Abstract

Alzheimer's disease (AD) is the most prevalent form of dementia and a public health priority. The causes of AD are not completely understood. Pathogenetic factors including mitochondrial dysfunction, oxidative stress, reduced energy status, and compromised ion channels contribute to the onset and progression of the disease. Flickering light therapy in experimental and clinical AD has shown promising outcomes. However, the mechanisms behind the effect of flickering light at the molecular and cellular level has not yet been fully investigated. In this study, we established streptozotocin (STZ)-induced AD models by intracerebroventricular (ICV) injection of STZ in Wistar rats and monitored their memory decline. Sham and AD rats were either exposed or not exposed to 40 Hz flickering light for 7 consecutive days after 7 days of STZ injection. Memory and cognition-related behavioral analysis, pathological, electrophysiological, and biochemical assessment of the brain tissue, and mitochondrial function assays were conducted after the treatment. Cognitive and memory impairment, examined by Morris water maze (MWM), novel object recognition (NOR), and passive avoidance (PA) test, was observed in the STZ-induced AD rats and light treatment improved these behaviors. STZ injection led to significant accumulation of reactive oxygen species (ROS) and amyloid beta (Aβ), decreased serotonin and dopamine levels, and mitochondrial respiration. The 40 Hz flickering light reversed all these parameters in the light treatment group. The synaptic plasticity of STZ-induced AD rats was severely affected, but flickering light prevented the loss of synaptic plasticity and activity in the light-treated AD rats. Additionally, flickering 40 Hz white light elevated the levels of mitochondrial metabolites and the current and possible opening of the mitochondrial calcium-sensitive potassium (mitoBK$_{Ca}$) channel which were significantly downregulated in AD rat neurons. The 40 Hz flickering light restored mitochondrial function and synaptic plasticity of AD rat neurons and improved the cognition of animals; therefore, it can be a promising strategy to reduce AD progression.

Keywords: Flickering 40 Hz white light; Alzheimer's disease; Mitochondrial function; mitoBKCa; Mitochondrial metabolites; LTP; Synaptic plasticity.

Introduction

Alzheimer's disease (AD) is a progressive neurological disease. It causes cognitive decline, behavioral abnormalities, memory loss, and intellectual deterioration [1, 2]. Despite considerable efforts, pharmaceutical disease-modifying therapies for AD have not yet achieved widespread success. Most of these attempts are based on the amyloid hypothesis, which states that the disease starts with an accumulation of amyloid and then more non-specific proteins, such as total and phosphorylated tau, which cause brain damage and cognitive decline. It also initiates a chain reaction of generalized neurotoxicity events, including hyperphosphorylation, oxidative stress, local inflammation, and an imbalance between neurotransmitters such as dopamine, serotonin, and acetylcholine [3, 4]. This could result in a reduction in synaptic transmission [5], which would then impede synaptic plasticity, long-term potential (LTP), or long-term depression (LTD) [6], particularly in memory-related areas, including the hippocampus area [7].

Photobiomodulation therapy (PBMT) is a nondrug, noninvasive, and nonthermal method that uses light sources, including LASERS, and LEDs, for multiple therapeutic purposes, such as enhancing synaptic function in neurons [8-10]. Low-level LED as a therapeutic technique has been described based on sensory (visual, nasal, and/or transcranial) characteristics, which in particular, stimulation at 40 Hz reduces AD neuropathology [11-16]. Due to light flickering at 40 Hz, the ability to reverse the pathological features of AD [11, 14, 17], ischemia [18], and traumatic brain injury [19] in animal models has led to the US FDA approving a breakthrough device in 2021 for further clinical investigation [20].

Accumulation of Aβ peptides over the course of AD causes mitochondrial dysfunction, abnormal Ca^{+2} influx, synaptic loss, inflammation, and cellular death [21-25]. However, it is still unclear how Aβ causes mitochondrial structural and functional abnormalities. It is now known that PBMT improves mitochondrial function and raises the ATP content and components of respiratory chain activity, especially cytochrome c oxidase (complex IV) [26, 27]. We have shown that Aβ impairs mitochondria function in AD rat brains, and flickering 40 Hz white LEDs restores its function by raising complexes I and IV activities and mitochondria membrane potential [28, 29]. Since the mitochondria are the main sources of energy for synaptic transmission and responsible for ions/metabolites homeostasis, cell survival, and motility, it's

likely that 40 Hz light flicker produces therapeutic benefits in AD by improving mitochondrial function [30-33].

Ion channels in mitochondria are essential parts of the organelle that appear to play an important role in neuroprotection [34]. Several lines of evidence have confirmed the putative role of mitochondrial voltage- and Ca^{2+}-activated K+ channel of large conductance (mitoBK$_{Ca}$) in cell viability via the prevention of mitochondrial $[Ca^{+2}]$ overload and the reduction of reactive oxygen species (ROS) [35]. Two ATP-insensitive mitoBK$_{Ca}$ (charybdotoxin- and iberiotoxin-sensitive) channels [36] and one ATP-sensitive mitoBK$_{Ca}$ channel [37, 38] have recently been characterized in rat brains which are altered in Aβ and streptozotocin (STZ) toxicity models of AD and diabetes. Aβ(1-42) peptides eliminate the ATP-sensitive mitoBK$_{Ca}$ channels, reduce conductance, and lessen the open probability of these channels in the inner membrane of the mitochondria of the neural synaptosome in AD and diabetic animal models [16, 39]. An independent study indicated that flickering 40 Hz LED could improve the activity of ATP-sensitive mitoBK$_{Ca}$ channels in rat brains [16]. The mitoBK$_{Ca}$ channels have not been fully investigated in STZ toxicity models of AD and the effect of 40 Hz LED on these channels remains to be determined.

In the current study, we evaluated mitochondrial metabolome as an output of the changes STZ could induce in the rat models of AD. We also studied the effect of 40 Hz LED on channel gating and permeability of mitochondrial mitoBK$_{Ca}$ channels and if this could restore changes in the metabolomics of mitochondria.

Materials and Methods

Chemicals

Sucrose, D-mannitol, HEPES (4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid), BSA (bovine serum albumin), EGTA (ethylene glycol-bis (β-aminoethyl ether)-N, N, N′, N′-tetraacetic acid), digitonin, nagarse, sodium bicarbonate, Trizma-HCl, potassium chloride, glibenclamide, ATP, Mannitol, sucrose, Tris–HCl, bovine serum albumin (BSA), EDTA, NADH, KCN (potassium cyanide), sodium dithionite, potassium phosphate dibasic (K2HPO4), potassium phosphatemonobasic (KH2PO4), ubiquinone-1 (coenzyme Q1), reduced cytochrome c, 2′,7′-dichlorofluorescein diacetate (DCFH-DA), and rhodamine 123 (Rh 123), mannitol, 75 mM sucrose, HEPES, EGTA, BSA, digitonin and nagarse were obtained from Sigma (Sigma-

Aldrich, St. Louis, MO, USA), and *n*-decane was purchased from Merck (Merck KGaA, Dermstadt, Germany.

Animals

Adult Wistar rats weighing 200-220g were purchased from Tehran University, Tehran, Iran. Every four rats were kept per cage under a standard condition, with a temperature of $23\pm1\,°C$ and humidity ranging from 50-60%. The rats were also subjected to a 12-hour light/dark cycle and had free access to food and water. This study was approved by the ethics committee of the Tehran University of Medical Sciences (IR.TUMS.MSP.REC.1399.066). All the experiments were conducted based on the Guide for the Care and Use of Laboratory Animals, National Insitute of Health.

Light Flicker Exposure Apparatus

The rats were exposed to flickering 40 Hz light in a black box with $50\times50\times50$ cm dimensions. The LED strip was positioned inside at the top of the box and emitted white light with a visible wavelength of 425-550 nm and an average irradiance of 12 mW/cm^2. White light pulses in a flickering 40 Hz pattern had a duration of 12.5 ms on and 12.5 ms off. LEDs' on/off state was controlled through an AVR microcontroller circuit connected to a computer via a USB cable. Other characteristics of the method included: Duty cycle: 50%; Average power: 30 Watt; Average irradiance/average power density: 12 mW/cm; Average energy density: 10.8 J/cm^2; Duration of exposure: 15 min/day.

Experimental Groups

The experimental groups were assigned randomly as follows: (1) Sham: intracerebroventricular (ICV)-saline injection with no light treatment; (2) Sham+light: ICV-saline injection with light treatment; (3) AD or STZ: ICV-STZ injection with no light treatment; and (4) AD+light or STZ+light: ICV-STZ injection with light treatment. Seven days following ICV-STZ/saline injections, the rats underwent daily exposure to 40 Hz flickering white light for 15 minutes over the 7 days of exposure. Figure 1 illustrates the experimental design (Figure 1).

Figure 1. Schematic diagram of the study's experimental design.

Morris Water Maze

The Morris water maze (MWM) is one of the most widely used tasks to assess spatial learning and memory in rodents [40]. The task consisted of two stages: the acquisition phase for spatial learning assessment and the probe test for retention retrieval of memory. MWM was performed on our experimental rats for four consecutive days. The acquisition phase comprised one session with four trials (with 30s intervals) lasting 90s for three consecutive days. A 60s probe test with a removed platform was given 24 hours after the completion of the last session.

During each trial, the path of the animals' swimming was automatically recorded using a video camera-based system (EthoVision, Noldus, Version 14). The latency time to find the hidden platform (escape latency) was the parameter analyzed in the acquisition phase, and the latency of the first entry to the target quadrant, the number of times crossed to the platform, and time spent in the target quadrant were the parameters analyzed for probe test. One rat was deemed a 'poor performer' in all groups and excluded from the study.

Novel Object Recognition Task

The Novel Object Recognition (NOR) test assesses rodents' cognitive ability by measuring their natural tendency to explore a new object more than a familiar one [41]. The test was performed over three days beginning with a habituation period in an empty arena ($60{\times}60{\times}50$ cm) on day 1, exposure to two similar objects on day 2, and exposure to a novel object with different colors and shapes on day 3. The animals' exploration of the objects was determined by the distance of their nose being within 2 cm of the object which was recorded using a video camera-based system (EthoVision, Noldus ,Version 14). Time exploring a novel object than a familiar object and the Recognition Index (RI) was calculated based on the time spent investigating the novel object (T_N) relative to the total object investigation (T_F+T_N).

Passive Avoidance

A passive avoidance apparatus was used to assess memory retention deficits. The apparatus consisted of a wooden box divided by a guillotine door into light and dark compartments, with a stainless-steel shock floor grid in the dark section [38]. Once the rat entered the dark compartment, the door was closed, and after 30 seconds, the animal was returned to its cage. The first day consisted of three trials with 30-minute intervals, two for adaptation and the last for training. During the adaptation trial, the rats were placed in the light compartment, and their latency to enter the dark room was measured to ensure that all rats entered the dark side in under 20s. In the training phase, the rats were placed in the light chamber and allowed to enter the dark compartment. As soon as they entered, the guillotine door closed, and an electric shock (50Hz square wave, 1mA for 1.5s) was delivered to the floor. The time it took for the animal to enter the dark compartment with all four paws was recorded as step-through latency (STL). The next

day, the retention latency time was measured similarly but without delivering a shock. Total time in the dark compartment (TDC) and STL were measured as memory retention evaluation, and the cutoff time was about 600s. The experiment was conducted under standard conditions between 10.00 a.m. and 2.00 p.m.

Tissue Collection for Biochemical Tests

After behavioral tests, rats were decapitated under ketamine (150 mg/ kg) anesthesia. Rat hippocampus tissue (n = 5) was dissected and homogenized in cold RIPA buffer (pH 7.4). After centrifugation (~10,000 g, 4°C, 15 min), the supernatant was used for biochemical tests. The Bradford assay was used to determine the total protein concentration.

Serotonin and Dopamine Assays

Dopamine and serotonin quantities in the hippocampus tissue were assessed using the ELISA kits (Cat#: RK00642 and Cat#: TN2437, Zellbio, Germany) according to the kit instructions.

Histological Evaluation using Congo Red Stain

Animals were anesthetized and transcardially perfused with heparinized normal saline and then 4% paraformaldehyde in 0.1 M phosphate buffer (PBS, pH 7.4). The brains were removed, and processed for sectioning and Congo red staining according to previously published protocols [42]. In the end, the hippocampus' cornu ammonis (CA) and dentate gyrus (DG) regions on both hemispheres were subjected to neuronal Aβ plaque counting.

Isolation of Mitochondria

The Navarro et al. protocol was utilized to isolate mitochondria [43]. Briefly, the brains were homogenized in mitochondrial isolation buffer containing 230 mM mannitol, 1.0 mM EDTA, 70 mM sucrose, and 10 mM Tris–HCl at a pH of 7.40. The homogenized brains were centrifuged at 700g for 10min, the supernatant was separated and centrifuged at 8000g for 10 to obtain mitochondria pellets. The mitochondrial samples were stored at −80°C for subsequent

biochemical analysis. The mitochondria protein content was determined (0.7 mg/ml) using a Bradford assay [34].

Mitochondrial Inner Membrane Isolation

Brain mitochondria were obtained 28 days after ICV-STZ injection using a modified version of the protocol previously published [44-46]. Briefly, dissected brains were homogenized in an MSE-nagarse solution containing 225 mM mannitol, 75 mM sucrose, 5 mM HEPES, 1 mM EGTA, 1 mg/ml BSA at pH 7.4, and 0.05% nagarse. The homogenized solution was centrifuged at 2000g for 4min, and the supernatant was centrifuged at 12000g for 9min to obtain a pellet. MSE-digitonin (0.02%) solution was used to dissolve the pellet, then centrifuged at 12000g for 11min to obtain the final pellet in cold MSE solution. The pellet was further processed according to the established protocol by Da Cruz et al. [46] to isolate and purify the inner mitochondrial membrane in the form of vesicles. To begin with, the acquired mitochondria were suspended in H_2O at a concentration of 5 mg/ml and stirred for 20 minutes. This was followed by homogenization of the suspension 20 times using a glass homogenizer. The resulting mixture was then centrifuged twice at 12,000 g for 5 minutes and the pellet (mitoplasts) was treated with 0.1 M Na_2C_{O3} (pH 11.5) for 20 minutes before being centrifuged again at 100,000 g for 30 minutes. Ultimately, the inner membrane vesicles of mitochondria were stored at −80 °C until required.

Extraction of L-α-Phosphatidylcholine

L-α-phosphatidylcholine (L-α-lecithin) was utilized to create a planar lipid bilayer. The Singleton and Gray's [47] method was applied to extract L-lecithin from fresh egg yolk, and the extracted lipid's purity was verified using thin-layer chromatography (TLC), which revealed a purity of approximately 98% compared to standard lecithin.

Single-Channel Recordings

A Delrin partition with a 150-µm-diameter hole was used to create two chambers, namely cis and trans, which served as cytoplasmic and luminal sides, respectively, for forming planar phospholipid bilayers. Both chambers were filled with 4 ml of KCl 200 mM cis/50 mM trans, and pH was adjusted to 7.2 on both sides using a Tris-HEPES solution. A solution of L-lecithin in n-decane at a concentration of 25 mg/ml was used to paint a planar lipid bilayer, which was then mechanically fused with a vesicle by gently touching the membrane from the cis side using a stainless-steel wire. Ag/AgCl electrodes were used to monitor the voltage across the bilayer, while a BC-525D amplifier (Warner Instrument, USA) in voltage-clamp mode was applied to amplify the current. To determine the thickness of the bilayer membrane, the BC-525D amplifier induced a low frequency (1-10 Hz) triangular wave with an amplitude of 5-20 mV (peak to peak), resulting in capacitance values ranging from 200 to 300 pF. The command voltage was set to the cis electrode while the trans electrode was grounded. Single-channel recordings were filtered at 1 kHz with a four-bessel low-pass filter and digitized at a sample rate of 10 kHz. The data was stored on a personal computer using Clampex10 (Axon Instruments Inc., USA) and analyzed using pCLAMP10 (Axon Instruments Inc., USA). The single-channel conductance was measured from the slope of the current-voltage curve, while the channel open probability (Po) was determined using standard event detection algorithms in pCLAMP10. Po was calculated on segments of continuous recordings lasting 40 seconds, and the results were presented as means ± S.E.

Field Excitatory Postsynaptic Potential (fEPSP) and Long-Term Potential

To record field excitatory post-synaptic potential (fEPSP), an extracellular bipolar stainless-steel stimulating electrode with a diameter of 0.125 mm was inserted into the medial perforant pathway (4.2 mm lateral to the lambda and -3.2 mm ventrally). In comparison, another one was placed in the DG with the maximum response (-3.8 mm posterior and 2.2 mm lateral to the bregma). Extracellular field potentials were amplified 1000 times, digitized at 10 kHz, and filtered with a differential amplifier at frequencies ranging from 0.1 Hz to 10 kHz. Biphasic square waves (with a width of 200 ms) were used as stimuli. A/D interface (Science Beam Co., Iran) was used to transmit signals to a computer, and the data was analyzed using eProbe software. The stimulation intensity was adjusted to elicit a response of 40% of the maximum response population spike (PS) and fEPSP. Before inducing LTP, we conducted stimulus-

response curves using various stimulus intensity levels ranging from 100 to 1200 µA. Following a minimum of 30 minutes of consistent baseline recording, we induced LTP by administering high-frequency stimulation (HFS), which consisted of 10 sets of 10 pulses at a frequency of 400 Hz, with a 10-second interval between each set. Following the tetanic stimuli, the baseline stimulation was resumed, and the recording was carried out for at least 60 minutes. The average of five successive evoked responses was taken at intervals of 10 seconds [48].

Paired-Pulse Response

After establishing a baseline for 30 minutes, we measured the effect of paired-pulse stimulation on depression/facilitation. The stimulation was delivered at 20, 30, 50, 70, 100 and 120 ms intervals and 40% of the maximum stimulus intensity. Ten consecutive evoked responses were averaged for each paired-pulse stimulation. Various interstimulus intervals were used to determine the fEPSP slope ratio [percentage of the second fEPSP slope/first fEPSP slope; fEPSP2/fEPSP1%] and the population spike amplitude ratio [percentage of the second population spike amplitude to the first population spike amplitude; PS2/PS1%] [48].

Tandem Mass Spectrometry (MS/MS) Analysis

After the isolation of mitochondria according to the Navarro et al. protocol [43], the acquired mitochondria were suspended in H_2O at a concentration of 5 mg/ml and stirred for 10 minutes. This was followed by homogenizing the suspension 20 times using a glass homogenizer. Using the isotope dilution mass spectrometry (MS), amino acids in butyl-ester forms in the mitochondria samples were assessed using the tandem mass spectrometry system (SHIMADZU, CLAM2040, MS/MS, JAPAN) and commercial kits [CHROMSYSTEM MS/ MS complete kits, amino acids in dried mitochondrial samples spots (DBS), CHROMSYSTEM Co, Germany]. According to the kit instructions, 10 µl of the samples were transferred to a microtube, then 200 µl of internal standard was pipetted on the sample, and vortexed for 10s. Then, centrifuged at 4°C for 10min with 10000 rpm, and 150 µl of supernatant was transferred to a microplate for 20min at 45°C to dry. Afterward, 50 µl of Acetyl chloride 1-butanol was added to the sample and was left for shaking for 1 min at 700 rpm. Samples were incubated at 65°C for 15min and dried under nitrogen gas at 45ºC for 15min. Then, 50 µl of 75% acetonitrile was added to the samples.

Finally, samples were shaken for 2min and introduced to the MS/MS system. The injection volume was 10 μl, the flow rate was 150 μl/min, and an analysis time of 2.074min was applied. MRM (multiple reaction monitoring) was adjusted as a scan mode [49].

Complex I (NADH-CoQ Oxidoreductase) Activity Assay

To determine the activity of complex I, the method described by Spinazzi et al. [41] was used with a slight modification. Briefly, mitochondria were isolated and added to an assay medium including distilled water, 500 mM potassium phosphate buffer (pH 7.5), 10 mM KCN, 10 mM NADH, and 50 mg/ml BSA without fatty acids. The reaction was initiated by adding ubiquinone-1 (10 mM) as an electron acceptor, and the decrease in absorbance was measured at a wavelength of 340 nm for 5min with 15-second intervals. The NADH has an extinction coefficient of 6.2/mM/cm.

Complex IV (Cytochrome c Oxidase) Activity Assay

The activity of Complex IV was determined using a previously described method [50]. In brief, the cytochrome oxidation process began after adding brain mitochondrial preparation to the reaction buffer solution. The reduction in absorbance was measured at 550 nm with 15-second intervals for 5min. The enzyme activity was expressed in nmol/min/mg of protein.

Mitochondrial Membrane Potential Measurement

Luo and Shi's [51] protocol was used to determine the brain's mitochondrial membrane potential (MMP). A cationic fluorescent dye called Rhodamin 123 (Rh123) was used to estimate the potential. In brief, the mitochondrial fractions were incubated with Rh123 for 5min and then excited at a wavelength of 490 nm. The emission wavelength of 530 nm was used to detect Rh123. The mitochondrial membrane potential was measured by analyzing the fluorescence intensity using a fluorescent microplate reader.

Reactive Oxygen Species Assay

DCFH-DA was utilized to measure ROS production, as it can easily cross membranes and transform into a highly fluorescent DCF when exposed to reactive oxygen during oxidation. The isolated mitochondrial samples (0.7 mg/ml protein) were incubated with DCFH-DA in microplate wells for 20 minutes at 25°C. The fluorescence was then measured using a Multi-Mode Microplate reader (synergy™ HTX) with an excitation wavelength of 485 nm and an emission wavelength of 528 nm [52].

Systems Biology: Metabolites-Related Pathway Identification

To identify the biological pathways affected by the metabolites dysregulated in our experiments, we used enrichment analysis, pathway analysis, and joint pathway analysis through MetaboAnalyst 6 (https://www.metaboanalyst.ca/) [53]. Before performing the joint pathway analysis, we identified the proteins related to metabolites (amino acids) through KEGG and MetaCyc, which are integrated into the Pathview Web server (https://pathview.uncc.edu/) [54].

Statistical Analysis

Statistical analysis was performed using Prism 8 software (Graph Pad Software, USA). In all of the groups, all experimental analyses were performed blindly. Statistical analysis was performed using two-way ANOVA followed by Bonferroni's post hoc test to compare MWM in the acquisition phase, exploring time in novel object test and fEPSP results. In addition, one-way ANOVA followed by Bonferroni's post hoc test to compare more than two groups. The data was presented as mean ± S.E. Statistical significance was determined by considering a P value of less than 0.05 (P < 0.05).

Results

Flickering 40 Hz white light improved the cognitive function of STZ-induced AD rats

To investigate the function of cognition, memory, and learning in our STZ-induced AD rats, and the effect of flickering 40 Hz white light on these animals, we performed a series of relevant behavioral tests in the following groups of animals: sham, sham+light, STZ-induced AD and STZ-induced AD+light groups.

In the MWM test, the STZ-induced AD rats showed higher latency to reach the platform during the learning phase (days 1-3) compared to the sham groups (sham and sham + light) (P<0.0001). Receiving flickering 40 Hz white light for 7 days significantly shortened the escape latency in STZ-induced AD rats (P<0.01; Figure 2A). The performance of rats in all groups progressively improved during days 1 to 3 of the training session and the difference in performance remained throughout the experiment.

A probe trial test evaluated memory retrieval twenty-four hours after the last training. There was a delay in the first entry of STZ-induced AD rats to the platform location compared to the sham groups ($F_{(3, 24)}$ = 42.73, P <0.0001) which was partially improved by the 40 Hz white light treatment (P<0.001) (Figure 2B). In this trial test, there was also a shorter time to spend in the target quadrant and less number of times crossing the platform by the STZ-induced AD rats compared to the sham groups (P<0.0001 and P <0.0001 respectively). The STZ-induced AD rats receiving flickering 40 Hz white light displayed significant improvement in these cognition parameters compared to the non-treated STZ-induced AD rats (P <0.01 and P <0.01 respectively) (Figure 2C-2E). There was no significant difference between the sham and sham-treated groups for these parameters.

Performance on the NOR task was measured by the total exploration time and recognition index. Our results showed that STZ-induced AD rats had less tendency to spend more time exploring the novel object in comparison to the sham groups as indicated by total exploration time (P < 0.001, for each subjects) and recognition index (50.16 ± 2.81%; P <0.05). Treatment of STZ-induced AD rats using flickering 40 Hz white light improved their recognition index (P<0.05). This treatment restored the behavioral deficits of STZ-induced AD rats to normal rats. Total exploration and recognition index were unaffected by flickering light in sham animals (Figure 2F-2G).

Passive avoidance behavior in shuttle box instruments involves learning to avoid certain stimuli. STL significantly decreased in STZ-induced AD rats when compared to sham group rats (P <0.0001) while receiving flickering 40 Hz white light rats increased STL by 3 folds compared to non-treated STZ-induced AD rats (P <0.01). As seen in Figure 3H, STL was unaffected by flickering light in sham animals (Figure 2H). These findings indicate that STZ-induced AD rats recall abilities and cognitive functions were enhanced by flickering 40 Hz white light.

Figure 2. Flickering 40 Hz white light improved cognitive function of STZ-induced AD rats. MWM: Comparison of the time escape latency to reach the hidden platform in the acquisition phase for 4 days and the time escapes latency, the total time spent in the target quadrant, and several time cross-platform in probe tests in sham, sham+light, STZ-induced AD and STZ-induced AD+light groups (A-D). Escape latency to platform for the 4 rat groups during the acquisition phase (A). Bar chart for the first entry to the platform location in the 4 rat groupd (B), the total time spent in the target quadrant (C) (A comparison of the average heatmap of MWM trials between groups. The heatmap scale bar indicates the time in seconds heatmap of time spent in the target quadrant (D)), and number of time crossed the platform (E) all examined

in the probe test. Novel object: Comparison of time exploring a novel object than a familiar object (F) and recognition index in all the four animal groups (G). Passive avoidance: The effect of light treatment on passive avoidance learning acquisition. Step through latency (STL) during the retrieval test performed 1 day after passive avoidance acquisition (H). One-way ANOVA analysis followed by Bonferroni post hoc test was performed to compare mean between groups. Data are expressed as mean ± SEM (n = 7 rat/group). P values are as follows: *: $P<0.0.5$, **: $P<0.01$, ***: $P<0.001$, ****: $P<0.0001$ for the sham groups vs. AD, and #: $P<0.05$, ##: $P<0.01$ for the AD groups compared to AD+light.

Flickering 40 Hz white light restored the deficits in serotonin levels and mitochondrial phenotype in the hippocampus of STZ-induced AD rats

At the cellular level, serotonin and dopamine levels were measured in the hippocampus tissue of the three animal groups: sham, STZ-induced AD, and STZ-induced AD+light groups (we excluded sham+light animal group from some of our analyses for simplicity since we didn't observe any behavioral and pathophysiological differences between sham and sham+light rats). Serotonin level was significantly reduced in the hippocampus of STZ-induced AD rats vs sham group ($P<0.01$) while there was no significant change observed in the dopamine concentration between groups. Interestingly, the flickering 40 Hz white light treatment restored the serotonin level to normal quantities in the STZ-induced AD ($P<0.05$) (Figure 3A).

In the hippocampus of the three groups of animals, we further analyzed the phenotype of mitochondria reflected in the following parameters: Complexes I and IV activities, MMP, and ROS levels. Complex I and IV activities were significantly diminished in the hippocampus of STZ-induced AD rats compared to the sham group ($P<0.0001$). Treatment of STZ-induced AD rats using flickering 40 Hz white light for 7 days improved the activity of both complex I ($P<0.001$) and complex IV ($P<0.05$) of the electron transport chain in mitochondria when compared to the non-treated STZ-induced AD rats (Figure 3B-3C).

To further explore mitochondrial function changes in the hippocampus of these animal groups, we evaluated the fluorescence intensity of Rh123 as an indicator of MMP. There was a significant increase in the MMP of mitochondria ($\Delta\Psi$m) in the hippocampus of STZ-induced AD rats compared to sham rats ($P<0.001$) which was driven back to normal potential when STZ-induced AD rats received flickering 40 Hz white light ($P<0.01$ for treated vs. non-treated AD rats)(Figure 3D). Higher ROS production was also observed in isolated mitochondria of the

hippocampus tissue of STZ-induced AD rats compared to sham rats (P<0.001). This ROS overproduction was eliminated in the STZ-induced AD rats when treated with flickering 40 Hz white light over 7 days (P<0.01 for treated vs. non-treated AD rats)(Figure 3E).

Flickering 40 Hz white light reduced Aβ plaques in the hippocampus of STZ-induced AD rats

The accumulation of Aβ in the hippocampus is a major pathological factor in the progress of AD. Congo red was used to stain brain sections derived from the following four groups of rats: sham, sham+light, STZ-induced AD, and STZ-induced AD+light groups. Clear accumulation of Aβ plaques was detected in the hippocampus of STZ-induced AD rats (P<0.001: AD vs sham). Flickering 40 Hz white light markedly reduced Aβ plaque formation in the hippocampus of STZ-induced AD rats (P<0.01: AD+light vs AD) (Figure 3F-3G).

Figure 3. Flickering 40 Hz white light restored the deficits in serotonin levels and mitochondrial phenotype in the hippocampus of STZ-induced AD rats. Neurotransmitter (serotonin and dopamine) levels (A) and mitochondrial phenotype (B-E) were analyzed in the hippocampus tissue of sham, STZ-induced AD, and STZ-induced AD+light rats. To measure serotonin and dopamine levels, the hippocampus tissue was homogenized and subjected to ELISA assay (n = 6) (A). Mitochondria were isolated for the measurement of Complex activities, MMP, and ROS levels (B-E). In F and G, brain sections from sham, sham+light, STZ-induced

AD, and STZ-induced AD+light rats were stained using Congo red, and the plaques were counted (F-G). One-way ANOVA analysis followed by the Bonferroni post hoc test was performed to compare the mean between groups. Data are expressed as mean ± SEM (n = 7 rat/group for B-E). P values are as follows: *: P<0.0.5, **: P<0.01, ***: P<0.001, ****: P<0.0001 for the sham groups vs. AD, and #: P<0.05, ##: P<0.01 for the AD groups compared to AD+light.

Flickering 40 Hz white light recovered the deficits in electrophysiological properties of hippocampal neurons in STZ-induced AD rats

To further investigate the long-term effects of flickering 40 Hz white light on neuronal activity, we assessed basal synaptic transmission and plasticity in the performant pathway of the hippocampal one month after STZ induction of AD. Basal synaptic transmission was studied by analyzing stimulus-response curves and short- and long-term potentiation by assessing paired-pulse facilitation (PPF) and LTP. The PS amplitude and the slope of the excitatory postsynaptic potential of a representative sample of the field potential and paired-pulse were recorded in lateral perforant pathway-dentate gyrus synapses of a sham, STZ-induced AD and STZ-induced AD+light groups. The acquired input/output (I/O) curve from recorded 60s periods revealed that PS amplitude increases with increasing current intensity from 100 to 1000μA. The acquired I/O measures revealed lower amplitude for the STZ-induced AD rats compared to the sham rats and flickering 40 Hz white light improved the I/O amplitude in the hippocampal neurons in STZ-induced AD rats, although these alterations were not significant (Figure 4A). After 60min of LTP induction, the dentate gyrus of STZ-induced AD rats exhibited significantly lower fEPSP compared to the sham rats (P<0.01) which were fully recovered by the flickering 40 Hz white light treatment in the light-treated AD group (Figure 4B).

High-frequency stimulation (HFS: 400 Hz) of lateral perforant pathway-dentate gyrus produced high PS amplitude and a long-lasting synaptic potentiation which were both depressed in STZ-induced AD rats (P<0.0001 and P<0.05, respectively). Intriguingly, the flickering 40 Hz white light treatment normalized both parameters in the light-treated AD rats (Figure 4C-4D).

In Figures 4E and 4F, short intervals were given between two strictly paired stimuli, and the PS amplitude and fEPSP slop were analyzed. Repeated measures for acquired input/output revealed a significantly lower PS amplitude in the STZ-induced AD rats compared to sham rats ($F_{(1.65, 6.62)}$ = 20.17, P <0.0006) which was recovered by 40 Hz light treatment at 20ms intervals (Figure 4E). Similarly, significantly lower fEPSP slop ($F_{(2.06, 8.26)}$ = 4.37, P =0.049) was observed

for the neurons in the dentate gyrus of STZ-induced AD rats. To our surprise, the flickering 40 Hz white light restored the defect in synaptic potentiation at 20, 30, and 50ms intervals of paired pulses in the hippocampal neurons of light-treated AD rats (Figure 4F). Overall, electrophysiological properties of hippocampal neurons including synaptic transmission and plasticity were defected in the STZ-induced AD rats and were recovered by flickering 40 Hz white light.

Figure 4. **Flickering 40 Hz white light recovered the deficits in electrophysiological properties of hippocampal neurons in STZ-induced AD rats.** The acquired input/output (I/O) curve from a 60s recording and single traces of the DG neurons' reaction to numerous stimulus intensities (100 to 1000 mA) (A). The effect of flickering 40 Hz white light on LTP induction and maintenance in the dentate gyrus up to 60 min after high-frequency stimulation (HFS) (B). Data were normalized against the baseline period (-30 to +60 min), and the single traces were recorded before/after HFS. fEPSP slope change (%) and time following HFS (B). The PS amplitude and slop mean were recorded at 0 to 60min after applying HFS (n=7) (C-D). In short intervals between two strictly paired stimuli, the amplitude of PS and fEPSP slope were prompted by a paired pulse in all groups (E-F). One-way or Two-way ANOVA analyses followed by the Bonferroni post hoc test were performed to compare the mean between groups. Data are expressed as mean ± SEM (n = 7 rat/group for B-E). P values are as follows: *: $P<0.0.5$, **: $P<0.01$, ***: $P<0.001$, ****: $P<0.0001$ for the sham groups vs. AD, and #: $P<0.05$, ##: $P<0.01$, ###: $P<0.001$ for the AD groups compared to AD+light.

Induction of AD caused a diminished channel gating and conductance in mitochondrial mitoBKCa channel, and 40 Hz light therapy reversed these defects

To explore if the biophysical properties of mitochondrial mitoBK$_{Ca}$ channels are affected by STZ injection and flickering light, the mitochondrial inner membrane was extracted as vesicles, and channel activities were studied. Following the incorporation of vesicles extracted from the brain mitochondrial inner membrane, the success rate of the mitoBK$_{Ca}$ channel was ~45%, 36%, and 40% of recordings for sham, STZ-induced AD, and STZ-induced AD+light rats, respectively (data not shown). Figure 5A shows examples of single-channel activities prepared from the brain mitochondrial inner membrane vesicles in 200 mM KCl cis/50 mM KCl trans condition in the sham, STZ-induced AD, and STZ-induced AD+light animal groups, respectively (Figure 5A). The channel conductance analysis showed a ~56% reduction (124± 7.2) in the mitochondrial inner membrane vesicles in STZ-induced AD rats compared to sham rats (channel conductance of 211) (Figure 5A-5C). As shown in Figure 5B-5C, we observed close to a 1.5-fold increase in unitary current amplitude in light-treated AD rats relative to the non-treated AD rats. Data have been summarized in Figure 5B-5C, where the slope of the I-V relationship estimates a channel conductance of 194± 11.5 pS in the light-treated AD group in contrast to 124 ±7.2 pS in the non-treated AD rats (Figure 5A-5C). Channel gating behavior indicated a voltage-dependent property, with increased longer silent periods at potentials lower than −40 mV. Figure 5A-5B indicates an outward current at potentials above −10 mV and a zero current potential value close

to − 30 mV; the reverse potential is expected for potassium ions. This result confirmed the cationic nature of the channel.

Channel open probability (Po) values were close to 0.9 ± 0.05 at + 40 mV in sham rats. In contrast, channel Po in STZ-induced AD rats exhibited a decrease of 0.29 ± 0.02 at − 40 mV and 0.52 ± 0.04 at + 40 mV (Figure 5D-5E). Curve fitting the observed Po voltage dependence to the Boltzmann distribution indicated a voltage for half-maximal activation (V1/2) of $− 67 \pm 1.14$ mV in the sham rats compared to 40.5 ± 4.2 mV in the STZ-induced AD rats, with an approximately equivalent gating charge zd of $− 2.74 \pm 0.42$ and $− 2.34 \pm 0.43$, respectively. Interestingly, flickering 40 Hz white light therapy increased the channel Po in STZ-induced AD rats from 0.16 ± 0.029 to 0.24 ± 0.05 at − 40 mV and from 0.52 ± 0.03 to 0.67 ± 0.04 at + 40 mV, respectively (Figure 5D-5E). Curve fitting the observed Po voltage dependence to the Boltzmann distribution demonstrates a $V_{1/2}$ of $− 45.25 \pm 4.1$ mV in the STZ-induced AD+light groups, with an equivalent gating charge zd of $− 2.74 \pm 0.86$. These results confirm that flickering 40 Hz white light therapy improves channel activities in the STZ-induced AD rats (Figure 5D-5E).

The effects of IbTx, ChTx, and ATP were examined to verify the type of the mitoBK$_{Ca}$ channel extracted from the rat brains of both STZ-induced AD and STZ-induced AD+light rats. Further experiments were conducted to distinguish between two different types of mitoBK$_{Ca}$ channels including ATP-sensitive mitoBK$_{Ca}$ channel (conductance of 565 ps and inhibited by IbTx but not ATP and ChTx) [55], and mitoBK$_{Ca}$ channel (conductance of 211 ps and inhibited by IbTx but not ATP and ChTx [55]. A single-channel behavior was considered before and after adding each drug to the same planar lipid bilayer.

As shown in Figures 5F and 5G, channel activity was inhibited entirely after adding 100 nM IbTx at negative and positive potentials in STZ-induced AD and STZ-induced AD+light rats (n = 4 in each group). Also, no inhibition of channel activity was observed following the addition of 2.5 mM ATP (at + 40 mV and − 40 mV for STZ-induced AD, and +20 mV and -40 mV for STZ-induced AD+light. Additionally, 500 nM ChTx (at + 50 mV and − 50 mV in STZ-induced AD and + 30 mV and − 50 mV in STZ-induced AD+light rats (n = 4) did not inhibit the channel activity. These results verify that the channels obtained from rat brain preparations of STZ-induced AD and STZ-induced AD+ligh rats were the mitoBK$_{Ca}$ channel (conductance of 211 ps and only inhibited by IbTx) (Figure 5F-5G).

Figure 5. Induction of AD caused diminished channel gating and conductance in mitochondrial mitoBKCa channel, and 40 Hz light therapy reversed these defects. Single channel recording in 200/50 mM (cis/trans) KCl solution was performed using the bilayer lipid membrane. Single channel current-voltage relationship for the mitoBK$_{Ca}$ channel and percent of changes in the channel's conductance and open probability (Po) as a function of voltage for mitoBK$_{Ca}$ channels was performed in animal groups (A-E). The closed state is marked by the black arrow. Each point represents the average open probability as a function of voltages from five different experiments. The effect of IbTx, ChTx, and ATP on the mitoBK$_{Ca}$ channel activity in the STZ-induced AD (F) and STZ-induced AD+light rats (G). One-way ANOVA analyses followed by the Bonferroni post hoc test were performed to compare the mean between groups. Data are expressed as mean ± SEM (n = 5 rat/group). P values are as follows: *: P<0.0.5, **: P<0.01, ***: P<0.001, ****: P<0.0001 for the sham groups vs. AD, and #: P<0.05, ##: P<0.01, ####: P<0.0001 for the AD groups compared to AD+light.

Flickering 40 Hz white light reversed the disruption in the mitochondrial metabolites quantities in STZ-induced AD rat brains.

Amino acids in mitochondria, as mitochondrial metabolites, were measured using MS-MS to inspect any changes in these metabolites as a result of the modified function of mitoBK$_{Ca}$ and mitochondrial function. There were ten amino acids with significant reduction in the STZ-induced AD rat brains compared to the sham rat brains [Tyrosine (P=0.0006), Tryptophan (P=0.0346), Alanine (P=0.0338), Leucine (P=0.0001), Methionine (P=0.0023), Proline (P=0.0172), Lysine (P=0.0076), Serine (P=0.0237), Aspartic acid (P=0.0499) and Glutamic acid (P=0.0001)]. Interestingly, flickering 40 Hz white light therapy restored the amounts of these amino acids back to normal amounts in sham rat brains (Figure 6A-6C).

Metabolites dysregulated in STZ-induced AD rats were mostly enriched in pathways regulating the Krebs cycle (citrate cycle/TCA), carbohydrate metabolism, and amino acid metabolism in mitochondria

The integration of the results obtained from KEGG and MetaCyc, as discussed in the methods section, finally revealed a final list consisting of 154 proteins (Supplementary Table 1). By considering a p-value < 0.05, 10 specific pathways were identified after enrichment analysis (Supplementary Table 2), and 8 distinct pathways were identified after pathway analysis (Supplementary Table 3). Moreover, metabolite-protein joint pathway analysis was performed in two contexts: i. metabolic pathways (integrated) and ii. all pathways (integrated). Metabolic pathways (integrated) approaches revealed 19 distinct signaling pathways (Supplementary Table 4), whereas all pathways (integrated) determined 39 key pathways (Supplementary Table 5) (Figure 6D).

In the next step, the seven common key pathways were identified by integrating four lists. These seven pathways included Alanine, aspartate and glutamate metabolism (rno00250), Arginine biosynthesis (rno00220), Histidine metabolism (rno00340), Cysteine and methionine metabolism (rno00270), Arginine and proline metabolism (rno00330), Phenylalanine, tyrosine and tryptophan biosynthesis (rno00400), and Nitrogen metabolism (rno00910) (Figure 6E).

The most significant signaling pathway (based on FDR < 0.05) was Alanine, aspartate, and glutamate metabolism (rno00250) which involved in 10 key pathways (Figure 6F). Alanine, aspartate, and glutamate metabolism and 10 associated pathways were tightly linked to STZ-induction of AD and recovery by the flickering 40 Hz white light treatment in rats.

Figure 6. Flickering 40 Hz white light reversed the disruption in the mitochondrial amino acid quantities in STZ-induced AD rat brains. Differential levels of mitochondrial amino acids measured using MS-MS were compared in sham, sham+light, STZ-induced AD, and STZ-induced AD+light rat groups (A-B). Ten significant metabolites were downregulated in STZ-induced AD rats vs sham groups (C). Data are expressed as mean ± SEM (n =7±1).

Discussion

We demonstrated in the present study that flickering 40 Hz white light has beneficial effects on the brain of STZ-induced AD rats and has the potential for treating Alzheimer's disease. We first showed that STZ induction of AD caused behavioral disorders, mitochondrial dysfunction (including its components and metabolites), plasticity impairment, neuronal death,

neurotransmitter changes, and beta-amyloid plaque accumulation in rats. When flickering 40 Hz white light was used as treatment, it improved cognition, dopamine and serotonin levels, and long-term and short-term memory in AD rats. Further, we showed for the first time that flickering 40 Hz white light optimized mitochondrial function, current changes, and the possibility of opening of mitoBK$_{Ca}$ in rat neurons.

As expected, we observed deficits, including cognitive memory deficits in the MWM, NOR, and PA tests, as previously reported in the rats subjected to ICV-STZ in AD research [56, 57]. After treatment with flickering 40 Hz white light, cognitive memory impairment induced by STZ was attenuated, indicated by appearing to decreased escape latency, increased time target and number of crosses in the prob test of MWM, increased RI in the NOR test, and increased step-through latency in passive avoidance test. Similarly, animal studies have suggested that photomodulation regulates cognitive memory [58, 59]; notably, it reduces cognitive impairments in AD rats [28, 60]. A recent study found that flickering 40 Hz white light ameliorated memory impairments in animal models of AD through inhibition of mitochondria dysfunction, stress oxidative, and suppression of apoptosis [29, 61]. These results support the idea that flickering 40 HZ white light has an anti-amnesic effect when used in an STZ-induced model of sporadic Alzheimer's disease.

Serotonin and dopamine are monoaminergic neurotransmitters in the brain which are downregulated in AD patients and animal models [62-64]. Serotonin is the earliest neurotransmitter downregulated in the brain of AD patients which regulates the release of other neurotransmitters including dopamine [65]. Light therapy has been shown to decrease serotonin transporter binding, improve serotonin levels, and increase dopamine in human and rat [66-68]. In line with our results, dopamine levels were elevated under 40 Hz light treatment. In the dark, levels of dopamine are reduced in our body and are elevated during our light cycle of the day, as opposed to melatonin levels [16, 69, 70]. The increase we observed in the levels of both neurotransmitters might be due to elevated energy supply for synaptic activities, increased intracellular calcium levels, and light-induced neuronal activity [71, 72].

Decreased neuronal plasticity is another hallmark of neurodegenerative diseases such as AD [73]. Neuronal plasticity is directly related to greater synaptic efficacy achieved through long-term potentiation (LTP). In animals, LTP is the long-term modification in synaptic strength induced by electrical stimulation which is used in AD research studies [48, 74]. To further investigate the long-term effects of flickering 40 Hz light and bilateral injection of STZ into the hippocampus on neuronal activity, we assessed basal synaptic transmission and plasticity in perforant hippocampi one month after injection. Our observation of reduced LTP and PPF in the hippocampus of STZ-induced AD rats can be due to compromised activity of NMDA receptor and constant increase in Ca^{2+} influx caused by STZ toxicity [75]. Similar studies have shown that short-term plasticity is dependent on residual Ca^{+2} in pre-synaptic terminals, and STZ causes calcium imbalance in pre- and post-synaptic regions [76]. Flickering 40 Hz light might counteract the action of STZ on NMDA receptors and modulate Ca^{2+} levels in the cells thus preventing suppression of LTP and synaptic plasticity [77].

Our histological results indicate overproduction and formation of Aβ plaques in the hippocampus of STZ-induced AD rats. Accumulating evidence shows that Aβ is physically localized in the mitochondria and interacts with mitochondrial proteins which might explain its dysfunction [78]. Few studies have shown that Aβ in the form of oligomers can directly lead to the inhibition of the mitoBK$_{Ca}$ channel activity which might cause mitochondrial dysfunction [21, 79]. These alterations were reported in the STZ-induced diabetic animal models [80]. In type 2 diabetic mice, insulin resistance in the periphery and the brain was associated with energy impairment [81-83]. O'Malley et al. have shown that insulin activates mitoBK$_{Ca}$ channels in the hippocampal cultured cells and modulates spontaneous $[Ca^{2+}]$ oscillations [84]. It's possible that insulin resistance in the brain of our STZ-induced AD rats in cooperation with Aβ plaques leads to decreased mitoBK$_{Ca}$ channel activity, mitochondrial membrane potential, and mitochondrial dysfunction [80]. Mitochondrial BKCa channel preserves mitochondrial function and plays a critical role in neuroprotection through inhibition of mito $[Ca^{2+}]$ overload and reduction of total ROS production [35, 85]. Our finding that intact animal IbTx, but not ATP and ChTx, inhibited the channel gating behavior confirms that the AD channel corresponds to the mitoBK$_{Ca}$ (ATP-insensitive mitoBK$_{Ca}$ channel) according to the previous reports [36, 55].

Elevation of cytoplasmic calcium can be explained by light-induced opening of calcium ion channels, such as members of the transient receptor potential (TRP) superfamily [86]. Since nanostructured water exists in all ion channels and is sensitive to heat and light, it's feasible that the mitoBK$_{Ca}$ channel phenotype is also changed under light treatment. Complex IV in ETC is no exception as an ion channel and might be affected by light treatment in a similar manner [87, 88]. From a mechanistic point of view, the emitted photons in the photobiomodulation are absorbed by complex IV to facilitate the availability of electrons for the reduction of oxygen, which increases mitochondrial membrane potential, ATP levels, and ETC activity [89, 90]. Studies also have suggested a direct structural-functional relationship between the ETC and the mitoBK$_{Ca}$ channel. It is proposed that a redox signal from the respiratory chain is transmitted to the mitoBK$_{Ca}$ channel through cytochrome c oxidase (complex IV) [91].

Studies on mice showed that the 590nm LED light significantly increased NO synthesis in the brain through stimulation of complex IV activity in mitochondria in hypoxic conditions, and through a feedback mechanism complex IV enzyme activity was inhibited by NO [92]. Photons of 40 Hz light absorbed by complex IV can dissociate this inhibitory NO in the presence of sufficient oxygen [9]. Dissolution of NO produced results in increased MMP, higher consumption of oxygen and metabolism of glucose, and generation of more ATP. This, in turn, triggers minimal quantities of ROS followed by activation of ROS-induced signaling pathways which have cytoprotective effects in the cells [93]. On the other hand, flickering 40 Hz white light might prevent mitochondrial [Ca^{2+}] overload by enhancing ETC and mitoBK$_{Ca}$ channel activities [85]. Optimal levels of mitochondrial [Ca^{2+}] prevent the overproduction of ROS, abnormally high MMP and mitochondria dysfunction [94]. This eventually promotes the viability of cells in the hippocampus and cortex, and improves cognition [26, 95]. Mitochondrial BK$_{Ca}$ channel opening under light treatment which keeps the calcium ions in the cytoplasm, might trigger the release of the neurotransmitter glutamate from the presynaptic neuron and improve the LTP in light-receiving animals [96, 97].

In our findings regarding metabolomics analysis, ten mitochondrial amino acids were significantly decreased in STZ-induced AD rats which are classified into three categories: 1) Aromatic (Tyrosine, Tryptophan), 2) Aliphatic (Alanine, Leucine, Methionine, Proline), and 3)

others (Lysine, Serine, Aspartic acid, Glutamic acid). Through different bioinformatics analyses explained in the results and methods sections, seven common pathways which had more enzymes/proteins affected by these ten amino acids were characterized. Among these, alanine, aspartate, and glutamate metabolism was the top hit with the lowest FDR and P values. In line with our findings, in a proteomic-metabolomic study of high-sugar-fat diet Wistar rats (an animal model of metabolic syndrome), 16 pathways were enriched. Three pathways were shared by metabolomics studies of serum samples from diabetic patients: 1) alanine, aspartate, and glutamate metabolism, 2) glycine, serine, and threonine metabolism, and 3) valine, leucine, and isoleucine biosynthesis [98]. Transcriptomic and metabolomic joint analysis after an immune challenge with LPS in Zebra fish, revealed enrichment of alanine, aspartate, and glutamate metabolism and aminoacyl-tRNA biosynthesis [99]. They reported Krebs cycle was one of the most affected cycles in the mitochondria and highlighted in both studies when analysis was performed by the KEGG pathway [98, 99].

Interestingly, the Krebs cycle was the most affected in all pathways enriched in our metabolomic and bioinformatic analyses. Krebs cycle is the vital component in the mitochondria for energy production in the form of ATP [100, 101]. The Krebs cycle is the last metabolizing hub for the metabolism of lipids, carbohydrates, and amino acids and is associated with age-related and metabolic diseases [98, 101, 102]. For example, in the process of aspartate conversion to asparagine, ammonia is transferred from glutamine to asparagine which converts it to glutamate. In the Krebs cycle, glutamate is used as a substrate to produce α-ketoglutaraldehyde and subsequently succinate, critical intermediates of the Krebs cycle [103-105]. Glutamate production and consumption reaches its highest level during an immune response in mammals [103-105]. It was found in a study that noninvasive 40 Hz flickering white light reduced Aβ load by recruiting microglia, immune cells in the brain, in AD mouse models [106]. Based on our observation, the flickering light might reduce Aβ plaque formation by triggering the immune response through activation of microglia in the brain of STZ-induced AD rats. Additionally, the 40 Hz light might induce glutamate metabolism and the Krebs cycle to improve energy production and normalize mitochondrial function [103-106].

The 40 Hz flickering white light has great therapeutic potential for treating neurodegenerative disorders since it has shown promising improvement in the pathophysiology of AD disease in animal models. Translational studies are needed to reproduce the outcome from

animal models in humans. In addition, more animal studies are required to examine the duration of light therapy and changes in the plasma membrane BK_{Ca} channels in parallel with $mitoBK_{Ca}$ channels to dissect the direct effect of light on each of these critical channels independently.
