 7 *eve* stripes, the majority of the nuclei (~80-85%) did not express the *lacZ* reporter. In these nuclei, the transgene was found to be at a considerable average physical distance from the *eve* locus (~700 nM). In the remaining nuclei, the transgene was located in closer proximity to the *eve* locus (~330 nM, on average). Within this subset, the transgene was expressed in most of the nuclei. Moreover, in most cases in which the transgene was active, it remained in close proximity and continued to express *lacZ* for the duration of the experiment (~30 min).

In the two models for TAD formation, quite different mechanisms must be invoked to account for activation of the reporter at –142 kb by the *eve* enhancers. In the boundary-pairing model, the transgene *homie* boundary at –142 kb loops over the intervening TADs and pairs with the *nhomie:homie* complex flanking the *eve* TAD (c.f., Fig. 3B and C). In the loop-extrusion model, a cohesin complex initiating loop extrusion in the *eve* TAD must break through the *nhomie* roadblock at the upstream end of the *eve* TAD. It must then make its way past the boundaries that separate *eve* from the *attP* site in the *hebe* gene, and come to a halt at the *homie* boundary associated with the *lacZ* reporter. This would generate a novel TAD, *eveMammoth* (*eveMa*), that extends from the *eve homie* all the way to the *homie* fragment at –142 kb, and

encompasses both the reporter and the *eve* gene, including its enhancers (c.f., Fig. 3D). Of course, the *eveMa* TAD could also be generated by a cohesin complex that initiated in, for example, TF. However, in this case, the runaway cohesin complex would have to break through the intervening boundary roadblocks in both directions. In both the boundary-pairing and loop-extrusion models, the configuration of the chromatin fiber would lead to the activation of *lacZ* expression by the *eve* enhancers, while the reporter would be protected from the *hebe* enhancers by the *homie* boundary.

To test these two models, we used a transgene that has two divergently transcribed reporters, *lacZ* and *gfp*, that are each under the control of an *eve* promoter (Fig. 3A). Two different versions of the transgene were generated. In the first, the *eve-lacZ* reporter is located "upstream" of *homie* (with respect to the 5'→3'orientation of *homie* in the *eve* locus), while *eve-gfp* is located downstream. In the second, the orientation of *homie* within the transgene is reversed, so that *eve-gfp* is upstream of *homie*, while *eve-lacZ* is downstream. These two transgenes were then individually inserted into the *attP* site at –142 kb. For the pair shown in Fig. 3A, *GeimohL* and *GhomieL*, the transgenes were inserted so that *eve-lacZ* is on the *eve* side of the *homie* boundary. The *eve-gfp* reporter is on the opposite side of the *homie* boundary and is farther away from the *eve* locus. This places the *eve-gfp* reporter next to a series of *hebe* enhancers located farther upstream (Fig. 2C), in the intron of the *hebe* gene, and thus it should be subject to regulation by these enhancers. In the other pair, *LhomieG* and *LeimohG*, the entire transgene is inserted in the opposite orientation in the chromosome so that *eve-gfp* is on the *eve* side of *homie*, while *eve-lacZ* is next to the *hebe* enhancers (Fig. 6A). As a control, we also generated a transgene in which *lambda* DNA instead of *homie* was inserted between the *eve-gfp* and *eve-lacZ* reporters. This transgene was oriented so that *eve-lacZ* was on the *eve* side of the *lambda* DNA, and *eve-gfp* was close to the *hebe* enhancers.

The eve enhancers drive lacZ expression in the GeimohL insert

The results for transgenes *GeimohL* and the control *GlambdaL* are most straightforward and will be considered first. In both the loop-extrusion and boundary-pairing models, the *GlambdaL* control is not expected to display any regulatory interactions with the *eve* locus. Fig. 4C shows that this is the case: the *eve-lacZ* and *eve-gfp* reporters in *GlambdaL* embryos are silent at the blastoderm stage, and transcripts are only very rarely detected. Later in development, both reporters are expressed in a repeating pattern along the dorsal midline (Fig. 4E). This expression is driven by the *hebe* gene enhancers located just beyond the *gfp*-reporter (Fujioka et al. 2009).

In the case of the *GeimohL* insert, regulatory interactions between the transgene and the *eve* locus will be observed if a stem-loop is established that links the transgene to *eve*. In the loop-extrusion model, the breakthrough cohesin complexes would generate a stem-loop, *eveMammoth* (*eveMa*), by coming to a halt at the *homie* boundary in the transgene and the *homie* boundary in *eve*, as illustrated in Fig. 3D. This will place the *lacZ* reporter in close proximity to the *eve* enhancers. It will also disrupt the *eve* TAD, as *nhomie* is no longer linked to the *homie* boundary by cohesin. In the boundary-pairing model, the *lacZ* reporter in the transgene is "upstream" of *homie* just like the *eve* gene and its enhancers are "upstream" of *homie* in the *eve* locus. Since *homie* pairs with itself head-to-head, pairing between *homie* in the transgene and *homie* in the *eve* locus will generate the same stem-loop as that generated by loop-extrusion (Fig. 3B). However, because *homie* pairs with *nhomie* head-to-tail, a more complex multi-loop structure like that in Fig. 3C would be expected if the pairing interactions with the transgene do not disrupt the *eve* TAD. Consistent with a tripartite structure of the sort shown here, previous studies have shown that three *Mcp* transgenes on three different chromosomes can interact with each other genetically (Muller et al. 1999). Subsequent direct visualization of *Mcp*-mediated pairing interactions in imaginal discs by Vazquez et al. (Vazquez et al. 2006) showed that four

Mcp-containing transgenes separated by Mbs (at Bridges cytogenetic intervals ~65 on the left arm of chromosome 3, and ~83 and ~95 on the right arm of chromosome 3) and/or located on different homologs, clustered in the same nuclear foci in 94% of the nuclei.

As predicted from the formation of a stem-loop linking the transgene to the *eve* locus, *lacZ* is expressed in blastoderm-stage embryos in 7 stripes that coincide with the 7 stripes of the endogenous *eve* gene. However, unlike *eve*, not all nuclei in the seven stripes express *lacZ* (compare with the *eve* control in Fig. 4A). Later, during mid-embryogenesis, *lacZ* is expressed in the mesoderm, the CNS, and the anal plate in a pattern that mimics the endogenous *eve* gene. At this stage almost all *eve*-positive cells are also positive for *lacZ*. Unlike the *GlambdaL* transgene, the *hebe* enhancers do not drive *eve-lacZ* expression, as they are beyond the *homie* boundary (Fig. 4E). The *eve-gfp* reporter in the *GeimohL* transgene responds differently. As was observed for the *GlambdaL* control, the *eve* enhancers drive little if any *gfp* expression, either at the blastoderm stage or later in development (Fig. 4C, E). Instead, *gfp* is expressed in the midline during mid-embryogenesis under the control of the *hebe* enhancers (Fig. 4E), which should be in the same TAD as *eve-gfp*. These results would be consistent with both the loop-extrusion (*eveMa*) and boundary-pairing models (Fig. 3B/C and D).

The eve enhancers drive gfp expression in the GhomieL insert

The situation is more complicated for the *GhomieL* transgene. This transgene is inserted in the same chromosomal orientation as *GeimohL*: *eve-lacZ* is on the *eve* side of the *homie* boundary and *eve-gfp* is on the *hebe* enhancer side of the boundary. However, the orientation of the boundary within the transgene is switched so that *eve-gfp* rather than *eve-lacZ* is "upstream" of *homie*. In the boundary-pairing model, flipping the orientation of *homie* in the transgene but keeping the same orientation of the transgene in the chromosome will have two consequences. First, as illustrated in Fig. 3E, the topology of the chromatin loop connecting the *homie* boundary

in the transgene and the *homie* boundary in the *eve* locus will change from a stem-loop to a circle-loop. The reason for the change in loop topology is that *homie* pairs with *homie* head-to-head (Fujioka et al. 2016). As before, the transgene *homie* will pair with *eve homie* head-to-head to generate a simple circle-loop (Fig. 3E); however, if, as expected, it also pairs with *nhomie* so that the *eve* TAD remains intact, a more complicated loop structure would be generated (Fig. 3F). Second, the reporter that is preferentially activated by the *eve* enhancers will switch from *eve-lacZ* to *eve-gfp*. In order to be activated by the *eve* enhancer, the reporter must be "upstream" of the transgene *homie*. This physical relationship means that the *eve-gfp* reporter will be activated by the *eve* enhancers independent of the orientation of the transgene in the chromosome. On the other hand, the *eve-lacZ* reporter will not be activated by the *eve* enhancers. In addition, it will still be insulated from the *hebe* enhancers by the *homie* boundary.

It is not possible to form a circle-loop in the loop-extrusion model. Instead, the breakthrough cohesin complex will come to a halt as before when it encounters the inverted *homie* boundary at –142 kb (Fig. 3D). This means that the *eve-lacZ* reporter will be in the same TAD (*eveMa*) as the *eve* enhancers and will be activated by the *eve* enhancers. In contrast, the *eve-gfp* reporter will be in the neighboring TAD and will not be activated by the *eve* enhancers. It will, however, be regulated by the nearby *hebe* enhancers.

Fig. 5 shows that the four predictions of the boundary-pairing model are correct: a) the *eve* enhancers drive *eve-gfp* expression, b) the *hebe* enhancers drive *eve-gfp* expression, c) *eve-lacZ* is not subject to regulation by the *eve* enhancers, and d) *eve-lacZ* is insulated from the *hebe* enhancers. This would also mean that pairing of the transgene *homie* in the *GhomieL* insert with *homie* in the *eve* locus generates a circle-loop (or a more complicated multi-loop structure if it also pairs with *nhomie*), not a stem-loop, as was the case for *GeimohL*. In contrast, since loop-extrusion cannot generate circle-loops, the key predictions of this model, namely that *eve-gfp*

will be silent while *eve-lacZ* will be regulated by the *eve* enhancers, are not satisfied. Instead, *eve-gfp* is activated by the *eve* enhancers, while *eve-lacZ* is not.

While the results described above for the *GhomieL* transgene are inconsistent with a "simple" loop-extrusion model, there is one potential caveat: the 5'→3' orientation of the *homie* boundary is inverted so that it is "pointing" towards the *eve* locus rather than away from it like the endogenous *homie* boundary. In this orientation, it is possible that *homie* no longer functions as an effective roadblock, and instead the cohesin complex emanating from the *eve* locus (or from a loading site somewhere in between) slips past this *homie* fragment and continues until it is blocked by a properly oriented boundary further upstream. In this case the newly formed stem-loop, *eveGargantuan* (*eveGa*) (Fig. 3G), would include the *eve-gfp* reporter, and it would then be activated by the *eve* enhancers. However, there are two problems with postulating this novel *eveGa* TAD. First, *eve-lacZ* would be in the same *eveGa* TAD as *eve-gfp*, and it should also be activated by the *eve* enhancers. Second, since the *homie* boundary was bypassed by the cohesin complex to form the larger *eveGa* TAD, it should not be able to block the *hebe* enhancers from activating *eve-lacZ*. Neither of these predictions is correct.

LeimohG and *LhomieG: Orientation of homie in the transgenes determines which reporter is activated*

To confirm these conclusions, we examined the expression patterns of the reporters when the transgene is inserted in the opposite orientation in the –142 kb attP site. In this transgene orientation, *eve-gfp* is on the *eve* side of the *homie* boundary while *eve-lacZ* is close to the *hebe* enhancers. In the boundary-pairing model, the orientation of *homie* in the transgene determines which reporter will be preferentially activated, while the orientation of the transgene *homie* in the chromosome determines topology of the resulting loop(s). The transgene *homie* will pair with the endogenous *homie* head-to-head. Since the transgene *homie* in *LeimohG* is in the opposite

orientation from the endogenous *homie*, this pairing interaction will generate a stem-loop, if

pairing interactions are exclusively pairwise. A more complicated multi-loop structure will be

formed if the transgene *homie* interacts simultaneously with both endogenous boundaries (Fig.

6B). In both cases, *eve-gfp* will be activated by the *eve* enhancers. On the other hand, since this

orientation places *eve-lacZ* on the same side of the transgene *homie* as the *hebe* enhancers, they

will activate it rather than the *eve-gfp* reporter (Fig. 6B). In *LhomieG*, the topology of the loop

(or multi-loop) will switch, and *eve-lacZ* will be activated by both the *eve* and *hebe* enhancers

(Fig. 6C).

 In the first version of the loop-extrusion model, the *eve-gfp* reporter in both *LeimohG* (Fig.

6D) and *LhomieG* (not shown) should be activated by the *eve* enhancers, since it is included in

the *eveMa* TAD when the transgenes are inserted so that *eve-gfp* is on the *eve* side of the *homie*

boundary, and *eve-lacZ* will be regulated by the *hebe* enhancers (Fig. 6D). In the second version

of the loop-extrusion model, the functioning of the *homie* roadblock depends upon its orientation

relative to endogenous *homie*. In this model, *LeimohG* is expected to form the *eveMa* TAD (Fig.

6D), while *LhomieG* will form the larger *eveGa* TAD (Fig. 6E).

 As would be predicted by all three models, the *eve* enhancers activate the *eve-gfp* reporter

in the *LeimohG* insert (Fig. 6F and G). Likewise, *homie* blocks the *hebe* enhancers from

activating the *eve-gfp* reporter, while they turn on *eve-lacZ* expression instead. As predicted by

the boundary-pairing model, *eve*-dependent expression of the reporters switches from *gfp* to *lacZ*

in the *LhomieG* insert (Fig. 6F and G). This would not be expected in the first version of the

loop-extrusion model, but it is predicted in the second version. However, as indicated in the

diagram in Fig. 6E, the two reporters, along with the *hebe* enhancers, are included in the larger

eveGa TAD, and for this reason both reporters should be activated equally by both the *eve* and

hebe enhancers. This is not the case. The *hebe* enhancers are blocked by the intervening *homie* boundary, while there is little or no *eve*-dependent *gfp* expression.

TAD formation by transgenes inserted at –142 kb

We used MicroC to examine the TAD organization of the genomic region extending from upstream of the attP site through the *eve* locus in 12-16 hr embryos carrying different transgene insertions. At this stage, *eve* is expressed in only a small number of cells in the CNS, mesoderm and anal plate, and *hebe* is also expressed in only a small subset of cells. This means that most of the interactions detected by MicroC are in cells in which both the *eve* gene and the two reporters are inactive. In addition, while the transgene co-localizes with *eve* in less than about a fifth of blastoderm stage nuclei (based on the fraction of cells within *eve* stripes that activate a transgene reporter) the frequency of physical contact is expected to be much higher in 12-16 hr embryos (c.f., Vazquez et al.: Vazquez et al. 2006). This is because at this stage of development, cell cycles are much longer, providing more time for transgene – endogenous *eve* pairing to occur. The key findings are summarized below.

GlambdaL: While there is no evidence of contact between sequences in *eve* and sequences around the attP site at –142 kb in wild-type embryos, this not true for embryos carrying the dual reporter transgene. Perhaps the most unexpected finding is a weak, but clearly discernable pattern of interaction linking the *GlambdaL* transgene to the *eve* locus (Fig. 7A). However, since the *GlambdaL* transgene does not respond to the *eve* enhancers, this low level of physical interaction is not sufficient to drive detectable expression of the reporters. Though our experiments do not allow us to unequivocally identify which sequences in the transgene are responsible for this long-distance interaction, the most likely candidates are the two *eve* promoters in the *GlambdaL* transgene.

GeimohL: Unlike *GlambdaL*, the *eve-lacZ* reporter in the *GeimohL* insert is activated by the *eve* enhancers, and this regulatory interaction is perfectly paralleled by the strong pattern of crosslinking between the transgene and the *eve* locus (Fig. 7B). On the *eve* side, the interactions between the transgene and the *eve* locus generate a heavily populated band of crosslinked sequences that span the 16 kb *eve* TAD. On the transgene side, there is an unequal distribution of crosslinked sequences to either side of the transgene *homie* boundary. As shown in the inset, the heaviest density of crosslinked sequences is on the *eve-lacZ* side of the transgene, consistent with the activation of this reporter by *eve* enhancers. To confirm that the interaction bias mimics the differences in activity of the two reporters in cells in which the reporters are expressed, we analyzed the interaction profiles from viewpoints within either the *eve-lacZ* or *eve-gfp* genes. Fig. 7D shows that *eve-lacZ* interacts with sequences extending across the *eve* TAD, while *eve-gfp* interactions are largely restricted to the *eve homie* element. While these results would seemingly be consistent with both the boundary-pairing and loop-extrusion models, there is no evidence of cohesin breaking through multiple intervening boundaries into order to establish the novel *eve(Mam)* TAD. Instead, the organization of the TADs and LDC domains in the interval in between the transgene and *eve* (Fig. 7B) resemble that seen in wild-type NC14 embryos (see Fig. 2) (with the caveat that there are significantly fewer reads in the transgene experiment). Equally important, the same is true for the *eve* TAD. In order to generate the *eve*(*Mam*) TAD, the cohesin complex must break through the *nhomie* boundary and, in so doing, disrupt the *eve* TAD. However, there are no obvious alterations in either the *eve* volcano or plume with respect to their structure or relative contact density compared to the *GlambdaL* and wild type NC14 embryos. Likewise, there is no evidence of novel vertical and 45° crosslinking stripes that would reflect the boundary breakthrough events that are expected in the loop-extrusion model to accompany the formation of a physical connection between the transgene and the *eve* locus.

We next used the transgene *homie* as the viewpoint to test the predictions of the boundary-pairing and loop-extrusion models. Since *homie* can pair with itself (head-to-head) and with *nhomie* (head-to-tail) in transvection assays (Fujioka et al. 2016), a prediction of the boundary-pairing model is that there will be physical interactions between the transgene *homie* and *both* *homie* and *nhomie* in the *eve* locus (c.f., Vazquez et al. 2006). Also based on what is known about how fly boundaries pair with each other (Chetverina et al. 2014; Chetverina et al. 2017; Kyrchanova et al. 2008a), self-interactions are expected to be stronger than heterologous interactions. In contrast, in the loop-extrusion model, the cohesin complex forms the *eveMa* TAD by linking *homie* in the transgene to *homie* in the *eve* locus, and this requires the cohesin complex to break through *nhomie* and disrupt the connections between *nhomie* and *homie* in the *eve* locus. In this case, *transgene:homie*←→*eve:homie* interactions should be observed, while *transgene:homie*←→-*eve:nhomie* should not. Fig. 8A shows that, as predicted by the boundary-pairing model, the transgene *homie* interacts with both *homie* and *nhomie* in the *eve* locus.

Since the *eve* TAD does not appear to be disturbed by the presence of the *GeimohL* transgene, these findings would suggest that the transgene *homie* likely pairs with both *nhomie* and *homie* in a pattern somewhat like that illustrated in Fig. 3C. While the physical interactions between the transgene and *eve* boundaries are inconsistent with the loop-extrusion model, one could make the *ad hoc* assumption that runaway cohesin complexes form not one but two different novel TADs. One would be *eveMa*. In the other, *eveElephant* (*eveEl*), a cohesin complex that initiates in, for example, the TE TAD would come to a halt on one side at the *homie* boundary in the transgene, and on the other side at the *nhomie* boundary in the *eve* locus (Fig. Supplemental 4). However, this configuration would not explain how the transgene reporter is activated by *eve* enhancers. Since the *eve* enhancers in *eveEl* are located in a different

TAD than the TADs containing *eve-lacZ* and *eve-gfp*, they would not be able to activate either reporter.

GhomieL: When *homie* is reversed in the *GhomieL* transgene, the *eve-gfp* reporter responds to the *eve* enhancers instead of *eve-lacZ*. In the boundary-pairing model, *eve-gfp* is activated because self- and heterologous-pairing interactions between *homie* and *nhomie* are orientation-dependent. As a result, the topology of the loop formed between the transgene and *eve* is transformed in a way that brings the *eve-gfp* reporter instead of the *eve-lacZ* reporter into close proximity to the *eve* enhancers (see Fig. 3E, F). Since only stem-loops can be generated in the loop-extrusion model, activation of the distal *eve-gfp* reporter would require the formation of a larger *eveGa* TAD in order to encompass both the transgene and the *eve* enhancers in the same looped domain (Fig. 3G). However, as shown in Fig. 7C, we do not observe the cross-linking pattern expected for a new *eveGa* TAD that includes the entire transgene at –142 kb and then extends to an even more distal boundary. Nor are there any novel vertical/45° crosslinking stripes or obvious perturbations in the basic TAD organization in the region beyond –142 kb, or between –142 kb and the *eve* locus, as might be expected for cohesin complexes breaking through multiple intervening roadblocks. Instead, as was the case for *GeimohL*, the *GhomieL* transgene is physically linked to the *eve* locus, and there is a prominent band of crosslinked transgene sequences that spans the *eve* TAD (Fig. 7C). Consistent with the expression patterns of the two reporters, the heaviest density of crosslinked sequences is on the *eve-gfp* side of the transgene (see inset). This is confirmed by the interaction profiles generated using either the *eve-gfp* or *eve-lacZ* gene body as the viewpoint: the most frequent contacts are between sequences within *eve* and the *eve-gfp* reporter (Fig. 7D). In addition, as was the case for *GeimohL*, when the transgene *homie* is used as the viewpoint, interactions are observed between both *homie* and *nhomie* in the *eve* locus, with the most frequent corresponding to self-pairing interactions (Fig.

8B). Other than postulating the *ad hoc eveEl* TAD (Fig. Supplemental 4), this would not be expected for either version of the loop-extrusion model.

LhomieG and *LeimohG*: To confirm that the orientation of the *homie* boundary in the transgene is the key determinant of the physical interactions between the transgene reporters and the *eve* TAD, we used MicroC to analyze the TAD organization of *LhomieG* and *LeimohG* (Figs. Supplemental 5 and 6). Like their counterparts *GhomieL* and *GeimohL*, both show a strong band of interaction between the transgene and sequences spanning the *eve* locus. In the case of *LeimohG*, the pairing of the transgene *homie* with the endogenous *homie* is predicted to generate a stem-loop, while a more complicated multi-loop structure will be generated if it also pairs with *nhomie* (see Fig. 6B). As shown in Fig. Supplemental 5A, these pairing interactions bring *eve-gfp* into contact with the *eve* enhancers and, as expected, the *eve-gfp* sequences interact more frequently with the *eve locus* than does *eve-lacZ* (inset Fig. Supplemental 5A). When *homie* is inserted in the transgene in opposite orientation, *homie* self-pairing is expected to generate a circle-loop, while the more complicated structure shown in Fig. 6C will be formed if it also pairs with *nhomie*. While the sample preparation for MicroC was of poorer quality than the others, the inset in Fig. Supplemental 6A shows that, as expected, *eve-lacZ* interacts more frequently with sequences in the *eve* locus than does *eve-gfp*. On the other hand, there is no evidence of a larger *eveGa* TAD, even though *eve-lacZ* is activated by the *eve* enhancers. These interactions are confirmed when either *eve-lacZ* or *eve-GFP* are used as viewpoints to plot the physical contacts between the *eve* TAD and the two reporters in *LhomieG* and *LeimohG* (Figs. Supplemental 5B and 6B). In addition, as was the case for the *GhomieL* and *GeimohL* transgenes, when the transgene *homie* is used as the viewpoint, interactions are observed between *homie* in the transgene and both *homie* and *nhomie* in the *eve* locus (Fig. 8A and B). Again, the most frequent interactions are self-pairing interactions between *homie* in the transgene and the *eve homie*.

Loop topology and interactions with neighbors: The results in the previous sections demonstrate that the orientation of *homie* in the transgene determines which of the two reporters physically interacts with sequences in the *eve* TAD, and this is independent of the orientation of the transgene in the chromosome. On the other hand, the orientation of the transgene *homie* in the chromosome impacts how sequences flanking the transgene *homie* and the *eve* TAD interact with each other. With the important caveat that the depth of our MicroC sequencing is limited, the interaction profiles reflect the topology of the transgene-induced loop. For *homie* pointing away from *eve* (*GeimohL* and *LeimohG*), sequences to the *TER94* side of *eve* and to the *hebe* enhancer side of the transgene are more frequently crosslinked with each other (Fig. Supplemental 7). These interactions would be expected for either a stem-loop structure in Fig. 3B or the more complicated multi-loop structure shown in Fig. 3C. For *homie* pointing towards *eve*, sequences on the *TER94* side of *eve* interact with sequences on the *eve* side of the transgene. This would be expected for either a circle-loop structure in Fig. 3E or the more complicated multi-loop structure shown in Fig. 3F (neither of which can be generated by a simple loop-extrusion mechanism).

Discussion

Two different mechanisms have been proposed to explain how TADs are formed and their endpoints determined. In the first, a cohesin complex first induces a small loop at a loading site within the TAD-to-be and then progressively extrudes one or both strands until the complex encounters boundary roadblocks. If the loading site is located asymmetrically within the TAD-to-be, extrusion will continue on the unblocked strand until a roadblock is encountered. The endpoints of the loops were initially thought to be determined by the location of the first two roadblocks encountered by the cohesin complex (Alipour and Marko 2012). In a refinement of this model, the orientation of a given roadblock relative to the direction of movement of the cohesin complex determines whether it will come to a halt (Davidson and Peters 2021; Fudenberg et al. 2016; Guo et al. 2012; Guo et al. 2015; Sanborn et al. 2015). It has also been suggested that cohesin complexes can break through a roadblock and come to a halt at more distant roadblocks, so that in a population of cells analyzed by Hi-C or MicroC, the basic units of organization, the TADs, are overlaid by a hierarchy of LDC domains (Hsieh et al. 2020; Krietenstein et al. 2020). However, the only loop topologies that are possible in the loop-extrusion model are a stem-loop and an unanchored loop.

In the other mechanism, TAD formation is governed by boundary:boundary pairing interactions. In this case, the critical factors are the pairing and orientation preferences of potential partners, together with proximity. Since boundary pairing interactions often exhibit an orientation preference, the topology of the loop formed by paired boundaries can be either a stem-loop or a circle-loop, depending on their relative orientation in the chromosome. In this respect it differs from the loop-extrusion model in that switching the orientation of the boundary does not preclude the formation of a TAD, whereas it can in some versions of the loop-extrusion model.

In the studies reported here, we have used MicroC to analyze the TAD organization of a ~150 kb chromosomal segment flanking the *eve* locus, and have experimentally tested the predictions of these two models for the mechanisms of TAD formation. Our studies do not support a loop-extrusion mechanism, and are inconsistent with this model on multiple levels. *Manipulating "TAD" formation:* In our experimental paradigm, a transgene containing two divergently transcribed reporters and the *eve* boundary *homie* is inserted 142 kb upstream of the *eve* TAD. Depending upon the orientation of the *homie* boundary within the transgene, either *eve-gfp* or *eve-lacZ* is activated by developmentally regulated enhancers in the *eve* TAD. Since there are a series of well-defined TADs and their associated boundary elements separating the transgene from *eve*, a version of the loop-extrusion model in which the cohesin complex invariably arrests upon encountering *nhomie* and *homie* at the ends of the *eve* TAD cannot account for this long-distance regulation. Instead, the extruding cohesin complex must be able to break through the boundaries located between *homie* in the transgene and *homie* in the *eve* TAD. This would generate a novel TAD, *eveMa*, with endpoints corresponding to the two *homie* boundaries (Fig. 3D). In this case, the reporter on the *eve* side of the transgene *homie* would be in the same domain as the *eve* enhancers, and thus potentially subject to regulation. While *eveMa* could account for reporter expression in inserts in which the transgene *homie* is pointing away from *eve* (and also away from the reporter on the *eve* side of the transgene insert), it does not explain reporter expression when the transgene *homie* is pointing towards *eve* (and in this case towards the reporter on the *eve* side of the transgene insert). In the latter case, the reporter activated by the *eve* enhancers lies outside of the *eveMa* (cf., Fig. 3D), and thus is not included in the same TAD as the *eve* enhancers. In order to account for activation of the distal reporter, one must imagine that the cohesin complex breaks through the *homie* boundary in the transgene and continues on until extrusion is halted by an even more distal boundary. In this revision of the

loop-extrusion model, both reporters would be included in the same TAD as the *eve* enhancers (c.f., Fig. 3G, *eveGa*), and both reporters should be activated. However, this is not observed.

TAD organization: loop extrusion versus boundary pairing: Analysis of the TAD organization in the region spanning the transgene insertion site and *eve* also does not fit with the expectations of the loop-extrusion model. To account for reporter activation, the cohesin complex must be able to break through the *nhomie* boundary. This breakthrough could be engineered by a cohesin complex that initiated loop extrusion either from within the *eve* TAD or from one of the TADs located between the *nhomie* boundary and the transgene at –142 kb. However, in the absence of the transgene, there is no indication that *nhomie* is particularly prone to break-through events. In fact, the *eve* TAD differs from most of the TADs in between *eve* and the transgene in that it is incorporated into larger LDC domains much less frequently. There is also no reason to imagine that the presence of a transgene carrying *homie* (or *nhomie*: see Fujioka et al. 2016) at –142 kb would somehow induce *nhomie* break-through events.

As expected from the regulatory interactions, *homie*-containing transgenes at –142 kb generate a strong band of crosslinking events that physically link the transgene to the *eve* locus. In the loop-extrusion model, this strong band of interaction should generate a novel interaction triangle (LDC or HDIC) with endpoints corresponding to the *homie* elements in the transgene and *eve*. Contrary to this expectation, a triangle of increased interaction frequencies spanning the entire region between –142 kb and *homie* is not observed for any of the transgene inserts. In viewpoints from the *homie* element in the *GeimohL* and *LeimohG* transgenes, there are two peaks in the *eve* TAD. The more prominent peak maps to *homie*, while the less prominent peak maps to *nhomie*. To account for these interaction peaks, the loop-extrusion model would have to assume that the presence of the *GeimohL* and *LeimohG* transgenes induces the formation of two novel TADs, the *eveMa* (*homie:homie*) TAD in Fig. 3D and another TAD, *eveElephant*, that

links the transgene *homie* to the *nhomie* element in the *eve* locus (Fig. Supplemental 4B).

However, while the *eveMa* TAD could potentially explain the activation of reporters on the

proximal side of the transgene *homie* by the *eve* enhancers, these TADs do not explain how the

eve enhancers are able to activate reporters on the distal (*hebe* enhancer) side of the *GhomieL*

and *LhomieG* transgene. This would require the formation of yet another TAD, *eveGa*, that

encompasses *eve*, the transgene, and one or more TADs beyond the *hebe* gene (Fig. 3G).

However, there is no indication of physical interactions between the *homie* boundary in *eve* and a

boundary located beyond the *hebe* gene. Moreover, like *eveMa*, *eveGa* would also have to be

accompanied by the formation of *eveEl*, since the *homie* element in *GhomieL* and *LhomieG*

interacts with both *nhomie* and *homie*.

     While these results are inconsistent with the expectations of the loop-extrusion model,

they dovetail nicely with many of the predictions of the boundary-pairing model. First, in all

four transgenes, *homie* interacts with both *homie* and *nhomie* in the *eve* locus, but does not

interact with the multiple boundary elements located in between. This is consistent with other

studies which show that boundaries often have strong partner preferences (Gohl et al. 2011;

Kyrchanova et al. 2011; Kyrchanova et al. 2008b). Second, interaction frequencies are greater

for self-pairing than for heterologous pairing. This fits with what is known about how partner

preferences are determined (Blanton et al. 2003; Chetverina et al. 2017; Erokhin et al. 2021;

Kyrchanova et al. 2008a; Zolotarev et al. 2016). Third, the pattern of reporter activation in the

four transgenes is precisely as expected from previous studies on the orientation dependence of

homie pairing with itself (head-to-head) and with *nhomie* (head-to-tail) (Chen et al. 2018;

Fujioka et al. 2016). This orientation dependence means that the reporter located "upstream" of

homie is the one that is activated, independent of the orientation of the transgene in the

chromosome. Fourth, the pattern of physical interactions between the *eve* locus and the

transgenes recapitulates the pattern of reporter activation. That is, when *eve-lacZ* sequences are preferentially crosslinked to sequences in the *eve* locus, then the *eve-lacZ* reporter is activated by the *eve* enhancers. Likewise, *eve-gfp* is preferentially crosslinked to sequences in *eve* when it is activated by the *eve* enhancers. Again, this is dependent on the orientation of *homie* in the transgene, but not on the orientation of the transgene in the chromosome. Fifth, unlike the loop-extrusion model where only stem-loops or unanchored loops can be generated, stem-loops, circle-loops and even more complicated structures can be, and, as we have shown here, actually are generated by boundary:boundary pairing.

Are the pairing interactions of homie and nhomie unusual? There are two reasons to think that the properties of most fly boundaries are similar to those of *homie* and *nhomie*. First, all of the fly boundaries that have been tested in assays that are expected to require pairing do have this activity (Blanton et al. 2003; Cai and Shen 2001; Erokhin et al. 2011; Gohl et al. 2011; Kyrchanova et al. 2008a; Kyrchanova et al. 2011; Kyrchanova et al. 2007; Kyrchanova et al. 2008b; Muravyova et al. 2001).

Second, multimerized binding sites for generic polydactyl zinc finger proteins like Su(Hw), Pita, dCTCF, Zw5, and Zipic that are found associated with many fly boundaries are not only able to block enhancer/silencer action but can also mediate pairing interactions in insulator bypass and transvection assays (Erokhin et al. 2021; Kyrchanova et al. 2008a; Zolotarev et al. 2016). Moreover, as is the case for *homie* and *nhomie*, pairing interactions require the appropriate partners: multimerized sites for Zw5 do not pair with multimerized sites for dCTCF (Erokhin et al. 2021; Kyrchanova et al. 2008a; Zolotarev et al. 2016). This makes good sense, since these proteins form dimers/multimers, as do other fly boundary factors like BEAF, Mod(mdg4), the BEN-domain protein Insensitive and the Elba complex (Avva and Hart 2016; Bonchuk et al. 2021; Bonchuk et al. 2011; Bonchuk et al. 2020; Fedotova et al. 2018;

Fedotova et al. 2019; Fedotova et al. 2017; Hart et al. 1997). The ability to multimerize means that boundaries that share binding sites for the same protein, i.e., for Pita, Zipic or CTCF, can be physically linked to each other by a single protein complex.

Third, *homie* and *nhomie* are not the only examples of fly boundary elements that engage in specific orientation-dependent physical pairing interactions. In addition to *gypsy*, *Mcp* and *Fab-7,* Mohana, et al. (Mohana et al. 2023) identified nearly 60 meta-loops in which distant TADs are linked together by what appears in most instances to be orientation-dependent boundary pairing interactions. Fig. 9 shows the MicroC contact profiles generated for two such meta-loops in 12-16 hr embryos. As observed in our *homie* transgene experiments, the meta-loop in panel A is formed by specific and orientation-dependent boundary:boundary (blue:purple) pairing interactions that bring together distant TADs. The blue boundary splits the *Leukocyte-antigen-related like* (*Lar*) gene into a small upstream TAD that contains the most distal promoter (black arrowhead), and a larger downstream TAD whose endpoint is close to an internal *lar* promoter (green arrowhead). The purple boundary is located ~600 kb away on the left arm of the 2nd chromosome between two TADs, Pa and Pb, in a gene poor region. The pairing of the blue and purple boundaries generates two rectangles of enhanced contacts. The one on the upper left corresponds to interactions of the sequences in the small TAD just upstream of the blue boundary with sequences in the Pa TAD located upstream of the purple boundary. The other box on the lower right is generated by interactions between sequences in the TAD downstream of the blue boundary and sequences downstream of the purple boundary. Based on the locations of interacting TADs, the blue and purple boundaries pair with each other head-to-head, generating the circle-loop in the diagram.

The meta-loop in panel B links a boundary (blue arrow) to a boundary (purple arrow) ~5 Mb away on the right arm of the 3rd chromosome. The blue boundary is located between a small

TAD that contains three genes encoding UDP-glycosyltransferases and a larger TAD that includes *CG10164* and the most distal *beat IV* (*beaten path IV*) promoter. The purple boundary separates a large TAD containing five genes (*Sid*, *CG33346*, *CG31050*, *CG14062* and *CG9988*) from a small TAD that contains the most distal promoter of the *snu* (*snustorr*) ABC transporter. The blue and purple boundaries pair with each other head-to-tail, and this generates a stem-loop meta-loop (see diagram). In this pairing configuration, sequences upstream of the blue boundary come into contact with sequences downstream of the purple boundary. This generates a box of interactions between the small TAD that contains the UDP-glycosyltransferase gene cluster and the small TAD that contains the most distal *snu* promoter. (Another weaker rectangular block of interactions links sequences in the TAD immediately upstream of the UDP-glycosyltransferase gene cluster, which contains *CG10175*, and the small TAD containing the distal *snu* promoter). A second, larger rectangular box is generated by contacts between sequences in the TADs downstream of the blue boundary and upstream of the purple boundary. Note that the positioning of the rectangular interaction boxes differs for circle-loops and stem-loops.

The pairing interactions in the *lar* and *beat IV* meta-loops are much simpler than those seen for *homie* in the dual reporter. In both cases, there is only a single contact point (blue:purple boundaries). In contrast, as shown in Fig. 7 and in Figs. Supplemental 5 and 6, the interaction between the dual reporter *homie* and the *eve* TAD generates a "stripe" that spans the *eve* TAD together with crosslinking events between TADs upstream and downstream of the dual reporters and TADs located to either side of the *eve* TAD. This more complicated interaction pattern is consistent with the viewpoint analysis (Fig. 8), which shows that the transgene *homie* physically interacts with both *homie* and *nhomie* in the *eve* TAD.

Boundary pairing orientation and loop topology: Our analysis of the TAD organization in the *eve* neighborhood suggests that the predominant loop topology may be a circle-loop, not a stem-

loop. Only the *eve* TAD (and perhaps the very small TAD TA) is clearly a stem-loop. It is

topped by a distinctive volcano plume and is not overlaid by a hierarchy of LDC domains,

indicating that it must be "insulated" from crosslinkable interactions with other nearby TADs.

By contrast, none of the TADs in the region spanning *eve* and the *hebe* gene have volcano

plumes at their apex. Instead, all of these TADs are overlaid by a hierarchal organization of

LDC domains (clouds) that diminish in crosslinking intensity as the number of in-between TADs

increases. As discussed above, the contact pattern of the TADs to the left of *eve* are likely to

arise from partner switching and/or head-to-head boundary pairing interactions that generate

circle-loops. Pairing orientation versus loop topology is considered further in the accompanying

paper (Ke et al. 2024).

Orientation and long-distance regulatory interactions: Our experiments highlight an important

constraint on long-distance regulatory interactions that are mediated not only by boundary

elements like *homie*, *nhomie*, and the meta-loop boundaries in Fig. 9, but also by the GAF-

dependent (LBC) tethering and bypass elements (Batut et al. 2022; Kyrchanova et al. 2023;

Kyrchanova et al. 2018; Kyrchanova et al. 2019a; Kyrchanova et al. 2019b; Levo et al. 2022; Li

et al. 2023; Mohana et al. 2023), namely the orientation of the physical interactions that bring

distant enhancers (or silencers) into close proximity with their gene targets. As we have shown

here, the orientation of the physical interactions that bring distant sequences close together

determines whether the enhancer will be able to activate its target gene. In principle the effects

of orientation could be mitigated by increasing the distance between the boundary/tethering

elements and either the enhancers (silencers) or the promoter. However, distance can be a

critical, rate-limiting step in transcriptional activation. For example, live imaging experiments

have shown that the frequency and amplitude of transcriptional bursts depend on the distance

between the enhancer and target promoter. Nearly continuous bursting and high amplitude

transcription was observed when the enhancer was located close the promoter (Fukaya et al. 2016). However, at distances as little as 6 kb, transcription became discontinuous with discrete bursts, while at 9 kb, the bursts were much less frequent, and the amplitude/output was substantially reduced (Yokoshi et al. 2020). If similar distance-dependent reductions in transcriptional efficiency are common, then it would not be possible to overcome the topological constraints on regulatory interactions by simply increasing the distance between the boundary/tethering elements and the enhancers/promoters. While our studies do not directly address how chromosome architecture impacts regulatory interactions in vertebrates, it is clear that long-distance regulatory interactions in vertebrates (c.f., Tan et al. 2023) will be subject to the same types of topological constraints as those that apply in flies.

Acknowledgements: We would like to thank Gordon Grey for running the fly food facility at Princeton, members of the Lewis Sigler Genomics Core facility for their invaluable assistance with DNA sequencing, and Sergey Ryabichko for his help with smFISH probes. We would also like to thank members of MOL431 for creative input. Special thanks to Qing Liu for invaluable technical assistance, and to Olga Kyrchanova, Daria Chetverina, Maksim Erokhin, Pavel Georigev, Tsutomu Aoki, Girish Deshpande, Airat Ibragimov, Sergey Ryabichko, Yuri Pritykin and Alex Ostrin for stimulating discussions and sharing unpublished data.

Plasmid construction and transgenic lines

The dual reporters construct was described previously (Fujioka et al. 2016). In short, both reporters contain the *eve* basal promoter (-275 to +106 bp relative to *eve* start site), the *lacZ* (*eve-lacZ*) or *EGFP* (*eve-gfp*) coding region, and the *eve* 3' UTR (+1300 to +1525 bp). These two reporters are divergently transcribed. The 367 bp *homie* fragment, or a 500 bp fragment from *lambda* phage DNA, was placed between the two reporters. For the *homie* fragment, we inserted it in the transgene in both orientations, giving *eve-gfp:homie:eve-lacZ* and *eve-gfp:eimoh:eve-lacZ*.

The -142 kb attP landing site was described previously (Fujioka et al. 2009). The -142 kb site contains two attP target sites for phiC31 recombinase-mediated cassette exchange (RMCE) (Bateman et al. 2006) and *mini-white* as a marker. RMCE can result in the insertion of the transgene in either orientation, and all four possible insertions of the two transgenes were recovered. For two of these, *GeimohL* and *GhomieL*, the *eve-lacZ* reporter is on the *eve* side of the transgene *homie*, while *eve-gfp* is on the *hebe* enhancers side of the transgene *homie*. For the other two, *LeimohG* and *LhomieG*, the *eve-gfp* reporter is on the *eve* side of transgene *homie*, while *eve-lacZ* is on the *hebe* enhancers side of the transgene *homie*. RMCE events were identified by loss of *mini-white*, and the orientation of each insert was determined by PCR.

smFISH probe preparation

The sequences of target genes were obtained from Flybase (flybase.org, Gramates et al. 2022). To design probes, the target gene sequences were submitted to the Biosearch Technologies Stellaris RNA FISH probe designer tool (biosearchtech.com), with parameters set to 20nt probes, 48 probes per gene, and mask level 5 for *Drosophila melanogaster*. The sequences of the probes used are listed in Supplemental Data S1. The probes with 3' MdC(TEG-Amino) modifications were then ordered from Biosearch Technologies in 96-well plate format,

cartridge purification and salt free conditions, and in 5 nmol scale. To prepare the fluorophore for probe labeling, the Sigma Atto NHS ester fluorophore (Atto 565 NHS or Atto 633 NHS) was dissolved in dimethylformamide at 5mg/mL as the stock solution. For probe labeling, 1 nmol of each probe was combined and mixed with Atto NHS ester fluorophore at 1mg/mL in 500μL of 0.1M sodium bicarbonate (pH 8.0-8.5) for 2 hours, and the probes were then precipitated with 0.5M potassium acetate (pH 5.2) in 75% EtOH. Then, the probes were dried and resuspended in 50μL of DePC-treated H_2O. The probes were then injected into HPLC columns in which the percentage 0.1M triethylammonium acetate varied from 7% to 30% with a flow rate of 1mL/min. To monitor coupled probes during the HPLC purification, the detector was set to 260nm for DNA and to the absorption wavelength of the coupled fluorophore. The coupled probes were collected when both 260nm and the absorption wavelength channel were detected. The coupled probes were then dried and diluted to the appropriate concentration for smFISH experiments in DePC-treated H_2O.

smFISH

smFISH methods were adapted and modified from previous studies (Little and Gregor 2018; Trcek et al. 2017). 100-200 flies were placed in a cage with an apple juice plate at the bottom of the cage. Early-stage embryos were collected for 7 hours, while for later-stage embryos, collection was overnight. Embryos from each plate were washed into collection mesh and dechorionated in bleach for 2min, then fixed in 5mL of 4% paraformaldehyde in 1X PBS and 5mL of heptane for 15min with horizontal shaking. The paraformaldehyde was then removed and replaced with 5mL methanol. The embryos were then devitellinized by vortexing for 30s, and washed in 1mL of methanol twice. Methanol was then removed and replaced by PTw (1X PBS with 0.1% Tween-20) through serial dilution at 7:3, 1:1, and 3:7 methanol:PTw. The embryos were washed twice in 1mL PTw and then twice in 1mL smFISH wash buffer (4X

SSC, 35% formamide and 0.1% Tween-20). Embryos were incubated with ~5nM coupled

smFISH probes in hybridization buffer (0.1g/mL dextran sulfate, 0.1mg/mL salmon sperm

ssDNA, 2mM ribonucleoside vanadyl complex, 20μg/mL RNAse-free BSA, 4X SSC, 1%

Tween-20 and 35% formamide) for 12-16h. Embryos were then washed twice for 2 hours in

1mL smFISH wash buffer, followed by 4X washing in 1mL PTw. For DAPI/Hoechst staining,

the embryos were stained with 1ug/mL DAPI or Hoechst in PTw, and washed 3X with 1mL

PTw. F inally, the embryos were mounted on microscope slides with Aqua PolyMount and a

#1.5 coverslip for imaging.

Imaging, image analysis and statistics

Embryos from smFISH were imaged using a Nikon A1 confocal microscope system with

a Plan Apo 20X/0.75 DIC objective. Z-stack images were taken at intervals of 2μm, 4X average,

1024x1024 resolution, and the appropriate laser power and gain were set for 405, 561, and 640

channels to avoid overexposure. Images were processed using ImageJ, and the maximum

projection was applied to each of the stack images. To measure the stripe intensity of early

embryos, multi-channel images were first split into single channels and the stripe signal was

highlighted and selected by the MaxEntropy thresholding method. For APR intensity

measurements, the ROI tool was used to crop out the APR region of late-stage embryos. The

cells with APR signal were also highlighted and selected by MaxEntropy thresholding. The

particle measurement tool was used to measure the average intensity of all cells that had a signal.

At the same time, the background signal (average intensity) was taken from cells without a signal

in the same embryo. The relative intensity (signal to background) for each embryo was

calculated using the stripe signal and background from the same embryo. To make comparisons

between independent biological replicates, the average background signal of all embryos from

each replicate was calculated. The relative intensity of each embryo from each replicate was

normalized based on the average background signal of all embryos from same replicates. GraphPad Prism was used for data visualization and statistical analysis. To compare intensity from embryos in different groups, different signals from the same embryo (e.g., *lacZ* and *GFP*) were paired, and paired two-tailed t-tests were used to calculate p-values. All raw measurements and normalized data are included in Supplemental Data S2.

MicroC library construction

Embryos were collected on yeasted apple juice plates in population cages for 4 hours, incubated for 12hr at 25°C, then subjected to fixation as follows. Embryos were dechorionated for 2min in 3% sodium hypochlorite, rinsed with deionized water, and transferred to glass vials containing 5 mL PBST (0.1% Triton-X100 in PBS), 7.5 mL n-heptane, and 1.5mL fresh 16% formaldehyde. Crosslinking was carried out at room temperature for exactly 15min on an orbital shaker at 250rpm, followed by addition of 3.7 mL 2M Tris-HCl pH7.5 and shaking for 5min to quench the reaction. Embryos were washed twice with 15 mL PBST and subjected to secondary crosslinking. Secondary crosslinking was done in 10mL of freshly prepared 3mM final DSG and ESG in PBST for 45 min. at room temperature with passive mixing. The reaction was quenched by addition of 3.7mL 2M Tris-HCl pH7.5 for 5min, washed twice with PBST, snap-frozen, and stored at -80°C until library construction.

Micro-C libraries were prepared as previously described (Batut et al. 2022) with the following modifications: 50uL of 12-16hr embryos were used for each biological replicate. 60U of MNase was used for each reaction to digest chromatin to a mononucleosome:dinucleosome ratio of 4. Libraries were barcoded, pooled and subjected to paired-end sequencing on an Illumina Novaseq S1 100 nt Flowcell (read length 50 bases per mate, 6-base index read).

Micro-C data processing

MicroC data for *D. melanogaster* were aligned to custom genomes edited from the Berkeley Drosophila Genome Project (BDGP) Release 6 reference assembly (dos Santos et al. 2015) with BWA-MEM (Li and Durbin 2009) using parameters **-S -P -5 -M**. Briefly, the custom genomes are simply insertions of the transgenic sequence into the –142kb integration site, as predicted from perfect integration. These events were confirmed using PCR post-integration. The resultant BAM files were parsed, sorted, de-duplicated, filtered, and split with Pairtools (https://github.com/mirnylab/pairtools). We removed pairs where only half of the pair could be mapped, or where the MAPQ score was less than three. The resultant files were indexed with Pairix (https://github.com/4dn-dcic/pairix). The files from replicates were merged with Pairtools before generating 100bp contact matrices using Cooler (Abdennur and Mirny 2020). Finally, balancing and Mcool file generation was performed with Cooler's Zoomify tool.

Virtual 4C profiles were extracted from individual replicates using FAN-C (Kruse et al. 2020) at 400bp resolution. The values were summed across replicates and smoothed across three bins (1.2kb). Viewpoints were determined based on the most informative region for interpretation. Ultimately we decided to use 800bp regions in the gene body of either *GFP* or *lacZ*, moving downstream from the *eve* promoter. However, similar results were obtained using viewpoints between transgenic *homie* and the promoters of either gene. For *homie* viewpoints, due to transgenic *homie* being masked, some loss of signal is expected at the viewpoint (Figs. 7D and 8).

Data availability

Sequence data are available at GEO(GSE263229). All confocal images are available upon request.

Figure Legends

Figure 1. Diagrams of possible loop topologies generated by loop extrusion and boundary:boundary pairing. A) Cohesin embraces a loop at a loading site somewhere within the TAD-to-be and then extrudes a loop at an equal rate on both strands. Extrusion continues until cohesin encounters boundary roadblocks on both strands. B) In one model, the orientation of the roadblock is important. As a consequence, the chromatin fiber will be organized into a series of stem-loops separated from each other by unanchored loops. C) If the presence of a boundary roadblock, but not its orientation, is sufficient to halt extrusion, the chromatin fiber will be organized into a series of linked stem-loops. The main axis of the chromosome will be defined by the cohesin:CTCF roadblocks. D) The pairing of two boundaries head-to-tail generates a stem-loop. E) If boundary pairing interactions are strictly pairwise, head-to-tail pairing will generate a series of stem-loops separated from each other by unanchored loops. F) If boundaries can engage in multiple head-to-tail pairing interactions, the chromosome will be organized into a series of linked stem-loops. The main axis of the chromosome will be defined by a series of paired boundaries. G) The pairing of two boundaries head-to-head generates a circle-loop. H) If boundary pairing interactions are strictly pairwise there will be a series of circle-loops separated from each other by unanchored loops. I) If boundaries can engage in multiple head-to-head pairing interactions, the chromatin fiber will be organized into a series of circle-loops connected to each other at their base. Pairing interactions between boundaries #1 and #2 need not be in register with pairing of boundaries #2 and #3. In this case, the main axis of the chromosome may bend and twist, and this could impact the relative orientations of the circle-loops.

Figure 2. TAD organization of the *even-skipped* locus and neighboring sequences. A) The *eve* TAD is a volcano with a plume that is anchored by *nhomie* and *homie*. ChIP-seq data below the MicroC map indicate that many of the known fly chromosomal architectural proteins are associated with the two *eve* boundary elements *in vivo* (Cuartero et al. 2014; Duan et al. 2021; Gaskill et al. 2021; Li et al. 2015; Sun et al. 2015; Ueberschär et al. 2019; Zolotarev et al. 2016). B) The *eve* locus forms a stem-loop structure. In this illustration, *nhomie* pairs with *homie* head-to-tail, and this forms a stem-loop which brings sequences upstream of *nhomie* and downstream of *homie* into contact, as is observed in insulator bypass assays (Kyrchanova et al. 2008a). The *eve* locus is shown assembled into a coiled "30 nM" chromatin fiber. C) MicroC contact pattern for the chromosomal region spanning the attP site at –142 kb and the *eve* locus. Like the *eve* volcano, this contact pattern was generated using aggregated previously published NC14 data (Batut et al. 2022; Levo et al. 2022). A black arrow indicates the –142kb locus where transgenes are integrated into the genome. A blue arrow indicates the position of the *Etf-QO* gene. Note the numerous TADs between the –142kb *hebe* locus from the *eve* "volcano TAD". Individual TADs are labeled TA—TM. Black boxes indicate positions of sequences that, based on ChIP experiments, are bound by one or more known insulator proteins *in vivo*.

Figure 3. Schematics of boundary pairing and loop extrusion. A) *GeimohL* and *GhomieL* transgenes and the *eve* locus on a linear map. The same color codes are used throughout. In the *eve* locus, *nhomie* (blue arrow) and *homie* (red arrow) are oriented, by convention, so that they are pointing toward the right. This convention is maintained in the two transgenes. In *GeimohL*, *homie* (top) is in the opposite orientation from *homie* in the *eve* TAD and so is pointing away from the *eve* TAD. In *GhomieL* (bottom) *homie* is in the same orientation as *homie* in the *eve* locus and so is pointing towards the *eve* TAD. B) Predicted boundary pairing interactions

between *GeimohL* and the *eve* TAD. *homie* in the transgene pairs with *homie* in the *eve* TAD head-to-head. Since *homie* in the transgene is pointing in the opposite orientation from *homie* in the *eve* TAD, a stem-loop will be generated. C) If *homie* in the transgene also pairs with *nhomie* in the *eve* TAD head-to-tail, a loop structure like that shown in C will be generated. In this topology, *eve-lacZ* is in close proximity to *eve* enhancers, and *eve-gfp* is in contact with the *hebe* enhancer. D) Loop-extrusion model for *GeimohL*. Transgene *homie* and endogenous *homie* determine the endpoints of the extruded *eveMammoth* (*eveMa*) loop. Like B, the topology of *eveMa* is a stem-loop. This topology brings *eve-lacZ* into close proximity to the *eve* enhancers, while *eve-gfp* is in another loop that contains the *hebe* enhancers. E) Predicted boundary pairing between *GhomieL* and the *eve* locus. The *GhomieL* transgene is inserted in the same chromosomal orientation as *GeimohL*; however, the *homie* boundary is inverted so that it is in the same orientation as the *eve homie*, and so it is pointing towards the *eve* TAD. *homie* in the transgene will pair with *homie* in the *eve* locus head-to-head, and this generates a circle-loop. F) If *homie* in the transgene also pairs with *nhomie* in the *eve* TAD, a loop structure like that shown in F will be generated. In this topology *eve-gfp* will be activated by both the *eve* and *hebe* enhancers. G) Loop-extrusion model for *GhomieL*. The cohesin complex bypasses transgenic *homie* and is stopped at an upstream boundary X, to generate a novel *eveGarantuan* (*eveGa*) loop. Both *eve-gfp* and *eve-lacZ* are located within the same *eveGa* TAD, and thus should interact with *eve*. Since the *hebe* enhancers are within this TAD as well, they would also be able to activate both reporters.

Figure 4. The *lacZ* reporter is activated by *eve* enhancers in the *GeimohL* insert. A) Expression patterns of endogenous *eve* in early (stage 4-5) and late (stage 14-16) embryos by smFISH. *eve* (Atto 633) probes were used to hybridize with *eve* mRNA. *eve* is shown in yellow and DAPI in blue. N>3. B) Schematics of transgenes. C) Expression patterns of transgenic reporters in early-stage embryos. Top: *GlambdaL*; bottom: *GeimohL*. GFP is in green, *lacZ* is in orange, and DAPI is in blue, here and in E. D) Quantification of normalized stripe signals for transgenes shown in C. The reporter smFISH intensity (signal to background), here and in F, was measured, normalized, and plotted as described in Methods. N>3. n=27 for *GlambdaL* and n=42 for *GeimohL*. E) Expression patterns of transgenic reporters in late-stage embryos. Top: *GlambdaL*; bottom: *GeimohL*. F) Quantification of normalized stripe signals for transgenes shown in E. N>3. n=27 for *GlambdaL*, n=56 for *GeimohL*. Scale bars = 200μm. N = # of independent biological replicates. n = # of embryos. The paired two-tailed t-test was used for statistical analysis. ****p < 0.0001, ns: not significant. Raw measurements are available in the Source Data files.

Figure 5. The *GFP* reporter is activated by both *eve* and *hebe* enhancers in the *GhomieL* insert. A) Schematics of transgenes. B) Expression patterns of transgenic reporters in early-stage embryos. Top: *GlambdaL*; bottom: *GhomieL*. GFP is in green, *lacZ* is in orange, and DAPI is in blue, here and in D. C) Quantification of normalized stripe signals as represented in B. The reporter smFISH intensity (signal to background) was measured, normalized, and plotted as described in Methods, here and in E. N>3. n=27 for *GlambdaL,* n=46 for *GeimohL*. D) Expression patterns of transgenic reporters in late-stage embryos. Top: *GlambdaL*; bottom: *GhomieL* . E) Quantification of normalized stripe signals for transgenes shown in D. N>3. n=27 for *GlambdaL*, n=59 for *GeimohL*. Scale bars = 200μm. N = # of independent biological replicates. n = # of embryos. The paired two-tailed t-test were used for statistical analysis. ****p < 0.0001, ns: not significant. Raw measurements are available in the Source Data files.

Figure 6. Expression of reporters in the *LeimohG* and *LhomieG* inserts. A) Schematics of GE transgenes. B) Boundary pairing for *LeimohG* transgene long-range interactions. In this topology, *GFP* is in close proximity to *eve* enhancers, and *lacZ* is in contact with the *hebe* enhancer region. C) Boundary pairing for the *LhomieG* transgene. In this topology, *lacZ* is in close proximity to both the *eve* enhancers and the *hebe* enhancers. D) Loop-extrusion model for *LeimohG*. Transgenic *homie* and endogenous *homie* flank the *eveMammoth* loop. In this topology, *GFP* is in close proximity to *eve* enhancers, and *lacZ* is close to the *hebe* enhancers. E) Loop-extrusion model for the *LhomieG* transgene. The cohesin complex bypasses transgenic *homie* and is stopped at an upstream boundary X, to create the *eveGarantuan* loop. Both *GFP* and *lacZ* are at a similar physical distance from *eve* enhancers and *hebe* enhancers in this topology. F) Expression patterns of transgenic reporters in early-stage embryos. Top: *LeimohG*; bottom: *LhomieG*. *GFP* is in green, *lacZ* is in orange, and DAPI is in blue. N=3, n=24 for both *LeimohG* and *LhomieG*. G) Expression patterns of transgenic reporters in late-stage embryos. Top: *LeimohG*; bottom: *LhomieG*. N=3, n=24 for both *LeimohG* and *LhomieG*. Scale bars = 200μm, N = # of independent biological replicates, n = # of embryos. Statistical analysis is in Table Supplemental #1.

Figure 7. *homie* in transgenes *LhomieG* and *LhomieG* mediates long-range physical interactions with the *eve* TAD. Diagrams for panels A, B, and C. yellow box: 5' end of the *hebe* transcription unit. Transgene: green box: *eve-gfp* reporter, orange box: *eve-lacZ* reporter, black box: *lambda* DNA, red block arrow: *homie* DNA. *eve* TAD: blue block arrow: endogenous *nhomie*, red block arrow: endogenous *homie*; the directions of block arrows follows the established convention for *nhomie* and *homie*; gray boxes: *eve* enhancers, yellow box: *eve* transcription unit. A) MicroC contact profile of the control *GlambdaL*. Inset shows a blow-up of the contacts between the *GlambdaL* transgene and the *eve* TAD. Note a slight increase in interaction frequency (compare to Figure 1A). B, C) MicroC map of *GeimohL* and *GhomieL*, respectively. The key difference between the two inserts is the contacts between transgenes and sequences in the *eve* TAD. Note the changed pattern of interaction with the endogenous *eve* locus due to the orientation switch. D) "Virtual 4C" maps obtained from MicroC maps of "B" (top panel) and "C" (bottom panel). Viewpoints are shown in both panels from either the *lacZ* gene (orange) or the *GFP* gene (green).

Figure 8. *homie* in the transgene interacts with *eve homie* and *nhomie*. "Virtual 4C" maps of the *GeimohL* and *LhomieG* (A) or *GhomieL* and *LeimohG* (B) transgenes oriented so that *lacZ* (blue) or *gfp* (orange) is located on the *eve* side of the *homie* boundary. Viewpoints are taken from the transgenic *homie* sequence. Note that transgenic *homie* preferentially interacts with endogenous *homie* in both orientations.

Figure 9. Circle-loop and stem-loop meta-loops. Distant boundary elements can find and pair with each other, forming large meta-loops. **Panel A** shows a circle-loop meta-loop formed by the head-to-head pairing of the blue (blue arrow) and purple (purple arrow) boundaries. As described in the text, the blue boundary separates a small TAD that contains the most distal *Lar* promoter (indicated by the black arrowhead) and a larger TAD that contains part of the *Lar* transcription unit (and is upstream of an internal *Lar* promoter: green arrowhead). The purple boundary is located between two TADS, Pa and Pb, in a gene-poor region of the 2nd chromosome approximately 600 kb away downstream of the *Lar* gene. When the blue and purple boundaries pair, sequences in the small TAD upstream of the blue boundary come into contact with sequences in the Pa TAD upstream of the purple boundary. This interaction generates the dark

rectangle on the upper left side of the interaction plot. Sequences downstream of the blue boundary in the TAD containing part of the *Lar* transcription unit are also brought into contact with sequences in the Pb TAD downstream of the purple boundary. This interaction generates the larger rectangular box on the bottom right side of the interaction plot. Shown in the diagram on the right is a schematic illustrating that the head-to-head pairing of the blue and purple boundaries generates a ~600 kb circle-loop. In the circle loop configuration, sequences in the TADs upstream of the blue and purple boundaries come into contact with each other, as do sequences downstream of the blue and purple boundaries (blue double arrows). **Panel B** shows a stem-loop meta-loop formed by the head-to-tail pairing of a boundary (blue arrow) located upstream of the *beat IV* gene with another boundary (purple arrow) located ~6 Mb away, between the *Sid* and *snu* genes. The blue boundary separates a small TAD containing three UDP-glycosyltransferase genes from a larger TAD containing the *CG10164* gene and the distal-most promoter of the *beat IV* gene. The purple boundary separates a ~20 kb TAD containing *Sid* and four other genes from a small TAD that contains the most distal *snu* promoter (green arrowhead). When the blue and purple boundaries pair with each other head-to-tail (see diagram on right), this interaction brings sequences in the large TAD downstream of the blue boundary into contact with sequences upstream of the purple boundary in the 20 kb *Sid* TAD, and this generates the large rectangular box to the lower left of interaction map. The stem-loop configuration also brings sequences upstream of blue boundary in the small TAD containing the three UDP-glycosyltransferase genes into contact with the TAD containing the distal-most *snu* promoter. This interaction gives a small rectangular box with a high contact density. Sequences in the TAD upstream of the UDP-glycosyltransferase TAD are also brought into contact with the small TAD containing the *snu* promoter. These two interacting "zones" are indicated by blue double arrows in the diagram on right. In addition to boundary:boundary pairing, both meta-loops have a prominent dot in the larger regular boxes indicated by the green (panel A) and blue (panel B) arrows. Based on the ChIP signature of the sequences giving rise to these dots, they likely correspond to elements that are bound by the GAF containing LBC complex, as indicated in the figure ("*LBC*" in both panels). LBC elements in other contexts function to bring enhancers into contact with promoters (Batut et al. 2022; Kyrchanova et al. 2023; Kyrchanova et al. 2019a; Kyrchanova et al. 2019b; Levo et al. 2022).

Supplemental Figures:

Figure Sup. 1. TAD organization of the *even-skipped* gene and upstream region. MicroC contact pattern for the chromosomal region spanning the attP site at –142 kb and the *eve* locus. Like the *eve* volcano, this contact pattern was generated using aggregated previously published NC14 data (Batut *et al.*, 2022; Levo et al., 2022). The large black arrow indicates the –142kb locus where transgenes are integrated into the genome. LDC domains are labeled according to the interacting TADs: for example, H-I indicates crosslinking events generated by physical interactions between sequences in two neighboring TADs, TH and TI, while I-J indicates interactions between sequences in TI and TJ. Likewise, G-I indicates crosslinking events generated by physical interactions between sequences in TADs TG and TI, which are separated from each other by TAD TH. Note that unlike the TADs to the left of *eve*, the *eve* TAD does not interact frequently with its neighbors. The small black arrow indicates an interaction "dot" between the boundary marking the border of TA and TB and the boundary marking the border of TI and TJ. Red, blue and green arrowheads mark boundaries that may engage in partner switching (see text).

Figure Sup. 2. Trouble ahead, trouble behind. A) Illustration of a broken zipper—zipping in front but not closing behind. **B)** Crosslinking pattern expected for cohesin loading at a site very close to the middle of the TAD-to-be: The vertical line of linked DNA is generated when the two chromatin fibers in the TAD-to-be are transiently linked together as cohesin passes. When cohesin bumps into the CTCF roadblocks (BE) at the boundaries of the TAD, the vertical line stops. **C)** Cohesin loading site is offset from center of TAD-to-be to the left. The crosslinking initiates at the loading site and extends vertically until the cohesin complex bumps into the CTCF roadblock on the left. At that point, extrusion of the left chromatin fiber halts, while the chromatin fiber on the right continues to be extruded. The line of crosslinked sequences then extends at a 45º angle until cohesin comes to a halt at the CTCF roadblock on the right. **D and E)** The loading site is at or close to the boundary on the left (D) or the right (E). In this case extrusion will be unidirectional, and the DNAs crosslinked as cohesin passes will form a line that extends at a 45º angle until cohesin comes to a halt at the CTCF roadblock. **F)** Cohesin is able to load at multiple sites in the TAD-to-be. In this case, there will be a series of vertical lines whose intensity will be correlated with the relative frequency that a give loading site is used. The vertical lines will extend in each case until cohesin comes to a halt at the closest CTCF roadblock. At that point, the line of crosslinked DNA will extend at a 45º angle until that particular cohesin complex comes to halt at the CTCF roadblock that is farther away. The 45º line of crosslinked DNA will become progressive more intense as it approaches the apex of the triangle. These vertical lines might follow other paths if the loop extrusion is not at equal rates on the two sides, or if it varies stochastically, but even in these cases, the expectation that the 45º lines will be more intense toward the top of the "peak" is still valid.

Figure Sup. 3. Models for the formation of LDC domains. Several different mechanisms could explain the LDC domains. **A-D)** In the loop-extrusion model, the LDC domains arise because cohesin sometimes breaks through a CTCF roadblock. In A) there are three primary TADs,: TAD1, TAD2, and TAD3. B and C) Occasional breakthrough events can generate a secondary TAD, LDC1:2 (TAD1+TAD2) or LDC2:3 (TAD2+TAD3). D) Even less frequent breakthrough events can generate a tripartite TAD (TAD1+TAD2+TAD3) that will correspond to LDC1:3. **E-G)** LDC domains arise because TADs sometimes bump into their neighbors. In

E, TAD1 bumps into TAD2 to give LDC1:2, while in F, TAD2 bumps into TAD3 to give LDC2:3. G) Less frequently, TAD1 bumps into TAD3 to give LDC1:3. **H-J)** LDC domains arise because boundaries can switch partners. H and I) In H, boundary A (dark green arrow) skips boundary B (red arrow) and pairs with boundary C (tan arrow). This generates a new TAD, TAD1+TAD2, which corresponds to LDC domain 1:2. In I, boundary B (red arrow) skips boundary C (tan arrow) and pairs with D (dark blue arrow). This generates a new TAD, TAD2+TAD3, which corresponds to LDC domain 2:3. In J, boundary A (dark green arrow) skips both boundary B (red arrow) and boundary C (tan arrow), which don't pair with each other, and pairs with boundary D (dark blue arrow). This generates a new TAD, TAD1+TAD2+TAD3, which corresponds to LDC domain 1:3.

Figure Sup. 4. Loop extrusion: *eveElephant.* **A)** Loop extrusion orientation-dependent model for *LeimohG* transgene as the sketched in Figure 3D. This configuration generates *eveMa*. **B)** Instead of running through *nhomie*, the cohesin complex comes to a halt at the *nhomie* boundary, generating *eveElephant*. A second cohesin complex generates the *eve* TAD by loading at a site within the *eve* locus. Both *eveElephant* and the *eve* TAD are stem-loops. However, while this double stem-loop configuration would explain why the transgene *homie* makes contact with both *nhomie* and *homie*, the *eve* enhancers are isolated in their own loop and would not interact with the two reporters in the transgene.

Figure Sup. 5. MicroC of *LeimohG*. A) MicroC contact map of *LhomieG*. Diagram below the contact map shows the *homie* transgene and the *eve* TADs. Gray lines are masked regions due to repeat sequences. Interactions between the transgene and the *eve* TAD are indicated by the boxed region, and this boxed region is also shown in the inset on the right. The inset shows that the physical interactions between *LhomieG* and sequences in the *eve* TAD are biased toward the *eve-gfp* reporter. **B)** "Virtual 4C" map from either the *lacZ* (brown line) or *GFP* (green line) gene body viewpoints.

Figure Sup. 6. Micro C of *LhomieG*. A) MicroC map of *LhomieG*. Diagram below the contact map shows the *homie* transgene and the *eve* TADs. Gray lines are masked regions due to repeat sequences. The interaction pattern is the opposite of that observed for *LeimohG* (Figure Sup. 5). Instead of interacting with the *eve-gfp* reporter, sequences in the *eve* TAD interact preferentially with the *eve-lacZ* reporter. The relevant region is boxed, and also shown in the inset. **B)** "Virtual 4C" map from either the *lacZ* (brown line) or *GFP* (green line) gene body viewpoints.

Figure Sup. 7. Blowup of interactions generated by the transgene with sequences neighboring –142 kb and the *eve* TAD. The interaction pattern indicates that the loop topology changes along with the orientation of transgenic *homie*. Blow-up of off-diagonal interactions, focused on the interaction between the endogenous *eve* locus and the –142kb transgenic insert with **A)** *LhomieG,* **B)** *GhomieL,* **C)** *GeimohL,* or **D)** *LeimohG.* Note the differences in preferential interaction between regions adjacent to transgenic *homie* and endogenous *homie* (indicated by the double arrow pairs). In the two cases where transgenic *homie* is in the same orientation in the genome as endogenous *homie* (A and B), regions downstream of the transgene preferentially interact with regions downstream of endogenous *homie* in the *TER94* TAD. In contrast, when transgenic *homie* is in the opposite orientation in the genome as endogenous *homie* (C and D), sequences upstream of the transgene preferentially interact with sequences downstream of endogenous *homie* in the *TER94* TAD.
