Abstract

ATAC-seq has emerged as a rich epigenome profiling technique, and is commonly used to identify Transcription Factors (TFs) underlying given phenomena. A number of methods can be used to identify differentially-active TFs through the accessibility of their DNA-binding motif, however little is known on the best approaches for doing so. Here we benchmark several such methods using a combination of curated datasets with various forms of short-term perturbations on known TFs, as well as semi-simulations. We include both methods specifically designed for this type of data as well as some that can be repurposed for it. We also investigate variations to these methods, and identify three particularly promising approaches (chromVAR-limma with critical adjustments, monaLisa and a combination of GC smooth quantile normalization and multivariate modeling). We further investigate the specific use of nucleosome-free fragments, the combination of top methods, and the impact of technical variation. Finally, we illustrate the use of the top methods on a novel dataset to characterize the impact on DNA accessibility of TRAnscription Factor TArgeting Chimeras (TRAFTAC), which can deplete TFs – in our case NFkB – at the protein level.

Author summary

Transcription factors regulate gene expression by binding sites in the genome that often harbor a specific DNA motif. The collective accessibility of these motifs, measured by technologies such as ATAC-seq, can be used to infer the activity of the corresponding transcription factors. Here we use curated datasets of 11 TF-specific perturbations as well as 116 semi-simulated datasets to benchmark various methods for identifying factors that differ in activity between experimental conditions. We investigate important analytic variations and make recommendations pertaining to such analysis. Finally, we illustrate the application of the top methods to characterize the impacts of a novel method for perturbing transcription factors at the protein level.

Introduction

Transcription factors (TFs) regulate transcription by binding specific sites in the genome, which often harbor a corresponding DNA motif. Identifying which TFs regulate a given transcriptional signature is critical to a mechanistic understanding of gene expression. The expression of the TFs themselves can sometimes be a useful indicator of their involvement, especially between cell types and developmental stages. However, it is often a poor proxy for their activity in dynamic settings, where their activity is often regulated post-transcriptionally. For example, the TF ATF4 is critical to the integrated stress response, and its mRNA is already present in cells but its translation is blocked by an upstream uORF until a translation initiation factor is modified [1, 42]. Another example is the cAMP-response element binding protein (CREB), which is fundamental to a number of processes: CREB is already translated but its phosphorylation strongly enhances its DNA binding ability and allows for the recruitment of co-factors ([20]). Further common examples are nuclear receptors, which in general are outside the nucleus until activated by their ligand, upon which they translocate to the nucleus to affect transcription [37]. It is therefore critical to have means of measuring TF activity independently of their expression.

An obvious approach is to profile TF binding through ChIP-seq or derivative technologies, which is however time-consuming, can only be done one TF at a time, and depends on the availability of high-quality antibodies. DNA accessibility instead promises a less biased approach for the discovery of TFs underlying a change in cellular phenotype. In particular, the Assay for Transposase-Accessible Chromatin with sequencing (ATAC-seq) has emerged as a simple, fast accessibility assay that requires little starting material [9, 11], being even amenable to single-cell analysis [8]. Since TF binding is associated with DNA accessibility, such assays offer genome-wide evidence for TF binding, though without TF specificity. In conjunction with a compendium of DNA binding motifs, however, the activity of different TFs can in principle be resolved in terms of global motif accessibility. A number of methods from transcriptomics can be repurposed for this task [21, 4, 2], and a number of others have been developed specifically for it [36, 25, 6, 5]. In general, they can be divided into two families: 1) 'fold-change-based' methods do not operate on individual ATAC-seq samples, but on a vector of per-peak fold-changes between conditions (e.g. obtained from differential accessibility analysis), while 2) 'sample-based' methods assign each motif a score in each sample, which can then, if desired, be compared between experimental groups. To our knowledge, these methods were never thoroughly compared and evaluated.

Here we benchmark methods for differential TF activity inference from ATAC-seq. We curated a set of ATAC-seq datasets with replicates, profiling genome-wide accessibility upon perturbation (activation or repression) of a specific TF with an annotated DNA binding motif. To limit the effect of indirect downstream effects, which would make the true perturbation (and hence the benchmark) ambiguous, we included only datasets in which the samples were profiled relatively early after the intervention. For ligand-based activation, which is very fast [26], we included only datasets up to 4h after intervention. For genetic deletion, which takes the longest to take effect, we used a cutoff of 72h. These cutoffs are obviously not perfect and were largely set in a compromise to gain a sufficient number of datasets while mitigating the impact of indirect effects. The included datasets are shown in Table 1, and the magnitude of peak-level changes in accessibility upon treatment are illustrated in Supplementary Fig S1. We further complemented these real datasets with semi-simulations incorporating perturbations of only one specific TF at a time using ChIP-seq derived peak coordinates.

Description of the benchmark datasets.

Materials and methods

Datasets preprocessing

For the baseline data for simulation, as well as for the NR3C1 benchmark dataset, filtered alignments and peaks were downloaded from ENCODE (NR3C1: ENCSR385LRX; for the datasets related to the simulations, see Table 2).

For the SpearATAC-seq datasets (GSE168851: GATA1, GATA2, RUNX1, RUNX2, KLF1, MYC), the fragment file and processed SummarizedExperiment object were downloaded from GEO. We used the processed object to identify the 3-day cell barcodes assigned to each guide RNA. Then, we merged the fragments for each guide RNA, creating 21 pseudobulk samples (3 guides per 6 target genes + 3 control guide RNAs). For methods that specifically require BAM files, the fragment files were converted using bedToBam.

For other datasets (ESR1/2: GSE117940, NR1H3/4: GSE149075, BANP: GSE155604), and the in-house TRAFTAC dataset, we downloaded the raw reads (if published) from SRA, removed adapters using Trimmomatic 0.38 [7], aligned using Bowtie2 2.3.4.3 [23] against either GRCh38.p10 or GRCm38. Duplicated fragments were marked by using Picard 2.18.27, and peak calling was done using MACS2 2.2.5 using BAMPE (or BEDPE) mode. Peaks overlapping ENCODE blacklisted regions [3] were removed. Consensus peaks were obtained by merging the peak calls of the peak samples (i.e. GenomicRanges::reduce). Since some methods recommend resizing peaks to a common size, we resized peaks (to 300bp, which is recommended by chromVAR and was close to the median peak size) for all methods, and then generated peak count tables using 'chromVAR::getCounts'.

For nucleosome-free filtering, we used fragments between 30 and 120bp. Given the reduction in effective number of reads, we called peaks with MACS2 on the merged fragments across samples, using a q-value threshold of 0.01. We then resized peaks to 150bp (again because this was very close to the median peak size).

Peak-level differential analysis was performed with edgeR 3.32.1 [32].

Motifs and motif matching

For all methods, we used the HOCOMOCO 10-11 motifs [22] available in the MotifDb package version 1.32.0 [38]. Specifically, we queried for HOCOMOCO motifs of the respective species in the database and kept the newest and highest-quality motif for

each gene symbol (see the 'getNonRedundantMotifs()' function of the repository). The BANP motif was not available in any database and therefore, we obtained the published one [14] from the authors and added it manually to the collection. Similarly, the NR1H3 had a human motif, but no mouse motif; we therefore complemented the mouse motif collection with the human motif.

To avoid this being a source of variation between methods, whenever possible we tried to standardize the motif matching across methods, using a common fimo 4.11.2 [15] motif scan with default parameters. monaLisa, however, did not allow us to provide the motif matches and performed its own motif matching.

Differential motif activity methods and their application

chromVAR

While originally designed to analyze sparse chromatin-accessibility data from scATAC-seq data, chromVAR [36] is also commonly applied to bulk ATAC-seq data. The algorithm computes deviations between the summed fragment counts of peaks containing a certain motif and the expected number of fragments based on the average of all samples/cells, and then compares these deviations to that of random sets of (background) peaks with similar GC content and average accessibility as those containing the motif, to adjust for technical biases. Specifically, the method produces two matrices of sample/cell- and motif-specific scores: bias-adjusted deviations, and z-scores compared to a background. These scores can then be used to perform differential analysis across groups of cells/samples. The package includes a function to this effect, 'chromVAR::differentialDeviations'. In addition, we tested a variation using 'limma::eBayes' [31] to test for differences in chromVAR activity scores between groups, either based on the adjusted deviations (denoted 'chromVAR(deviations)>limma') or on the z-scores (denoted 'chromVAR(z)>limma'), as well as different normalizations of these scores before differential analysis. Importantly, we observed that the results of the differential analysis were not reproducible across different random seeds unless we considerably increased the default number of background sets (Supplementary Fig S2A). All comparisons were therefore run with 2000 background iterations. Otherwise, the package's guidelines were followed.

monaLisa: Binned motif enrichment

MonaLisa [25] comes with two distinct algorithms, and the first follows a binned enrichment analysis approach. First, ATAC-seq peaks are grouped into bins according to their change in accessibility (i.e. log-fold-change, or logFC) across conditions. Motif over-representation is then assessed for each bin, either in comparison to the bin centered around a logFC of zero, i.e. the peaks not changing (this variant is here denoted as 'monaLisa.vsZero'), or against all other bins (denoted 'monaLisa.vsOthers'). The method can also correct for differences in sequence composition including GC bias in the same fashion as HOMER [17]. In some rare cases, the binning procedure triggered an error due to ties in the logFCs; to avoid this, we therefore added a very small amount of noise to the logFC vector (jitter with a factor of 0.001). monaLisa produces a p-value for each bin and motif, which is not easily comparable to alternative methods that produce a single p-value per motif. Since the bins' p-values cannot be deemed independent, we tested different p-value aggregation methods that did not assume so, including Simes, Cauchy [24], mean and geometric mean p-values and settled for Simes' as offering the best results (data not shown).

monaLisa: Randomized Lasso stability selection

The second method included in monaLisa follows a randomized lasso stability selection. The goal here is to select TFs as predictors for the observed changes in accessibility. Due to the nature of the robust regression approach, similar motifs compete to be selected. To correct for GC bias, the GC content of the peak sequences can be included as an additional predictor. The model returns a selection probability for each predictor, which we used as a ranking of the motifs for benchmarking. The selection probability cannot be interpreted as a p-value, and since the authors recommend a threshold of 0.9 for stringent selection, we used this threshold for computing precision and recall.

diffTF

diffTF [6] is another method based on peaks logFC between conditions, but which bins peaks by GC content to be more robust to technical variations. Within each bin, the logFCs of peaks with the given motif are compared to those without. It can be run in two modes: in the sample permutation mode, the differences are compared to differences between permuted groups of samples, while the analytic mode establishes p-values analytically. The latter is theoretically more appropriate for small sample sizes, as is the case in our benchmark datasets. We nevertheless tested both modes. diffTF was used via the pre-configured Singularity container provided by the authors, following the quick start guide. We configured diffTF with a maximum usage of 8 cores with each rule being allocated a maximum of 4 cores. The number of permutations was raised from 50 to 1000 as recommended by the developers (however due to sample size the effective number of permutations was substantially lower). To make the method comparable with alternatives, we provided the motif occurrences using the same scans as for other methods. Everything else was kept to the default settings.

VIPER and msVIPER

The viper package was especially developed to infer differentially-active TFs from transcriptomic data, using either co-expression networks [2] or curated regulons [13]. While it was not used in the context of ATAC-seq to our knowledge, given the similarity of the tasks it was a natural solution to try, simply by converting motif matches into regulons, which become the sets of peaks containing each motif, along with the motif matching scores (scaled by the maximum observed matching score for each motif). The 'tfmode' (repression or activation) was set to 1 for all targets. Based on the same regulons, the package offers two main functions: the 'viper' method uses an analytical rank-enrichment analysis to compute per-sample TF activity score, while the 'msviper' method works on the vector of per-peak fold-changes between conditions. For the 'viper' method, we first transformed the expression matrix using DESeq2's variance-stabilizing transformation and then used viper's t-test method, and then used limma on the samples' activity scores. Otherwise, both methods were used with default parameters. We tested both approaches using either regulons weighted (likelihood of the links) by the motif scores (denoted e.g. 'VIPER(scores)'), or with all likelihoods set to 1 (denoted e.g. 'VIPER(binary)').

decoupleR

decoupleR is a generic package to extract, from -omics data (typically transcriptomics or proteomics), what it conceptualizes as 'biological activities' – of transcription factors, pathways, or enzymes, etc [4]. It includes a unified interface to use a variety of methods, as well as an ensemble ('consensus') method. We tested the top methods from the decoupleR paper: univariate linear models (ulm), multivariate linear models (mlm),

weighted sum (wsum), univariate decision tree (udt), as well as the consensus thereof. [175] Of note, decoupleR can in principle be applied to the peak logFCs, yielding direct [176] significance estimates of differential activity, or (the typical workflow) to the normalized [177] peak count matrix, yielding motif activity scores per sample. We tested both [178] approaches, and for the second (denoted here 'decoupleR>limma') once again applied [179] limma::eBayes to perform differential activity analysis on the motif activity scores. [180]

fGSEA [181]

Geneset Enrichment Analysis (GSEA) is a powerful way to look for enrichment of [182] certain sets (in this case, sets of peaks containing each motif) in a vector of scores per [183] element (in this case, peaks' logFC between conditions). To circumvent the long [184] running time of traditional GSEA, we used the fast multi-level implementation from the [185] fgsea package [21]. To avoid ties in the results, we set nPermSimple=10000 and eps=0. [186]

ATACseqTFEA [187]

ATACseqTFEA [28] works under the premise that TFs leave a footprint, and calculate, [188] for each site, a weighted binding score that takes the insertion counts proximal to the [189] motif in relation to those at the motif, weighted by the distal count. It then computes [190] the difference in mean scores between the two experimental groups for each site and [191] performs a GSEA-like enrichment score across the ranked peaks for all sets of peaks [192] containing each motif. The method was run on motif matches inside peaks, as [193] recommended. [194]

BagFootLike [195]

The original BagFoot method [5] does not involve proper statistical testing, is bound [196] not to work for the many factors that do not leave a footprint [39], and furthermore we [197] had some difficulties running the code. For these reasons, we implemented a logic [198] inspired by BagFoot, again using limma to test for differences in both the footprint [199] depth and the flanking accessibility, and then combining those tests using Fisher's [200] method. As in the original BagFoot, we used 20bp on each flank of the motif to [201] calculate footprint depth, while flanking accessibility was calculated on the 200bp on [202] each side. We left out the sequence bias correction (reasoning that it is the same across [203] samples, and should not impact relative analyses). [204]

Insertion model [205]

Inspired by various methods [5, 28] and the fact that, when hypothesizing a difference [206] in motif activity, one commonly compares the aggregated insertion profiles around motif [207] instances, we developed a method that counts the (shifted) insertion events around (+/- [208] 200bp) motif matches overlapping peaks for each sample, then for each motif, weights [209] the insertions based on their position to the motif match. The weights are based on the [210] global insertion profile of the motif across samples, smoothed and made symmetrical [211] (see for example Supplementary Fig S2B). The weighted insertion counts are then [212] summed to produce a score per motif and sample, and differential motif activity is done [213] using limma. [214]

Simple linear regression approaches [215]

We also tested simple per-motif linear regression of the logFCs on either 1) whether or [216] not the peak contains the motif ('ulm(binary)'), 2) the motif matching scores [217]

('ulm(scores)'), as well as 3) whether or not the peak contains the motif plus the peak's GC content as a covariate ('ulm+GC').

Finally, we tested a lasso- or ridge-regularized linear regression of the logFCs on the matrix of (binary) motif matches.

Benchmark metrics

For rank-based metrics, the results of each method were sorted first according to uncorrected p-values, then by absolute effect size (e.g. logFC, coefficient or enrichment score). This was especially important for permutation-based methods that often produce ties.

To compute the rank of the true motif, we considered the true motif that of the manipulated TF, with some special cases: the estradiol treatment is expected to affect both estrogen receptors (ESR1 and ESR2), and therefore both were considered as true; as far as is known, MYC only binds to DNA in cells when in a heterodimer with MAX, and since the MYC motif was not detected by any method but the MAX was by the top methods, we considered both as 'true motifs'; similarly, NR1H4 (also known as FXR) typically binds DNA as a heterodimer with RXR, and were therefore included also RXRA and RXRB as true motifs. For datasets that had more than one true motif, we used the best rank of any true motif per method as the 'rank of the true motif'.

For the 'network score', we first downloaded from BioGRID 4.4 all the known physical interactors of each true TF (in the species of the respective dataset), and any motif that overlapped with these interactors (as well as the true motif itself) was considered a network member. For each method, and for k=1:100, we calculated the proportion of top k motifs that are network members, producing a curve as shown in Supplementary Fig S2C. We then computed the area under this curve (AUC) and divided it by the maximum AUC theoretically obtainable for the dataset (which depends on the number of annotated interactors).

Precision and recall were calculated using an adjusted p-value $<= 0.05$, except for monaLisa's stability selection method (which does not provide p-values), for which we used a selection probability of 0.9 as the threshold. Otherwise, if the methods did not report an adjusted p-value, one was generated using the Benjamini, Hochberg, and Yekutieli methods. To calculate precision, network members were counted as positives. However, since not all network members can be expected to be relevant in a given cellular context, only the aforementioned 'true motifs' were considered for calculating recall (i.e. sensitivity).

Semi-simulations

The semi-simulations were performed by introducing perturbations in the signal of one TF at a time in a baseline ATAC-seq dataset.

As a baseline, six (control) samples of a lymphoblastoid cell line (HG03442) dataset were downloaded from ENCODE [40] (see Table 2 for an overview of the data used for the semi-simulations). To obtain specific perturbations, the baseline ATAC-seq datasets were overlapped with ChIP-seq peaks of that TF from the same cell type. The baseline ATAC-seq samples were divided into two groups, and peak-overlapping regions were downsampled in one of the groups (see Supplementary Fig S7).

Fold-changes

The extent of downsampling followed one of two differential binding scenarios (TF activation and haploinsufficiency), each based on a real reference ChIP-seq dataset (Table 2) in which the distribution of log-fold-changes between conditions is associated

to the degree of respective peaks' enrichment over the input (Fig 4B). Specifically, the enrichment of the peaks to be downsampled was quantile normalized to those of the reference peaks in order to select the fold-change of the closest matching reference peak. The resulting log fold changes were introduced in the baseline ATAC-seq samples by down-sampling ATAC-seq fragments overlapping ChIP-seq peaks in one of the groups (Fig 4A). To test sensitivity of the methods to the strength of the perturbations, the fold changes were further multiplied by different factors (0, 0.25, 0.5, 1, 3) that we refer to as 'perturbation strength'.

Of note, this semi-simulation procedure rests on the assumption that changes in binding are associated to corresponding changes in accessibility, which is not always the case.

Technical variation

Further, technical variations were inserted in some semi-simulations by varying GC content and fragment length (FL) distributions (see Supplementary Fig S7C for an overview of the semi-simulated datasets). Fragment GC content distributions were varied sample-wise by sampling fragments according to their GC content, mimicking reference GC content distributions. FL distributions of the baseline ATAC-seq samples were varied by sampling nucleosome-free-, mono-, di- and multi-nucleosome (>2) containing fragments with differing sampling probabilities. Fragments were classified by applying fixed thresholds on their lengths ($<= 120$, > 120 & $<= 300$, $300 >$ & $<= 500$, > 500).

After obtaining the semi-simulated ATAC-seq profiles by (under-)sampling fragments in ChIP-seq peak regions or according to their GC content or length, peaks were called for each of the groups separately using MACS2 and merging the peaks of both groups using the bedtools [30] merge command.

TRAFTAC experiment

Cell culture

HEK293 cells were cultured in Dulbecco's Modified Eagles Medium (DMEM) with 10% Fetal Bovine serum (FBS) (Gibco,10500064) and 1% Penicillin/Streptomycin (P/S) (Gibco,15140122). All of the incubation steps were performed at 37 °C and CO2 content of 5%. For the transfection cells at a confluency of 70-90% were incubated for 6 h with 1 μg/mL of a plasmid encoding N-terminal HA-HaloTag7-containing dCas9 fusion protein and 25 nM TRAFTAC using Lipofectamine 3000 following the suppliers' instructions. The plasmid used was published and kindly provided by the Crews lab [35]. Cells were then incubated for 19h with 5 ng/mL of TNF-α (Sigma-Aldrich, H8916) and 25 μM HP14 (dissolved in DMSO) (WuXiAppTec) respectively DMSO. 30 min before harvest, cells were treated with 200 units/ml DNase (Sigma, DN25). HEK293 cells were then washed twice with PBS (Gibco, 10010023) and detached with TrypLE (Gibco, 12605010). Enzymatic digestion was quenched with growth medium and cells were washed once again with PBS.

Protein detection

Western blot was performed to qualitatively and quantitatively assess NFkB levels. Overall protein abundance was determined via BCA assay following the ThermoFisher scientific protocol. The obtained values were normalized and utilized to calculate the sample volumes to be loaded. Samples were mixed with Laemmli buffer (BioRad, #1610747) and β-Mercaptoethanol (Sigma, M6250) (1:10) and boiled for 10 min at 70 °C. SDS-PAGE was performed using 10% Mini-PROTEAN TGX precast gels and the

Data used for the semi-simulations.

proteins were transferred from the gel to a Trans-Blot Turbo Mini nitrocellulose ₃₁₂
membrane via electroblotting. Membranes were then blocked in 5% milk in TBST (1 x ₃₁₃
TBS, 0.1% Tween 20, pH=7.6) for 1h and incubated overnight in primary antibody ₃₁₄
against NFkB (SantaCruz, sc-8414) (1:200 diluted in 5% milk in TBST), HA (Cell ₃₁₅
signalling, 3724) (1:1000 diluted in 5% milk in TBST) and GAPDH (Millipore, ABS16) ₃₁₆
(1:1000 diluted in 5% milk in TBST) at 5 °C. The next day the membranes were ₃₁₇
incubated for 1 h in HRP-coupled secondary antibody (Sigma Aldrich, AP308P) (1:20 ₃₁₈
000 diluted in 5% milk in TBST). Proteins were then visualized via chemiluminescent ₃₁₉
detection (Clarity^TM Western ECL Substrate) at a BioRad imager. ₃₂₀

Library preparation for ATAC-sequencing ₃₂₁

ATAC libraries were prepared from 50 000 cells per sample according to the published ₃₂₂
OmniATAC protocol [11] with minor adaptations. In short, samples were washed with ₃₂₃
cold 50 μl of PBS, afterwards cells were incubated in 50 μl lysis buffer (10 mM Tris-HCl ₃₂₄
pH 7.4, 10 mM NaCl, 3 mM MgCl2, 0.1% NP-40, 0.1% Tween-20, 0.01% Digitonin) for ₃₂₅
3 min on ice. Cells were washed with 1 ml of lysis buffer without Digitonin and NP-40. ₃₂₆
Transposition was done in 50 μl reaction buffer (1x tagmentation buffer (Diagenode, ₃₂₇
C01019043), 0.1% Tween-20, 0.01% and 2.5 μl Tn5 (Diagenode, C01070012)) for 30 min ₃₂₈
at 37 °C and 1000 RPM shaking. Subsequent DNA purification was performed with ₃₂₉
MinElute Reaction Cleanup Kit (Qiagen, 28204). PCR amplification was done with ₃₃₀
NEBNext High Fidelity 2X PCR Master mix (NEB, M0541) and UDI primer ₃₃₁
(Diagenode, #C01011034) with concentrations according to manufacturer's ₃₃₂
recommendation. Total number of needed amplification cycles (8x) was controlled with ₃₃₃
qPCR. Library purification and fragment size selection was done with AMPure XP ₃₃₄

beads (Beckmann, A63880). 20 μl of 10 nM was sent for sequencing externally with Novogene (Cambridge, UK). A minimum of 20 Mio PE reads were sequenced per sample. The data is available under the GEO accession GSE260504.

Packages versions and code

We used the following package versions: chromVAR 1.12.0, monaLisa 1.5.0, ATACseqTFEA 1.5.0, viper 1.24.0, decoupleR 2.3.3, fgsea 1.16.0, diffTF 1.8.

The code used to run the methods and simulations, evaluate the results, and create the figures is available on https://github.com/ETHZ-INS/DTFAB.

The semi-simulated datasets can be retrieved from Zenodo: 10.5281/zenodo.10732704, 10.5281/zenodo.10781849, 10.5281/zenodo.10781759, 10.5281/zenodo.10781109.

Results

The top methods were specifically designed for chromatin data

Fig 1 shows the results of the methods on the benchmark datasets. A good method for identifying differentially accessible motifs should rank the the motif of the perturbed TF (henceforth 'true motif') top, i.e. most significant. We therefore first monitored the rank that each method attributed to the true motif (Fig 1A, left). Of note, the MYC and NR1H4 motifs were not accurately detected by any method in their corresponding datasets, but their obligatory binding partners (respectively MAX and RXRA/B) were. These were therefore included in the set of true motifs for the benchmark. The top performing methods were all methods specifically designed for chromatin data, in particular, chromVAR (adapted, see below) and monaLisa. Proven methods for geneset enrichment analysis (GSEA) as well as methods with demonstrated performance for transcriptome-based master regulator analysis, such as decoupleR- and viper-based methods [4, 13], underperformed. Of note, the two datasets in which none of the methods ranked the true motif in the top 10, RUNX2 and MYC, both showed no peak-level change in accessibility with genome-wide significance (Supplementary Fig S1A), suggesting the lack of a clear treatment effect in the first place. However, for datasets that showed no significant peak-level change (e.g., RUNX1 and GATA2), some methods ranked the true motif towards the top (though not with an adjusted p-value < 0.05), thus indicating that global differences in motif accessibility can be detected even in the absence of significant peak-level changes.

TFs do not act in isolation, but most often form heterodimers or complexes that cooperatively regulate gene expression. Therefore, perturbations on one TF will likely disrupt whole complexes and the binding of its co-factors as well. We therefore devised a 'network score', based on the ranking of known physical interactors of the perturbed TF (see Methods and Supplementary Fig S2B), shown on the right of Fig 1A. This second metric confirms the findings of the first: except at very low (1-3) or high (>100) ranks (i.e. where ranks cease to be discriminatory), the two metrics show a strong agreement, although the network score is not comparable across datasets (Supplementary Fig S2D).

Ranking the true motif (and its interactors) top is critical, but it does not assess whether a method can discriminate a real signal from the absence of a signal, in other words if the reported significance of the differential activity is calibrated. We therefore measured the sensitivity in detecting the true TF (recall) in relation to precision. Fig 1B reports those values for the top variant of each method. To calculate precision, motifs of known interactors were considered as true positives. As expected, we observed

Fig 1. Benchmark of differential TF activity methods. A. Ranking-based metrics for each method across each dataset. The left part of the heatmap indicates the rank of the true TF (top one if the dataset has more than one true target), the numbers are the actual ranks and the colors are mapped to the squared root of the ranks (because differences in very high ranks are irrelevant in practice). The right part shows the network score, i.e. the AUC of the proportion of top X TFs that are in the network of interactors of the true TF, relative to the maximal possible AUC for the dataset (see Methods and Supplementary Fig S2C for details). The labels indicate the actual scores, while for the color mapping, the values are relative to the maximum achieved value for each dataset. For ATACseqTFEA, NA values indicate that the method repeatedly crashed on those datasets, presumably due to unsustainably high (>70GB) memory usage. **B.** Sensitivity and specificity (considering interactors as positives) of the top alternative per approach. The methods are coloured by family (sample-wise methods in blue, logFC-based methods in pink). **C.** Mean (and standard error of the mean) running time (elapsed, as well as total CPU time when multithreading) across datasets of the top alternative per approach (the x axis is squared-root-transformed for visibility). Note that because it was done separately for reasons of standardization, the running time does not include the generation of the peak-count matrix, nor, except for monaLisa, the motif scanning. monaLisa is therefore disadvantaged in this comparison, and these times should be interpreted as rough estimates.

a trade-off between precision and recall, with fGSEA offering the highest sensitivity but ₃₈₁
at the cost of a very high FDR, while VIPER, for example, controlled FDR but had a ₃₈₂
very low sensitivity (Fig 1B). As with the rank-based metrics, our adjusted chromVAR ₃₈₃
method (chromVAR>Qt>limma) showed the best trade-off between precision and recall. ₃₈₄
While monaLisa (without stability selection) performed well in ranking the motifs ₃₈₅
(Fig 1A), it had a low precision, indicating that it should be used for discovery rather ₃₈₆
than confirmatory purposes, or in conjunction with the stability selection strategy. That ₃₈₇
said, it should be noted that monaLisa reports a p-value for each motif and fold-change ₃₈₈
bin, and that while our use of Simes' aggregation to obtain a single p-value per motif ₃₈₉
(needed for benchmarking purposes) is not unreasonable, it does not come from the ₃₉₀
method's authors. ₃₉₁

Also note that diffTF(permutations) did not yield anything passing FDR, most ₃₉₂
likely due to the limited sample size, however it is plausible that its sensitivity could ₃₉₃
have been better with larger datasets. Despite multi-threading (see Methods), diffTF ₃₉₄
was considerably longer to run than other methods, with runtimes per dataset ranging ₃₉₅
from several hours to more than a day (permutation mode). The estimated mean ₃₉₆
runtime per dataset for each method is shown in Fig 1C. fGSEA, ATACseqTFEA and ₃₉₇
decoupleR also had elevated runtimes, taking several hours per dataset, while all other ₃₉₈
methods performed within a reasonable time. ₃₉₉

Improvements to chromVAR-based approaches ₄₀₀

The chromVAR package includes a function to perform differential analysis ₄₀₁
('chromVAR::differentialDeviations'), which performs t-tests on the adjusted deviation ₄₀₂
scores of each motif. We found that using limma [31] on chromVAR's motif z-scores ₄₀₃
('chromVAR(z)>limma') considerably outperformed this original approach (Fig 1 and ₄₀₄
Fig 2A). Presumably, this is because of limma's moderation of the variance. In addition, ₄₀₅
we observed that in some datasets, the per-sample distributions of z-scores could exhibit ₄₀₆
major shifts and differences in width that were not associated with experimental groups ₄₀₇
(Supplementary Fig S3A-B). In particular, not resizing peaks to a common size (as is ₄₀₈
recommended) tended to result in large shifts in the distributions, but some variations ₄₀₉
in the distributions – especially in their width – persisted despite resizing ₄₁₀
(Supplementary Fig S3A). ₄₁₁

Since these distributional differences were sometimes correlated to other technical ₄₁₂
sources of variation (data not shown), and are unlikely to have a biological meaning, we ₄₁₃
hypothesized that something in the chromVAR method did not perfectly adjust for ₄₁₄
technical differences between the samples. Internally, chromVAR uses a simple library ₄₁₅
size normalization to compare each sample to expectations, which is known often not to ₄₁₆
be adequate for NGS data [33]. We therefore hypothesized that these shifts could be ₄₁₇
due to inadequate normalization, and adapted chromVAR to use more robust ₄₁₈
normalization procedures, including the well-established TMM normalization [33]. ₄₁₉
However, these changes had little impact on the distributional differences, nor the ₄₂₀
differential TF identification (data not shown). ₄₂₁

We therefore tested whether a further, downstream normalization of the motifs ₄₂₂
z-scores would improve the detection accuracy. Quantile normalization appears to ₄₂₃
perform best (Fig 1A and Fig 2B). This was also confirmed by comparing the t-value ₄₂₄
attributed to the motif of the true TF, which is more sensitive (Supplementary Fig ₄₂₅
S3C-E). ₄₂₆

In light of these results, we took advantage of the fact that some of the benchmark ₄₂₇
datasets are in fact (aggregated) single-cell ATAC-seq datasets [29] to see whether such ₄₂₈
normalization also had a beneficial impact at the single-cell level. As a proxy for the ₄₂₉
signal-to-noise ratio, we computed the standardized mean difference of the respective ₄₃₀
motif upon each knockdown. Centering the z-score distributions was always beneficial, ₄₃₁

Fig 2. Impact of modifications on top workflows. A. Comparison of the true motif ranks obtained by a *limma* analysis on the chromVAR deviations, versus using chromVAR's native *differentialDeviations*. **B.** Comparison of the true motif ranks obtained by a *limma* analysis on the normalized chromVAR z-scores, versus on the chromVAR deviations. **C.** Comparison of the true motif ranks obtained by the top method of each family of approaches, when using peaks called from nucleosome-free fragments (but counting all fragments overlapping them). **D.** Comparison of the true motif ranks obtained by the top method of each family of approaches, when using only nucleosome-free fragments. In each case, the TFs in blue indicate an improvement, those in red a worsening, and those in black no change.

quantile normalization also tended to be beneficial most of the time, while unit-variance scaling showed mixed results (Supplementary Fig S4).

Focusing on nucleosome-free peaks/fragments yields mixed results

ATAC-seq data has a characteristic, roughly periodic fragment length distribution, where smaller fragments (e.g. <100-125bp) are too small to be wrapped around a nucleosome and are therefore deemed 'nucleosome-free' (NF), while larger peaks correspond to mono-nucleosome-, di-nucleosome-, and eventually tri-nucleosome-containing fragments. Since most TF compete with nucleosomes for binding, and NF fragments are enriched at the core promoter, NF fragments are often thought to be particularly characteristic of TF binding. Therefore, we tested whether using filtering based on fragment size could improve the benchmark results, focusing on the top method for each of the two families of approaches. Specifically, in addition to the previous results based on all fragments, we tested i) counting only NF fragments, ii) counting all fragments but on peaks called only on NF fragments, as well as iii) counting only NF fragments on NF peaks (i.e. using only NF fragments throughout). While these alternatives did appear beneficial on some datasets, their impact on discriminatory power was not consistent across datasets (Fig 2C-E). In particular, chromVAR hardly ever benefited from these variants, whereas it sometimes made major differences to monaLisa, for instance with GATA2 being much better ranked when counting NF fragments (Fig 2E).

Using GC smooth quantile normalization improves non-specialized methods

Sample-specific GC bias is a known source of variation in ATAC-seq, and methods have recently been developed to address it, in particular, smooth-quantile normalization within GC bins [41]. We therefore tested whether using this normalization, in particular for calculating the peak-level log(fold-change) between conditions, could improve in particular logFC-based and non-specialized methods. As shown in Fig 3A, which compares key methods with and without GC smooth quantile normalization, most methods benefited from this specialized normalization method, vindicating the procedure (see Supplementary Fig S5 for the full rank-based metrics on all variants). Indeed, even monaLisa stability selection, which already includes some form of control for GC bias, seemed improved. With this normalization, the sample-based decoupler(mlm)>limma approach even became competitive with the top chromVAR variant (Fig 3B-C).

Limited gain from simple method aggregation

Reasoning that different approaches could in principle offer complementary advantages, we next investigated whether aggregating the results of the three top-performing methods could yield superior results. We tested common p-value aggregation methods (despite the assumption of independence underlying some of them being violated), as well as a non-parametric, rank-based alternative (Supplementary Fig S6). The latter proved best but did not show consistent improvement upon the best single methods. We next tested combining the per-sample motif activity scores produced by chromVAR and by the multivariate model applied on GC smooth quantile normalized counts, before computing differential analysis (Supplementary Fig S6). This was always better or equivalent to chromVAR, although the improvements were mild. While it is possible that more sophisticated ensemble methods could yield an improvement, these results suggest a low degree of complementarity between methods.

Fig 3. Impact of using GC smooth quantile normalization. A. Comparison, across key methods, of the ranks of the true motif when using GC smooth quantile normalization instead of standard (TMM) normalization to calculate per-peak log(fold-change). **B.** Comparison of the ranks of the true motif with GC smooth quantile normalization, compared to the two best-performing methods from the earlier benchmark. **C.** Comparison of the precision and recall (at adjusted p-value <= 0.05) when using GC smooth quantile normalization (in blue), compared to the two best-performing methods (in pink).

A semi-simulation framework confirms the results from real benchmark datasets

Even when focusing on early time-points, the real benchmark datasets have a problem of ambiguity with respect to the truth, as interfering with a factor is likely to impact other interacting factors, as well as indirectly interacting factors competing for binding. To confirm the robustness of our results, we therefore developed a semi-simulation framework. We generated, from baseline ATAC-seq profiles of lymphoblastoid cell lines, cohorts of two groups of samples with a difference in accessibility at binding sites of a

single given TF at a time (Fig 4A; see also Supplementary Fig S7 and methods). Briefly, fragments overlapping the ChIP-seq peaks of the given TF were subsampled in one of the two groups following one of two realistic differential binding scenario (Fig 4B): an activation (where the high-occupancy peaks are the most affected), modeled on the ligand-based activation of the glucocorticoid receptor [26], and a haploinsufficiency (where the TF amount is halved, and the remaining TF preferentially goes to high-occupancy peaks, leaving the low-occupancy peaks most affected), modeled on the heterozygous loss of function of YY1 [12]. In the activation paradigm, the difference between conditions affects virtually all sites (and many by a lot), whereas in the haploinsufficiency many peaks are very mildly affected (Fig 4B). Specifically, we simulated various perturbation strengths (i.e. multiplicators of the original differential binding fold-changes) for four factors that had 1) high quality ChIP-seq data for the simulated celltype (lymphoblasts), 2) a clear associated motif, and 3) represented distinct factor families and properties (Supplementary Fig S8).

We first confirmed that the simulated data was distribution similarly to the real data (Supplementary Fig S9), and that the effects introduced were as expected (Supplementary Fig S10-11), and next ran the top methods on each dataset. The results, presented in Fig 4C (and Supplementary Fig S12), afford the following observations. As expected, stronger perturbation strengths made the task easier, and the haploinsufficiency scenario was systematically harder to detect, owing potentially both to the lower general fold-changes and comparative sparing of high-occupancy sites (Fig 4B). As with the real datasets, limma on the chromVAR z-scores (scaled or not) gave the best overall results in terms of ranks, while monaLisa (vsOthers) provided a good performance so long as the perturbation strength was sufficient. Furthermore, monaLisa (vsOthers) offered greater sensitivity than other methods, being the only approach marking the true factor for all simulated TFs and paradigms as significant and also in some cases at lower perturbation strengths, however at the cost of a generally lower precision (Fig 6, Supplementary Fig S15). Once more the original chromVAR differentialDeviations did not perform well, and the multivariate model had mixed, somewhat unstable performance.

Given the controlled setting of the simulations, any difference between the factors necessarily hinges on the relationship between its motif and its experimental binding sites. The easiest factor was CTCF, which had the highest number of experimental binding sites, but especially the highest proportion of those harboring its motif, as well as the highest enrichment for the motif in bound (i.e. overlapping a ChIP-seq peak) vs all ATAC-seq peaks (Supplementary Fig S8A). On the opposite spectrum, CEBPB was the hardest, with few binding sites, few of which with a motif. Interestingly, ZNF143 was easier to detect than MAZ, despite having a similar number of sites and a motif less specific to the bound peaks (Supplementary Fig S8A). Closer investigation revealed that a large number of motifs co-occur with MAZ, and in fact show a stronger enrichment in its bound peaks (Supplementary Fig S8B). While it is also the case with ZNF143 that many other motifs are more enriched in its bound peaks, this is chiefly because the ZNF143 peaks are GC-rich (Supplementary Fig S8C-D), and the fact that the top methods correct for GC presumably enables an accurate detection nonetheless. To confirm the importance of the relationship between motif and binding site, we created simulations in which only the ChIP-seq peaks containing a motif for the respective TF were perturbed. As expected, for all TFs but in particular for CEBPB and MAZ performance of all methods improved considerably (Supplementary Fig S11).

Finally, the simulation framework further enabled us to introduce sample-wise variations in two known factors of technical variation: fragment length (FL) distribution (Supplementary Fig S13) and GC content (Supplementary Fig S14). Methods were generally robust to both kinds of variation, despite not correcting for FL biases.

Fig 4. Semi-simulation framework and impact of perturbation strength. A. Strategy for sampling ATAC-seq fragments: ChIP-seq peaks of the TF to be perturbed are overlapped with the baseline ATAC profiles (1); a fold-change is determined by per ChIP-seq peak fold changes from a reference distribution (2) and used to sub-sample the overlapping fragments of the ATAC-seq profiles of one of the two groups (3). **B.** Two group designs were simulated by downsampling ATAC-seq fragments in one group according to the obtained fold changes of the overlapping peaks. Pertubation strength was varied by multiplying fold changes with different factors (0, 0.25, 1, 3), i.e. the perturbation strength. Further technical variations were introduced in some datasets by varying GC contents and fragment length distributions. **C.** Performance of variants of the top performing methods on the semi-simulated datasets with varying pertubation strength. Numbers in the line plot represent the rank of the perturbed TF as detected by the respective method. Colors of the boxes signify the corresponding adjusted p-value obtained in the differential activity analysis. Bold vs plain text indicates if the adjusted p-value was found to be significant (adjusted p-value $<= 0.05$).

However, for some of the biased settings (both GC and FL), monaLisa (vsOthers) detected false positives in datasets were no perturbation was simulated (perturbation strength 0).

In summary, the simulations confirm the main results of the benchmark on real datasets, reveal the top methods to be robust to technical biases, and indicate the relevance of how distinct and informative the motif is for actual binding.

Application of the methods to characterize TRAFTAC-mediated TF degradation

PROTACs (PROteolysis TArgeting Chimera) are a particularly successful technology that hijacks the cell's endogenous protein degradation machinery (the ubiquitin-proteasome system) and targets it to a protein of interest [27]. However, each PROTAC requires careful chemical design and validation. A recent, attractive derivative technology harnesses the versatility of the CRISPR technology to target and degrade TFs in a more flexible fashion. With TRAFTACs, or TRAnscription Factor TArgeting Chimeras [35], the targeting specificity is not encoded in the design of the PROTAC molecule, but by a double-stranded DNA containing the target TF's binding motif. This oligo is covalently linked to a single-stranded RNA that functions as a guide to recruit a deactivated Cas9 fused with a HaloTag7, which in turn can be bound by a generic HP14 PROTAC. As a result, binding of the oligo was shown to lead to ubiquitination and subsequent cleavage of the target TF [35].

Using the top differential motif accessibility methods identified above, we sought to characterize the impacts of a validated TRAFTAC against NFKB [35]. Replicating the authors' experiment, we transfected HEK cells with the dCas9-HT7 plasmid and DNA-RNA hybrids (NFkB or scrambled TRAFTAC) for 6h, before treating the cells TNF-α (to trigger NFkB activation) and the PROTAC against the Halo tag (HP14) for 19h. We confirmed the reduction of NFKB1 protein levels using western blot (37% reduction with respect to scrambled control, Supplementary Fig S16), and generated ATAC-seq profiles. We then ran differential motif accessibility analyses using chromVAR and monaLisa (Fig 5). Interestingly, although the NFkB motifs have a weak trend of decreased accessibility, they are far from significance (Fig 5A). Instead, the strongest signal is in motifs related to the AP-1 complex, i.e. JUN/FOS family members (which all bind a similar motif), showing a decreased accessibility in the knock-down according to both the chromVAR and monaLisa analyses. Beside activating NFkB through IKK, TNF-α is expected, through MKK7, to trigger the MAPK/JNK pathway, which in turn activates AP-1 [34]. However, the reduction in AP-1 activity that we observe in the NFkB knockdown suggests a cross-talk between these two downstream signaling pathways.

Fig 5C shows some example significant motifs across the top three methods. Some are consistent: for example, the GC-rich GLIS2 motif appears enriched in a dose-dependent fashion in monaLisa bins that increase in accessibility, and depleted in those that decrease; it is moreover increased in activity in the knockdown according to both chromVAR and GCsmoothQ>MLM>limma. NFE2 and FOSL1 show the same consistency, with the opposite pattern. In contrast, some inferred motifs activities are inconsistent across methods: while both chromVAR and MLM suggest a reduction in NFYA accessibility in the knockdown, which would be consistent with reported links between NFkB and CCAAT elements [10], the monaLisa results shows that the motifs are depleted in both upregulated and downregulated peaks, and instead enriched in the bin of peaks that do not change. JUNB and FOS, instead, show the same pattern as FOSL1 according to both monaLisa and chromVAR, as expected given that the motifs are virtually the same, while MLM shows no clear pattern. This is precisely because the

Fig 5. Characterizing the impacts of a TRAFTAC against NFkB after TNF-α activation in HEK cells. A. Results of the 'chromVAR(z)>limma' analysis, highlighting the motifs with strongest changes between conditions and high absolute deviations. The two overlapping red circles highlight NFKB1 and NFKB2. **B.** Comparison of the per-motif p-values assigned by monaLisa (simes p-value) and chromVAR, showing an agreement only on the strongest differences. **C.** Representative examples of motifs called as differentially-accessible by some method, showing side by side monaLisa's enrichment scores across logFC bins, as well as the per-sample chromVAR z-scores and z-scores of the MLM t-values.

three motifs are largely equivalent: because the multivariate approach regresses accessibility on the combined effect of the different motifs, highly-similar motifs will nevertheless have different coefficients. This suggests that, while the presence of an effect in the MLM method is further corroborating a candidate, the absence of such an effect cannot rule it out, especially in the context of similar (i.e. highly correlated) motifs.

Conclusion

Summary and general recommendations

Fig 6 summarizes the main benchmark results. Overall, chromVAR performed very well and runs fast, however we recommend increasing the number of backgrounds iterations (to 1000-2000) to improve reproducibility (not easily done with single-cell data), and on

using limma to perform differential analysis (as opposed to the native 'differentialDeviations'). Moreover, its results were improved by post-processing of the scores, suggesting that some technical variation is not entirely accounted for by chromVAR's background strategy. We found the sample-wise methods useful in relaying to the analyst the variability across samples. On the other hand, those methods are limited to detecting global increases or decreases in TF activity, and in principle cannot detect the displacement of a TF's binding at constant global activity (although it is unclear how likely a scenario this is). monaLisa also gave good results, and its bin-based strategy and plotting functions have the advantage of providing the user with a more fine-grained view of where the enrichment is observed, relative to where the changes in accessibility are happening. Observing a dose-response (i.e. an increased enrichment in bins of greater foldchage) bolsters our confidence in the enrichment. We tried to capture this computationally by dividing, for the purpose of ranking, the aggregated p-values by the absolute Spearman correlation between the fold-enrichment and the bins order (denoted 'monaLisa.vsOthers+spearman' in Fig 1), however it did not yield a clear improvement.

Fig 6. Summary of the benchmark on variants of the top methods. A.
Sensitivity (left and center) and precision (right) of each method across real (left) and simulated (datasets). The size of the points indicate whether or not the method found the true motif significant (FDR<0.05). For real datasets, the color indicates the rank of the true motif, while for simulated datasets it indicates the perturbation strength at which the true motif was found significant. **B.** Sensitivity and specificity (considering interactors as positives) of the top methods, aggregating both real and simulated datasets. The methods are coloured by family (sample-wise methods in blue, logFC-based methods in pink).

While methods not specifically designed for chromatin data performed poorly in the main benchmark, they were improved when using smooth quantile normalization in GC bins, confirming the value of the normalization method. In particular, the GCsmoothQ>decoupleR(mlm)>limma approach performed as good as, and in some datasets better than, the top specialized method. This method fits a multivariate linear model on the peak accessibility of each sample, using all motifs as covariates. Of note, it is one of the few methods (along with monaLisa stability selection and the similar

lasso-linear model, which are however logFC-based rather than sample-based) that handles motifs together, rather than separately. This suggests that this general strategy should be further investigated. However, as the TRAFTAC example illustrates (Fig 5C), a high motif similarity within the collection causes major problems for multivariate approaches, whether regularized or not. Most likely, harnessing the potential of the multivariate approach will involve explicitly addressing, in one way or another, this relationship between motifs.

Simple results aggregation of these three methods did not yield clear improvements. Nevertheless, we recommend using the three top methods to increase confidence, given their different strategies and benefits. Furthermore, we observed that the p-values were not generally well-calibrated (i.e. FDR was nearly always higher than the nominal threshold). It must be noted, however, that the motif library used includes many highly similar motifs, which are likely to inflate the reported FDR. Additionally, knowledge of cofactors co-binding with the true factors taken into account for calculation of the FDR is most likely neither exhaustive nor specific to the cell types used. Precision estimates show strong differences across datasets, and high precision typically only occurred when no effect was detected (Supplementary Fig S15). Hence, we recommend caution in interpreting the obtained precision (and FDR) estimates, and for this reason we especially focused on ranks of the true motif for reporting performance. However, for similar reasons also the ranks should be interpreted on a rather coarse scale, and might not be comparable across TFs given differences in the number of factors co-binding/co-occurring with the true factor.

Open questions

An issue that was barely touched in our study is the definition of the consensus peaks on which to work. How peak calling should best be done in ATAC-seq, especially across samples, is still an open debate. Our attempt to restrict to peaks called on nucleosome-free fragments, in particular the fact that counting all or only nucleosome-free fragments on nucleosome-free peaks both give similar results, suggests that the peaks, rather than the counting, is the decisive factor. Further study will be needed to establish what type of peak calls, and whether leniency or stringency in the thresholding, is best for TF activity inference.

The nature of the binding sites used (e.g. motifs collection) is also something that we left out of the current study. TFs of the same family (e.g. hormone receptors) often share very similar motifs, which are bound to influence the identification. Moreover, our simulations indicate that, as expected, with constant perturbation strength the difficulty in detecting a difference in TF activity is strongly related to how good a proxy for binding the motif is. Unfortunately, it is well known that motifs are in general poorly informative of TF binding. Further work should be put in comparing motif collections against other forms of binding site predictions, or collections of experimental binding sites [19].

Supporting information

Fig S1   Overview of the benchmark datasets and TFs. A. Volcano plot of the peak-level differential accessibility analyses, illustrating the extent and significance of changes upon treatment in each dataset. The dashed line represents a 0.05 FDR threshold, and indicated are the number of ATAC-seq peaks passing this threshold, as well as the proportion of peaks with an uncorrected p-value lower than 0.05. **B.** Enrichment for experimental binding sites of the factor (main TF after which the datasets are named) in ATAC-seq peaks containing the respective motifs, versus all

ATAC-seq peaks. **C.** Proportion of ChIP-seq peaks (overlapping ATAC-seq peaks) that contain the respective motif.

Fig S2 Reproducibility of chromVAR-based differential accessibility analysis. A. Each color represents a dataset. The line and shaded area respectively represent the mean and standard error of the pairwise correlations across 7 independent runs of the chromVAR>limma pipeline for each dataset and setting, of the ranks of the (union of) top 20 motifs. **B. Illustration of the motif-specific position weights for the insertionModel method. C. Illustration of the computation of the network score.** The motifs are ranked for each method, and for each k=1:100 the proportion of top k motifs that are part of the known network of the true TF is computed. The area under the curve is then reported, relative to the AUC of the best possible motif ordering for that factor (gray area). The example plotted here is from the GATA1 dataset. **D. Agreement between the two rank-based metrics.** Each point represents the results of a method (colour) in a dataset (shape). The network score is not entirely comparable across datasets. Beside this effect, and except at very low (1-3) or high (>100) ranks (i.e. where the ranks stop being discriminatory), there is a good agreement between the two metrics.

Fig S3 Differences in the chromVAR motif score distributions across samples, and impact of their normalization A-B. Example of a subset of ATAC-seq samples from Caradonna, Paul and Marrocco (2022) (GSE200670), where different samples show different shapes of motif z-scores distributions. When peaks are not resized to all have the same width, as recommended, the distributions are often globally shifted (**A**, left). Even when peaks are resized (**A**, right), differences in the width of the z-scores distributions that are not related to experimental groups can persist in some datasets. This is not specific to the z-scores, but also present in the bias-corrected deviations (**B**). **C-F.** For each comparison, the limma's t-value for the true TF is reported; for datasets involving a downregulation of the TF, the sign of the t-value was inverted. For ease of visualization, t-values below 0 were set to zero, and the axes were square-root transformed. TF in blue show an improvement, while those in red show a worsening, and those in black are unchanged.

Fig S4 Impact of chromVAR motif z-score normalization at the single-cell level. As a proxy to signal-to-noise ratio, we computed the standardized mean difference of the respective motif for each guide RNA (individual lines) to the mean of the control guide RNAs. Centering is always beneficial (Wilcoxon p¡8e-06), unit-variance scaling is often beneficial (Wilcoxon p 0.07) but sometimes detrimental, and quantile normalization also tends to be beneficial (Wilcoxon p 0.041). Differences in the chromVAR motif score distributions across samples, and impact of their normalization.

Fig S5 Rank-based metrics of all variants, including smooth quantile normalization in GC bins.

Fig S6 Simple aggregation of top methods' results does not improve inferences. A. The results of the top method from each of the two families of approach (on the left) are compared to those of simple aggregation methods (on the right). Beside the established Fisher's, Stouffer's and Simes' methods, a rank-based permutation approach was tested, establishing the probability of having a sum of ranks across methods lower or equal to the observed one. We also tested using limma on merged per-sample activity scores from chromVAR and GCsmooth+MLM. **B.** Same comparison, in terms of Precision and Recall at adjusted p-value <= 0.05.

Fig S7   Overview of the semi-simulations. A. 6 baseline ATAC-seq   719
lymphoblastoid cell lines (LCLs) are divided into two groups. Differences will be   720
introduced through downsampling of fragments in one of the groups, and eventual   721
per-sample GC and fragment length biases are introduced. **B.** The extent of   722
downsampling is based on the enrichment over the input of the ChIP-seq peak,   723
following one of two differential activity scenarios: an activation and a   724
haploinsufficiency (see Figure 4B). The magnitude of the effect is further scaled up and   725
down (perturbation strength). **C.** Settings used for the semi-simulated datasets. The   726
resulting datasets can be divided into three groups, a first set where only the strength of 727
the perturbation was varied by a factor (perturbation strength), a second and third one   728
were additionally differences in respectively fragment length distribution and GC were   729
introduced across samples.   730

semi-simulated datasets with a pertubation strength of 1 in the activation paradigm. **A.** 732
Number of peaks, proportion of ChIP-seq and/or ATAC-seq peaks with a motif, and   733
fold-enrichment of the ATAC-seq peaks overlapping ChIP-seq peaks (i.e. bound peaks)   734
relative to all ATAC-seq peaks for the motif across the four TFs. **B-C.** Fold-enrichment 735
of all tested motifs among the bound peaks (relative to all ATAC-seq peaks), with the   736
true motif labeled in black. The dots are colored either by co-occurence with the true   737
motif (**B**) or by GC content of the motif (**C**). **D.** GC content distributions of the 738
ChIP-seq peaks of each TF.   739

Fig S9   Distribution of fragment counts and variance of the simulations A.   740
Per peak fragment count distributions of the original (denoted "0") and simulated   741
samples with 1-fold and 3-fold perturbation strengths, for an example TF (CEBPB)   742
across both paradigms. **B.** Mean-variance relationship of the original (denoted "0") and 743
simulated samples.   744

Fig S10   MA plots of the simulated effects. For each factor, simulated paradigm   745
and perturbation strength, the distribution of peaks $\log_2$FC of raw fragment counts   746
between conditions as a function of mean accessibility is plotted as 2d kernel density,   747
separating either (**A**) ATAC-seq peaks overlapping a ChIP-seq peak or not, or (**B**)   748
ATAC-seq peaks containing a motif or not for the TF. For visibility, the peaks were   749
subsampled to a more comparable size across the simulated datasets (10^5 peaks per   750
dataset). Colored Points indicate the means of the respective distributions.   751

Fig S11   Positive control of the simulations. Shown are ranks and significance   752
assigned by each method to the true motif across simulation parameters (TF, paradigm   753
and perturbation strength). In light gray are the normal simulations (as shown in Fig 4),   754
while dark line and colored boxes correspond to the positive controls where a difference   755
between the groups was only introduced in the peaks overlapping a motif of the true TF.   756

**Fig S12   Heatmap of performance of variants of top methods on the   757
semi-simulated datasets.**. As in Fig 1, the left part of the heatmap shows the ranks,   758
while the right part shows the corresponding network scores obtained on the simulated   759
datasets.   760

Fig S13   Robustness to simulated variations in fragment length. In addition   761
to the simulated TF effect, two different fragment length distributions (**B**) were   762
simulated by differential sampling of the fragments according to their length for the   763
different samples as in scheme **A**. The distribution in light green corresponds to   764

sampling mononucleosome containing fragments with higher probability, whereas for the distribution in dark green nucleosome-free fragments were sampled preferentially. The results of the methods are shown in **C**. Colors of the points correspond to the rank of the true TF obtained, point size if the corresponding adjusted p-value was found to be significant (adjusted p-value $<= 0.05$).

Fig S14   Robustness to simulated variations in GC content. In addition to the simulated TF effect, two different GC content distributions (**B**) were simulated by differential sampling of the fragments according to their GC content for the different samples as in scheme **A**. The results of the methods are shown in **C**. Colors of the points correspond to the rank of the true TF obtained, point size if the corresponding adjusted p-value was found to be significant (adjusted p-value $<= 0.05$).

Fig S15   Estimated precisions per dataset A. Heatmap of precision estimates obtained per dataset and method on the 11 real datasets (**A**), as well as averaged across each perturbation strength of the simulations (**B**).

Fig S16   Successful downregulation of NFkB1 at the protein-level using the TRAFTAC. Western Blot (**A**) and derived densitometry (**B**) of NFkB1 (aka p50) in HEK cells transfected with the dCas9-HT7 plasmid and a TRAFTAC (either against NFkB or a scrambled control) for 6h, before treating the cells TNF-α (to trigger NFkB activation) and the PROTAC against the Halo tag (HP14) for 19h. The DMSO control sample was the same as a NFkB1, except that it received DMSO instead of the PROTAC.

Acknowledgments

We thank Lukas Burger for providing the BANP motif.
