ABSTRACT
Microbiome is increasingly recognized as a key factor in health. Intestinal microbiota modulates gut homeostasis via a range of diverse metabolites. Molecules such as short chain fatty acids (SCFAs), the microbial fermentation products of dietary fiber, have been established to be reflective of microbiome and/or dietary shifts and have been linked to multiple gastrointestinal disorders from cancer to colitis, and thus present an excellent diagnostic target. Yet, technical bottlenecks preclude broad translation of such established biomarkers into routine medical practice. In particular, easily accessible, reproducible and robust sampling of stool remains challenging. Here we present Stool Wipe (S-Wipe), an ultra low cost, simplified fecal specimen collection approach designed to overcome key translational barriers without compromising analytical rigor. This sampling approach harnesses lint-free mass spectrometry-compatible cellulose wipes used as a regular toilet paper. The collected stool specimens are then preserved in ethanol solution, do not require refrigeration and can be shipped via regular mail. Using mass spectrometry, we have demonstrated a broad range of captured metabolites, both volatile and non-volatile. The reproducibility and stability of the method was validated for a panel of molecules of particular diagnostic interest, including SCFAs and p-cresol. We demonstrate sensitivity as well as stability and reproducibility of various metabolites collected with S-Wipe. We further demonstrate that S-Wipe is equivalent to the direct stool collection and thus could be used interchangeably and compared to other studies where stool is collected directly. This methodology is ideally suited and is scalable for broad population-based studies, longitudinal tracking such as therapeutic interventions and personalized medicine.

IMPORTANCE
Gut microbiome and intestinal metabolome present invaluable diagnostic and therapeutic targets. However, conventional stool testing has several barriers limiting bioassessment from populations. Routine, high temporal resolution monitoring of stool metabolome, including validated biomarkers such as SCFAs, is not implemented due to relatively high cost and inconvenience of sampling, possible need for clinical setting for sample collection, difficulty to collect samples reproducibly, especially due to possible user errors, requirement for freezer storage and maintaining cold chain during shipment. We present a sampling strategy specifically designed to overcome these obstacles. This method can enable capturing accurate molecular snapshots at massive scales, at ultra low cost. The approach collapses complex medical-grade

collection into easy self-administration. Individuals can thereby self-monitor therapeutic responses through routine metabolome tracking, including the volatilome, otherwise hindered by infrastructure restrictions. Ultimately, this sampling approach is intended to enable participatory wellness transformation through practical high frequency self-sampling.

The gut microbiome plays a central role in human health in profound and wide-ranging ways through nutrient metabolism, immune modulation, and metabolic regulation, including production of bioactive metabolites (1–3) . Through production of molecules like short-chain fatty acids (SCFAs), gut bacteria influence processes spanning digestion, immunity, metabolism, and even mental health (4–6). SCFAs can be measured across the gut, with fecal samples being the most accessible (7–10). SCFAs are predominantly produced through fermentation of dietary fibers, subsequently permeate throughout the body, and affect a diverse range of tissues and physiological processes (10–12). The clinical potential of these microbial metabolites as measurable biomarkers continues to be unraveled across investigations - from IBD, all the way to the inflammatory cascade and metabolic syndrome underpinning contemporaneous epidemics of obesity and cardiovascular disease afflicting aging populations (13–17). SCFAs deficiencies have been associated with low-fiber intake diets, altered gut permeability and inflammation, thereby promoting insulin resistance, elevating risk factors, and increasing probability of cardiovascular events (18–21). SCFAs quantification and profiling offers clinical opportunities for non-invasive monitoring, not only for disease diagnostics, but potentially early risk assessment and exposure-response monitoring, as well nutritional or therapeutic gut microbiome modulation.

However, capturing translational insights into these molecular distributions is challenging, as the biological, interpersonal and technical variations tend to obscure molecular trends. Overcoming inherent irreproducibility requires large-scale population measurements where different influencing factors could be assessed. Such large-scale sampling poses practical barriers. Fecal samples rapidly degrade in ambient conditions due to chemical degradation and microbial growth, while reliance on specialized collection and handling infrastructure, cost and complexity of collection, coupled to a wide range of non-standardized sampling protocols poses logistical challenges. Consequently, at the present time, both patients and the general public do not have access to reliable personalized monitoring of gut molecular biomarkers. Last, but not the least, collecting feces is objectionable to many people, limiting their willingness to participate in studies that require fecal testing, especially those that entail frequent longitudinal collection. Current stool sampling collection methodologies for fecal sampling for microbiome and metabolomics analysis used in clinical practice are predominantly traditional stool collection kits consisting of stool hats, swabs, or small containers (22–28). Samples must be immediately frozen and then transported frozen to a lab to help preserve their integrity. This method can

have high variability due to differences in storage and transportation temperature, transit time and exact collection methods between patients. Another common method is fecal occult blood test (FOBT) cards (29–33). In FOBT sampling fecal smears are collected at home on specialized sample cards designed to detect blood. Those cards help stabilize some molecules for transport at room temperature. However, the small sample size and difficulties in using and handling cards limit broader profiling. Specialized solutions such as the Cologuard® can be used for non-invasive tests that analyze stool samples patients collect on a commercial kit with a preservative buffer. This test uses genetic sequencing to detect colorectal precancers but is not optimized for metabolomics (32–34). For the majority of stool-based tests (screening for blood in the stool, stool culturing for bacterial or viral infections diagnostics, ova and parasite exam, fat malabsorption assessment, etc.), stool is collected in research labs or hospitals, where clinicians may collect fecal samples directly, or during procedures like lavage or endoscopic biopsies. Obviously, such invasive techniques limit practical scalability (32). Overall, sampling methods that are scalable, patient- and consumer-friendly and preserve integrity during non-refrigerated transportation, have remained an unmet need. Most testing today still relies on traditional immediate frozen collection protocols (22, 24), which are logistically impractical for population-level studies. To bridge this gap, we developed the S-Wipe, an ultra low-cost fecal collection method. Cellulose collection paper used in S-Wipr acts as lavatory towels, which makes sampling identical to a normal bathroom routine. Using GC-MS and LC-MS, we demonstrate that S-Wipe captures native SCFAs and other diverse diet-/host-associated metabolites at highly reproducible levels over weeks, without cold storage. The S-Wipe method is designed to enable democratized, scalable gut molecular monitoring to stimulate personalized solutions across global populations.

RESULTS

The S-Wipe sample collection matrix utilizes cellulose adsorbent paper to passively capture fecal material when used as conventional toilet paper during normal bathroom routines. Approximately 100 mg of stool can be typically collected. The wipe is then placed by the user into a 20 mL wide-mouth S-Wipe funnel or 50 mL centrifuge tube with 5mL of MS-grade 60% ethanol spiked with internal standard, sealed, and then can be both stored and/or shipped at room temperature until extraction and analysis (Figure 1).

Figure 1. S-Wipe* sampling. a) Sampling and shipping workflow using the kit (Sample collection kit is shown in Supplementary Figure 1). The users are not required to modify their bathroom routine with the exception of placing the user paper into a collection tube rather than flushing/throwing it away. Due to simplicity of collection, every bowel movement could be sampled, if needed, and large longitudinal sampling with each subject being their own control for intervention studies are facilitated. b) Schematic sample preparation and analysis workflow. During shipment, the extraction solvent remains absorbed by the wipe. Upon arrival at the analysis lab, the samples are centrifuged to separate supernatant from the wipe (the cap has a coarse mesh to retain the wipe in the cap). The supernatant is compatible with mass spectrometry analysis, such as GC-MS for SCFA measurement, without any additional sample preparation steps. The absolute measured abundances of biomarkers of interest, as well as longitudinal trends can then be used to inform users.
*The patent application is pending (US Application #63/570,322)

The S-Wipe sampling was found to capture the compounds of interest such as SCFA, p-cresol and other molecules that are expected to be detectable in stool, such as indole, bile acids, vitamins, amino acids, lipids etc. (Protocol Optimization study, see Methods)(Supplementary Figure 2 and (Supplementary Figure 4). As S-Wipe allows for measuring the stool weight, the abundances of metabolites could be normalized (r(Pearson) = 0.95, p < 0.001, Figure 2A)(Stability study, see Methods). Also, with the use of external calibration, absolute quantities for various molecules could be calculated and used as biomarkers to gain lifestyle or other information, e.g. Supplementary Figure 2A,B. (Interpersonal Variability Study, see Methods) The ratios of metabolites are not dependent on the absolute quantitation, and can also be linked to specific conditions (35-46, 39) (Supplementary Figure 2D).

Stability achievable with the S-Wipe was demonstrated for 9 endogenous short chain fatty acid peak areas over the course of 7 days for samples stored at room temperature. The average relative standard deviation error was found to be 23.48% for all time points of 2 replicates

(Stability study, see Methods)(Figure 2B). The sensitivity of the approach was on par with conventional stool collection, while sample-to-sample variability is comparable or lower (Figure 2C). Quantitative linearity of short-chain fatty acid detection spanned physiologic concentrations ($r2 > 0.99$)(Supplementary Figure 3). Absolute concentrations aligned with values reported from conventionally-collected samples, confirming compositional integrity.

In the proposed approach, 60% ethanol solution is used for sample preservation. The ethanol is known to both denature enzymes, preventing enzymatic degradation (47–51), and kill microorganisms preventing bloom (47, 51–53). Focusing on the SCFAs, it is evident that S-Wipe-collected organic acid remained stable for at least several days at ambient temperature. GC-MS indicated negligible changes, with no statistically significant degradation trends over the entire interval ($p > 0.24$) (Figure 2B).

To more rigorously assess the stability of metabolome, we have further conducted a shipping/storage experiment, where the samples were compared between different handling conditions: refrigerated storage, room temperature storage, short- and long-distance shipping (Figure 3). Correspondingly, the samples collected by S-Wipe were stored at -80C immediately after collection, stored at room temperature for the duration of the study (1 week), shipped, then returned, locally (within the state) and shipped/returned long distance (from the East to West coast of the US). The shipping reflects representative sum total fluctuations in ambient conditions, in particular exposures to high temperatures and humidity. The measured abundances of SCFAs are consistent across all three sample handling scenarios, indicating that their degradation did not occur in a noticeable manner (Figure 3B). Consequently, such a handling strategy is at least appropriate within the outlined conditions for the molecules of interest described here.

The metabolome captured by the S-Wipe was further broadly compared to that of conventional stool collection methods for both volatile and non-volatile molecules. Principal component analysis (PCA) plots revealed no statistically significant differences between the two collection methods (Figure 3A). Further investigation using molecular networking (54, 55) confirmed that the biogenic molecules were consistently captured by S-Wipe in the same way as for the direct stool collection (for example, Figure 3C and Supplementary Figure 4). All of the noted differences between the collection methods were found to correspond to background molecules present in blank samples (Supplementary Figure 5). This corroborates that the S-Wipe methodology collects stool samples without alteration and, with appropriate normalization and blank subtraction, should be directly comparable to any other methodology that does not alter stoll metabolome upon collection.

Figure 2. A) Scatter plot of total abundance of C2-C7 SCFAs vs. the measured mass of collected samples for both stool and S-Wipe. A significant positive correlation ((Pearson's R = 0.95, p < 0.001)) is evident. B) Stability of SCFAs. A 500µl aliquot of the Accustandard FAMQ-004 standard at 10mM concentration was spiked onto S-Wipe. The wipes spiked with standard, and two sampled wipes were then stored for times ranging from one day to one week at room temperature. GC-MS analysis was conducted for each time point to measure abundance of SCFAs. The observed lack of pronounced changes in abundance is

suggestive of analyte's stability within one week time frame.   C) Comparison of variability in SCFAs for stool collected with scooping method (conventional sample collection) vs. S-Wipe collection. Sample collected by both methods was extracted and abundances of three SCFAs of primary diagnostic interest (left) and other SCFAs and p-cresol (right) were measured by GC-MS. For all metabolites, the measured abundances generally align, while variability is consistently lower for S-Wipe collection. The variability of acetic acid is greatest due to its highest volatility. D) Plot showing the total abundance of SCFAs, collected using regular stool collection and S-Wipe (green trace). Plot is also showing mass of stool collected in milligrams on the secondary axis (blue bars) as well as Normalized density (ND) of samples as determined by CellsBin proprietary technology (description is given in the Methods section) of real time cell counting (Supplementary video and data). It is evident that the abundance of metabolites is similar between conventional stool collection and S-Wipe, but the cells are generally absent in S-Wipe samples, ostensibly due to their retention on the tissue.

To confirm the suitability of the S-Wipe method for streamlined metabolomics workflows, we assessed its compatibility with mass spectrometry (MS) analysis without the need for extensive sample manipulation and cleanup. In MS-based metabolomics, various methodologies such as lyophilization/reconstitution, solid-phase extraction, and bi-phase extraction are commonly employed to remove unwanted background components, including proteins, lipids, and cell debris, which can interfere with MS analysis by causing clogging, introducing background noise, and affecting analyte solubility and ionization efficiency (56–58).

Fecal samples naturally contain a large number of host and microbial cells that must be removed before introduction into the MS system (58–60). Unlike direct fecal sample collection methods, the S-Wipe approach is designed to retain the fecal material within the paper matrix while allowing soluble metabolites to partition into the solvent. We hypothesized that this feature of the S-Wipe method would result in a lower cellular content in the collected samples compared to traditional fecal collection techniques. To test this hypothesis, we conducted a comparative cell counting analysis between samples obtained using the S-Wipe approach and those collected through conventional methods. The results confirmed that specimens collected with the S-Wipe approach contained substantially fewer cells (Figure 2D). Correspondingly, by minimizing the presence of cell debris, the S-Wipe method mitigates the risk of instrumentation contamination and circumvents issues such as clogging that may arise from excessive cellular material. The reduction in cellular content thus enables simplified extraction protocol for S-Wipe samples described in the Figure 1B, where a single centrifugation step yields a supernatant that is ready for direct MS analysis.

Figure 3. A) Principal coordinate analysis plot of samples from the conventional stool collection and S-Wipe. Several extraction protocols have been tested, as described in the Methods section, to account for possible biases due to the sample preparation. No statistical difference between methodologies is notable. B) Bar plot showing the distribution of short- and medium- chain fatty acids as well as p-cresol and phenol across three different conditions in the shipping study: Neg80 - samples stored at -80C immediately after collection; Intrastate - samples shipped within the state (approximately one week passed in between shipping and receiving samples); Across US - samples shipped from East to West coast of the US (approximately two weeks passed in between shipping and receiving samples). The "Intrastate" and "Across US" samples were stored at 2°C-4°C until analysis. All of the samples were analyzed by GC-MS at the same time. C) Molecular co-network of GC-MS data collected using S-Wipe and regular sample collection approaches; an inset shows clusters of SCFAs. The pie-chart coloring for each molecule's node corresponds to an averaged abundance of the molecule across all samples collected with the corresponding method; the abundances of various SCFAs are generally comparable and consistent for both methodologies.

DISCUSSION

The motivation behind the present work is to develop an easy-to-use and inexpensive method for stool sampling, focusing on capturing metabolites important for health diagnostics, especially short-chain fatty acids (SCFAs). Such methodology is essential for large-scale projects that explore the metabolome in conjunction with human gut health. Combination of food molecules, exposures, host's endogenous metabolites, and their various transformations, including microbially-contributed metabolites, make gut some of the most molecularly complex environments. To capture the intricacies of native biological complexity and account for the variability in the general population, studies must be conducted on a fundamentally different scale, involving large, diverse cohorts. In practical terms, this necessitates the collection and analysis of an immense number of samples, ranging from thousands to ultimately millions or even billions.

Revolutionary advances in sequencing two decades ago have enabled previously unimaginable magnitudes in studies such as the Human Microbiome Project (61–68) and the Earth Microbiome Project (EMP) (69–71). The latter project intends to capture the full microbial diversity of the entire planet. Studies of this magnitude must be community-driven, as no single lab would be able to conduct such research by itself. Harmonized, large-scale sampling is central to making such efforts feasible, as it allows multiple laboratories to collect samples independently and then conduct joint co-analysis of collected data (61–63, 71).

Unlike in DNA sequencing, metabolomics sampling approaches are generally neither standardized nor optimized for broad-range molecular explorations. This is due to the inherent difficulty to standardize sample collection in MS, and, concurrently, the current lack of truly large-scale efforts of population-wide studies similar to those done by 16S or metagenomics sequencing (64)(72). This creates a negative feedback loop, where the lack of established standardized sampling methodologies complicates large-scale metabolomics studies, and conversely, the lack of large-scale studies comparable in ambition to EMP does not provide the impetus to develop sample methodologies appropriate for population-wide scale studies.

A major factor in lack of sampling standardization in metabolomics is due to the fact that, unlike in sequencing, where DNA properties are relatively consistent across samples, molecular properties vary widely, as molecules differ in size, polarity, volatility, solubility, stability, etc. Standardizing any one methodology inevitably creates the possibility of bias, where a subset of the metabolome is efficiently detected, but some molecules are either not collected, or lost during the sample handling, or would not be detectable with the sample processing (e.g., due to poor solubility). A methodology choice is often dictated by the research question at hand and the molecules of interest in each individual study. In particular, the choice of solvent is crucial, as it selectively dissolves certain molecules and directly affects the detectable metabolome. Aqueous solvents are more suitable for detecting polar molecules, while organic solvents are better for detecting less polar compounds. Considering these limitations, a "universal methodology" in metabolomics would be different from that in DNA sequencing. Such standardized sampling methodology cannot be absolutely uniform, but instead it needs to: 1) collect native samples to preclude bias due to the sampling itself; 2) avoid or minimize method-specific distortion due to sample handling, preparation etc. of detectable molecular distributions; and 3) be amenable to a variety of analysis methodologies. The choice of

methodology will then dictate the downstream sample manipulation. In the context of metabolomics, the main methodologies are predominantly GC-MS (73–75) and LC-MS (76–80), and less often, NMR (81–83). Additionally, the sampling methodology should be inexpensive, simple to use to minimize user error, widely accessible (including minimizing or, preferably, eschewing the use of critical materials, particularly metals (56, 84–89), and scalable.

The S-Wipe methodology was developed with the above considerations in mind. This sampling manifold is cheap (<$1 per kit), easy to manufacture, and uses broadly available components and materials with minimal design complexity. More importantly, the approach is intended to minimize user burden, enabling individuals to adopt it without disrupting their established routines. Using the toilet wipe allows collecting neat fecal samples without alteration, as evidenced by the results presented above (Figure 3A and SUpplementary Figure 4). Since the samples collected by S-Wipe are directly comparable to neat stool samples, data from any study utilizing S-Wipe, in principle, should be directly comparable to studies where neat stool is collected by any other means, enabling continuation of existing studies, building biobanks, routine sampling, cross-laboratory data comparison, etc., provided standardization of downstream analysis protocols.

In this study, 60% ethanol was chosen as a "middle ground" solvent. It is suitable for sample preservation during shipping and for capturing and detecting many important metabolites, particularly short-chain fatty acids (SCFAs). Ethanol is also convenient due to its relatively low toxicity, cost-effectiveness, and suitability for a broad range of mid- to low-polarity molecules. We suggest using 60% ethanol for gut metabolome studies in particular, as we found convincing evidence that the degradation of the SCFAs is negligible, even when stored at room temperature for multiple days (Figure 2B). While SCFAs demonstrated stability under the studied conditions, it is important to note that other, less stable molecules may still be susceptible to degradation. Therefore, when considering other molecules for diagnostic purposes, it is crucial to establish their stability, if not already known, in order to ensure the reliability and accuracy of the results obtained using the S-Wipe methodology.

Ethanol denatures enzymes and kills off microflora, thus minimizing the biochemical alteration of molecules in the sample and preventing microbial blooms. However, ethanol may not be the best choice for all applications. For instance, other solvents may need to be used in addition to or instead of ethanol, depending on the specific application. Use of certain solvents is necessary for optimizing the detection of particular molecules or molecular classes. The S-Wipe sample preparation workflow could be adopted accordingly. By lyophilizing the sample and reconstituting it in a different solvent, a broad range of molecules present in the sample can be detected (this is only applicable for non-volatile molecules, as lyophilization step will remove or distort abundances for volatile and semi-volatile molecules). This allows for the optimization of the solvent for compatibility with the analytical methodology (e.g., RP vs. HILIC for LC-MS) based on the specific compounds of interest. Since the use of different downstream sample handling will result in the detection of different molecular distributions, it is essential to standardize the use of the same solvent throughout each study or set of studies to ensure consistency and reproducibility across.

The key advantage of the S-Wipe method is the minimal complexity of sample acquisition, so any able person can use it without requiring specialized facilities or equipment. The amount of material can vary with each use, but the collected sample weight can be directly measured.

Both the weight of the collection tube with solvents and the weight of the wipe are standardized, allowing for the determination of the collected sample weight by subtracting these known values from the weight of the used kit. Fecal metabolite concentrations often demonstrate poor direct correlations to total stool mass due to considerable individual variations in water content and dietary fiber, as the water and non-fermented fibrous fraction expands stool weight without affecting bioactive compounds. With the use of S-Wipe, we observed a strong correlation between the total amount of SCFAs and biomass, indicating the utility of normalization by mass (Figure 2A).

Finally, we note the minimal presence of cells in the collected samples. This further makes the methodology conducive to high-throughput metabolomic profiling by alleviating the need for extensive sample cleanup, rendering this novel collection strategy well-suited for large-scale studies.

Taken together, the results demonstrate that the S-Wipe method collects and preserves stool metabolites that could be used in health assessments. The methodology itself is a very simple to use, cost-effective, and versatile approach to stool sampling for metabolomics analysis. By enabling the collection of native samples without bias, minimizing method-specific distortions, and allowing for adaptability to various analytical methodologies, this method has the potential to facilitate large-scale, population-wide gut metabolome studies. The standardization of sample handling and the use of appropriate solvents, such as 60% ethanol, would ensure consistency and reproducibility across studies. With its ease of use and minimal sample cleanup requirements, the S-Wipe method is well-positioned to support the growing need for large-scale metabolomics investigations in the context of human gut health and beyond.

Conclusion

This study describes a fecal sampling routine designed for high-frequency metabolomics sampling. The approach condenses into the ubiquitous toilet wipe use without compromising analytical sensitivity or quantitative molecular preservation. We have shown the intrinsic capacity to stably sorb, store, and release key gut metabolites such as SCFAs using an inexpensive, immediately accessible paper matrix suitable for self-administration. By simplifying the process, this approach is designed to translate monitoring of the gut microbiome on the molecular level from an academic curiosity into a practical tool for personalized nutrition and disease management. Similar to how affordable genetic testing has allowed proactive mitigation of hereditary risks, routine measurement of molecular biomarkers such as SCFAs has a potential to shift gastrointestinal disease management from reactive to predictive by providing easy access to gut metabolome monitoring.

Materials and Methods

Protocol Optimization Study

A healthy volunteer donor has provided all stool samples. The protocol described in the "Sample Extraction" section was run alongside a long sonication and incubation extraction protocol. The long protocol included a 10 minute sonication on ice and six hours on a vibration table at 2 - 4°C for homogenization. Samples included S-Wipe kits with no wipe, S-Wipe kits complete, and S-Wipe kits with no stool. Samples were generated in triplicates. After sample extraction, samples were analyzed by GC-MS and LC-MS/MS.

Stability Study

A healthy volunteer donor has provided all stool samples. Samples collected by S-Wipe kits and controls were incubated at 25°C for 0-, 3-, 5-, and 7- days. Negative controls contained no stool and positive controls contained no stool and Accustandard FAMQ-004 at 1mM. All samples were collected in triplicates. Sampled kits were stored at -80°C until analysis and all samples were extracted together. After sample extraction, samples were analyzed by GC-MS and LC-MS/MS.

Shipping Study

A healthy volunteer donor has provided all stool samples. Samples collected by S-Wipe kits and controls were sent and returned via United States Postal Service to a short-distance (36-miles) and long-distance (2,950-miles) address. Negative control contained no stool. All samples were in triplicates. Upon reception in the mail, the S-Wipe kits were stored at 2 - 4°C until analysis. All samples were extracted and analyzed by GC-MS and LC-MS/MS at the same time.

Interpersonal Variability Study

10 healthy volunteers were provided with S-Wipe collection kits and US mail return labels to return samples to the lab. No personal or any other information was collected throughout the study.

Sample Extraction

Completed S-Wipe kits kept at -80°C were thawed on ice prior to extraction. Pre-sample and post-sample kit mass was recorded. The completed kits were first placed in an iced ultrasonic bath for 10 minutes and then on a vibration table for 10 minutes at room temperature for homogenization. 1000µL aliquot was taken and transferred to 1.5 mL microcentrifuge tubes. The samples were centrifuged for 5 minutes at 14,000 revolutions per minute. After centrifugation, aliquots of 100 uL were taken from each sample and transferred to vials with conical inserts, and analyzed by GC-MS and/or LC-MS/MS. Samples were directly loaded onto GC-MS, and were added to C18 resuspension buffer (15% Acetonitrile (Sigma, USA) in LCMS grade water, Sulfachloropyridazine (TCI, USA) and Sulfamethazine (Sigma, USA) to 25uM), for LC-MS/MS.

GC-MS data acquisition and processing

1 µL aliquot of the S-Wipe kit supernatant was directly injected into an Agilent 6890 GC interfaced to a mass spectrometer Hewlett Packard MSD 5973 for electron ionization GC-MS. The GC utilizes a 30m ZB-FFAP column (0.25 mm i.d., 0.25 µm film thickness) for metabolite separation with 1.2mL/min constant He flow. The oven temperature program initiates at 50°C rising to 240°C at 10°C/min. Lint particulate traces from wipe material were found to contribute no observable analytical interference. The data were then deconvoluted with the MSHub algorithm (54). The experimental spectra were searched against the NIST 2023 library with ≥80% spectral match defining putative identifications, and the retention times falling within <0.01 min of the corresponding reference standards.

LC-MS/MS data acquisition and processing

The samples were injected and chromatographically separated using a Vanquish UPLC (Thermo Fisher Scientific, Waltham, MA), on a 100 mm × 2.1 mm Kinetex 1.7 µM, C18, 100 Å chromatography column (Phenomenex, Torrance, CA), 40 °C column temperature, 0.4 mL/min flow rate, mobile phase A 99.9% water (J.T. Baker, LC–MS grade), 0.1% formic acid (Thermo Fisher Scientific, Optima LC/MS), mobile phase B 99.9% acetonitrile (J.T. Baker, LC–MS grade), 0.1% formic acid (Fisher Scientific, Optima LC–MS), with a the following gradient: 0–1 min 5% B, 1–8 min 100% B, 8–10.9 min 100% B, 10.9–11 min 5% B, 11–12 min 5% B.

MS analysis was performed on Orbitrap (Q Exactive, Thermo Fisher Scientific, Waltham, MA) mass spectrometer equipped with HESI-II probe sources. The following probe settings were used for both MS for flow aspiration and ionization: spray voltage of 3500 V, sheath gas (N_2) pressure of 35 psi, auxiliary gas pressure (N_2) of 10 psi, ion source temperature of 350 °C, S-lens RF level of 50 Hz and auxiliary gas heater temperature at 400 °C.

Spectra were acquired in positive ion mode over a mass range of 100–1500 *m/z*. An external calibration with Pierce LTQ Velos ESI positive ion calibration solution (Thermo Fisher Scientific, Waltham, MA) was performed prior to data acquisition with ppm error of less than 1. Data were recorded with data-dependent MS/MS acquisition mode. Full scan at MS1 level was performed with 30K resolution. MS2 scans were performed at 11250 resolution with max IT time of 60 ms in profile mode. MS/MS precursor selection windows were set to *m/z* 2.0 with *m/z* 0.5 offset. MS/MS active exclusion parameter was set to 5.0 s. Raw MS/MS data were converted to mzXML files using MSConvert.

LC-MS raw data files were converted to mzML format using msConvert (ProteoWizard). MS1 features were selected for all LC-MS data sets collected using the open-source software MZmine 3 (90) with the following parameters: mass detection noise level was 10,000 counts, chromatograms were built over a 0.01-min minimum time span, with 5,000-count minimum peak height and 5-ppm mass tolerance, features were deisotoped and aligned with 10-ppm tolerance and 0.1-min retention time tolerance, and aligned features were filtered based on a minimum 3-peak presence in samples and based on containing at least 2 isotopes. Subsequent blank filtering, total ion current, and internal standard normalization were performed for representation of relative abundance of molecular features and for principal-coordinate analysis (PCoA).

Cell counting assay

Blind samples were analyzed using CellsBin's VEGA platform at an external lab. The normalized density of each sample was calculated by imaging 20 μl through CellsBin's microfluidic optical device. The company's machine learning algorithm detected and classified particles, estimating the relative size and normalized density of each sample.
