Abstract

The intrinsic cardiac nervous system is a complex system that plays a critical role in the regulation of cardiac physiological parameters and has been shown to contribute to cardiac arrhythmias. To date, several types of neurons with distinct neurochemical and electrophysiological phenotypes have been identified. However, no study has correlated the neurochemical phenotype to a specific electrophysiological behavior. Calbindin-D28k, a calcium binding protein, is expressed in numerous cardiac neurons. Given that changes in neuronal excitability have been associated with arrhythmia susceptibility and that calbindin expression has been associated with modulations of neuronal excitability, our objective is to assess whether the cardiac calbindin neuronal population has specific properties that could be involved in cardiac modulation and arrhythmias. By using a Cre-Lox mouse model to specifically target calbindin neurons with a fluorescent reporter, we characterized the neurochemical and the electrophysiological phenotype of this cardiac neuronal population. Calbindin neurons exhibit a specific neurochemical profile and a larger soma with shorter neurite length compared to other neurons. This was combined with a distinct electrophysiological signature characterized by a lower excitability with a predominantly phasic profile associated to a lower N-type calcium current density. These properties resemble to the cardiac neuronal remodeling observed in pathologies such as type II diabetes and heart failure. Therefore, we believe that this specific neuronal population deserves investigations in the context of these pathologies.

Keywords: intrinsic cardiac neurons, calcium current, Calbindin, N-type calcium channel, autonomic nervous system

Introduction

The nervous control of cardiac functions involves the coordinated action of central and peripheral nervous structures. This coordination results in the modulation of various cardiac parameters including heart rate, contractile force, and electrical conduction velocity. Specifically, these regulatory mechanisms involve a cluster of neurons located within the cardiac tissue forming the intrinsic cardiac nervous system (ICNS). Initially perceived as simple parasympathetic relays, recent studies spanning three decades suggest a more intricate organization of this system. These studies propose that the ICNS is engaged in establishing local and autonomous regulatory loops facilitated by the presence of sensory neurons, interneurons and autonomous neurons [3].

Thus, the ICNS emerges as a sophisticated system pivotal in regulating cardiac physiological parameters and has been shown to contribute to cardiac diseases, particularly cardiac arrhythmias. Notably, excessive ICNS activity has been correlated with atrial fibrillation [4, 8]. Ablation of the ganglionated plexus stands out as one therapeutic strategy effectively reducing atrial fibrillation incidence [5, 19]. In addition to atrial electrical disorders, this system has also been implicated in ventricular arrhythmia susceptibility by modulating ventricular refractory periods [16]. In heart failure, both structural remodeling of the ICNS and electrophysiological alterations of this system driven by changes in ion channel expression levels also increase susceptibility to ventricular arrhythmias [27, 36]. Consequently, the ICNS represents a crucial yet understudied cardiac cell type that intricately regulates both cardiac physiology and physiopathology. To date, various types of neurons exhibiting distinct neurochemical and electrophysiological phenotypes have been recognized. Although most cardiac neurons exhibit a cholinergic phenotype, they can also express markers such as catecholaminergic, nitrergic as well as additional ones like the calcium-binding protein calbindin-D28K, neuropeptide Y (NPY) or the cocaine and amphetamine regulated transcript peptide (CART) [14, 21, 25, 26].

From an electrophysiological perspective, cardiac neurons can exhibit diverse excitability properties. For example, most cardiac neurons demonstrate a phasic discharge profile, while others are categorized as either accommodating or tonic neurons [13, 21, 31, 32]. The rheobase and afterhyperpolarization properties of cardiac neurons are also parameters of discrimination within the cardiac neuron populations [21]. However, to our knowledge, no study has correlated the neurochemical phenotype with specific electrophysiological properties. Such investigations would elucidate the impact of cardiac neurons on the physiological and pathophysiological functions of the heart. This become increasingly pertinent given that these neurons have been associated in the initiation and perpetuation of cardiac arrhythmias [5, 8, 12].

In a previous study on the mouse heart, we discovered that approximately 46% of cardiac neurons express calbindin-D28k protein [21]. This neuronal population has also been observed in the rat heart [25]. Yet, there is currently no information available regarding the specific neurochemical and excitability properties of these neurons. Calbindin-D28K belongs to the family of calcium-binding proteins expressed in various classes of neurons and whose expression serves as a discriminative marker of neuronal populations in both the central and peripheral nervous system [10, 11, 15, 28]. Interestingly, calbindin-D28K protein expression has been correlated with distinct neuronal excitability properties. For instance, calbindin-D28K expression has been linked to alterations in neuronal action potential frequency [15, 17]. Additionally, Calbindin-D28K expression has also been associated with changes in the activity of ionic channels, such as voltage-gated calcium or potassium channels [17, 18].

Considering the correlation between changes in neuronal excitability and susceptibility to arrhythmias in cardiac pathology [27, 36] and the association of calbindin expression with modulation of neuronal excitability and ion channels [15, 17, 18], it becomes crucial to investigate whether the cardiac calbindin neuronal population possesses specific properties potentially involved in cardiac modulation. Therefore, employing a Cre-Lox mouse model that enabled precise targeting of calbindin D-28K expressing neurons, our aim is to characterize the neurochemical and electrophysiological properties of this particular cardiac neuronal population.

Methods

Animals and viral transduction

Experimental procedures were conducted using adult (8-20 weeks) Calb1-IRES2-Cre-D mice (JAX stock #028532) in accordance with the guidelines outlined in European Union Directive (2010/63/EU) concerning the protection of animals used for scientific purposes. The investigation of calbindin-D28K-expressing cardiac neurons employed a viral transduction strategy utilizing Calb1-IRES2-Cre-D heterozygous mice. Viral transduction was carried out in mice aged between 4 to 6 days. The mice were anesthetized by hypothermia on ice ensuring the mice were adequately sedated. Subsequently, intraperitoneal injection of AAV1 pAAV-FLEX-tdTomato (#28306, Addgene) diluted in 40 µL PBS ($6.25.10^{12}$ VG/mL) was administrated using a 30G needle (Terumo, VWR). The protocol was ethically approved by the local ethics committee "COMETHEA". The animals were then bred and subsequently used for experimental purposes.

Immunohistochemistry

Immunohistochemistry experiments were conducted following previously established protocols [21]. Following heparin injection, mice were euthanized via intraperitoneal injection of pentobarbital sodium (100 mg/kg). Hearts were promptly excised, rinsed in cold Tyrode solution and fixed in 4% paraformaldehyde for 24h at 4°C. Subsequently, hearts underwent three 3 washes in Phosphate-Buffered Saline (PBS, Corning), followed by cryoprotection in 30% sucrose overnight at 4°C. Prior to sectioning, samples were embedded in OCT tissue compound (Tissue Tek, Sakura Finetek, VWR) and frozen in cold ethanol. Sections 50 µm thick were obtained using a cryostat and mounted onto microscope slides (Adhesion slides, Menzel Gläser, SuperFrost® Plus, Thermo scientific). Sections were washed three times with PBS and permeabilized with 0.5% TritonX-100/1% Bovine Serum Albumin (BSA) in PBS for 2 hours at room temperature. Incubation with primary antibodies (see table 1) was carried out overnight at 4°C. Following three washes with PBS, sections were incubated with secondary antibodies for 3 hours in the dark at room temperature. Nuclei were stained with DAPI (4′,6-diamidino-2-phenylindole, 1:200) and sections were mounted in Mowiol mounting medium. Images were acquired using a confocal laser scanning microscope (FV3000 Olympus, Tokyo, Japan). As a control, images obtained after incubation with the secondary antibodies in the absence of primary antibodies did not elicit any labelling. Quantification was performed by manual cell counting using NIH ImageJ (Bethesda, Maryland, USA). For each marker, quantification was conducted with sections obtained from at least two distinct animals. All micrographs are a projected confocal Z-series from sectioned material.

iDISCO

Mouse hearts were stained and cleared using a modified iDISCO+ protocol [6, 23] as previously described [21]. Fixed hearts were dehydrated with a graded methanol series (50%, 80% and 100% methanol in PBS, each for 1.5 h at room temperature and bleached overnight with 6% H202 in methanol at 4 °C. Following two washes in 100% methanol, hearts were gradually rehydrated (80%, 50% methanol and PBS, 1 hour and 30 minutes each). Samples were blocked and permeabilized with PBS containing 0.2% gelatin 0.5% triton X-100 and 50mM sodium azide (PBSGT) for 4 days at room temperature. The primary tdTomato antibody (see table 1) was then incubated during two weeks in PBSGT supplemented with 0.1% saponin at 37°C. Subsequently, samples were washed in PBSGT for 1 day followed by a 48 hours incubation with secondary antibodies. After another day of washing, samples were again dehydrated in methanol (20%, 40%, 60, 100% and 100% methanol, 1 hour each) and incubated overnight in a mixture of dichloromethane (DCM) – methanol (2:1) at RT. Samples were incubated in 100% DCM for 30 minutes and finally incubated and stored in DiBenzyl Ether. Imaging was performed by light-sheet microscopy using a UltraMicroscope II (LaVision BioTec, Bielefeld, Germany). Image processing was carried out using Bitplane Imaris 9 software (Oxford instruments company, Abingdon, UK).

Neuronal dissociation

Neuronal dissociation was conducted following the procedure outlined in our prior research [21]. Mice were injected with heparin and euthanized with pentobarbital sodium (100 mg/kg). Hearts were swiftly excised and rinsed in cold HBSS solution. The fat pads located between both atria were dissected, cut into small fragments and dissociated in 2 mL HBSS containing 3 mg/mL collagenase type II (Worthington), 7.5mg/mL dispase II and 0.25 mg/mL DNase I for 30 minutes at 37°C. This was followed by an additional incubation in 2 mL trypsin-EDTA 0.25% supplemented with 0.25 mg/mL DNase I for 35 minutes at 37°C. After two washes in culture media, cells were gently triturated with fire-polished Pasteur pipettes coated with SVF and plated onto laminin-coated 35 mm glass bottom Petri dishes. The cells were maintained in Neurobasal-A medium (ThermoFisher Scientific, Villebon sur Yvette, France) supplemented with 2mM L-glutamine, B27 supplement (ThermoFisher Scientific, Villebon sur Yvette, France), 5% horse serum and 1% penicillin/streptomycin in a humidified chamber at 37°C with 5% CO_2.

Morphological analysis

The neuronal size was assessed by measuring the soma perimeter and area of both tdTomato positive and negative neurons. These measurements were obtained using NIH ImageJ software on images of neurons utilized in patch-clamp experiments. In the same neurons, the membrane capacitance recorded during patch clamp experiments was used as an indicator of neuronal size. For axonal length measurement, neurons were maintained in the culture medium for 24h to allow axonal growth. Neurons were then fixed with 4% paraformaldehyde in PBS for 10 min, washed (PBS) and permeabilized with 0.1 % TritonX-100 in PBS for 10 min at RT. After washing with PBS, unspecific sites were saturated using PBS containing 1% of BSA and 0.1 % Tween 20 for 30 min and incubated with primary antibody directed against β3-tubulin (Tuj1, see Table 1) diluted in the saturation solution overnight at 4°C. Cells were then washed with PBS and incubated with secondary antibody (see Table 1) for 2 hours in the dark at room temperature. After another PBS wash, cells were mounted in Mowiol mounting medium. Images

were captured using a confocal laser scanning microscope (FV3000 Olympus). Neurite length was determined by Tuj1 immunolabelling and quantified using the filament tracer module of Bitplane Imaris 9 software.

Electrophysiology

Electrophysiological properties of isolated cardiac neurons were determined using the whole-cell configuration of the patch clamp technique. Recordings were carried out at room temperature within 24 hours following neurons isolation with Patch electrodes pulled from glass capillaries (PG150T-7.5, Harvard Apparatus, Les Ulis, France) using a vertical micropipette puller (Narishige, Tokyo, Japan). Recordings were made with an Axopatch 200B amplifier (Molecular devices, San Jose, California, USA) with a 5-kHz low-pass filter. Data were sampled at 20 kHz and digitized by a Digidata 1550 B (Molecular devices, San Jose, California, USA). Data acquisition and analysis were performed using pClamp software (v11, Molecular devices, San Jose, California, USA).

For action potential (AP) recordings in current clamp mode, the patch pipettes ($\approx$4 MΩ) were filled with (mM): 130 K-gluconate, 10 KCl, 1 MgCl$_2$, 10 HEPES, 1 CaCl$_2$, 5 EGTA, 2 Mg-ATP, 10 Na$_2$-phosphocreatine and 0.3 Na-GTP, (pH adjusted to 7.2 using KOH). The bath solution contained (mM): 150 NaCl, 5 KCl, 1 MgCl$_2$, 1.5 CaCl$_2$, 10 glucose, and 10 HEPES, (pH adjusted to 7.4 using NaOH). Liquid junction potential was +16 mV and was not corrected. Input resistance was determined by measuring voltage changes evoked by injection of hyperpolarizing current (from -10 pA to -40 pA; in 10 pA increments). Discharge characteristics were determined by injecting depolarizing current of increasing amplitude (from 20 to 400 pA ; 20 pA increment) during 500 ms. AP properties were determined upon brief injection (2 ms) of suprathreshold current. AP amplitude was measured as the difference between the AP peak amplitude and the resting membrane potential. Spike half-width was calculated as the AP duration measured at 50% of its amplitude.

Voltage clamp experiments were carried out in order to record voltage-gated calcium channel currents. for this purpose the patch pipettes (3-4 MΩ) were filled with (in mM) 120 CsCl, 10 KCl, 1 MgCl$_2$, 40 HEPES, 1 CaCl$_2$, 5 BAPTA, 4 Mg-ATP, 0.1 leupeptin, 10 Na$_2$-phosphocreatine and 0.3 Tris-GTP, (pH adjusted to 7.3 with CsOH). The bath solution contained (in mM) 140 TEA-Cl, 5 BaCl$_2$, 1 MgCl$_2$, 2 4-aminopyridine, 10 glucose et 10 HEPES (pH adjusted to 7.4 with TEA-OH). The calculated junction potential of +10,4 mV was corrected before recordings. For Current-voltage relationships, cells were held at -80 mV and a ramp depolarizing protocol was applied from -80 mV to +40 mV during 300 ms. The current voltage relationships were then constructed by reporting the amplitude of the current recorded every 5 mV divided by the cell membrane capacitance measured by the Clampex module of pClamp software. Currents were recorded in the same cell under the perfusion of the bath solution (Control) and with the bath solution containing 1 µM of Omega-conotoxin GVIA (Smartox biotechnology, Saint Egrève, France).

Chemicals

Unless stated, all chemicals were obtained from Sigma-Aldrich (Lyon, France).

Statistical analysis

Statistical analysis was performed using GraphPad Prism (San Diego, California, USA). Data are presented as mean ± SEM. Depending on the data, statistical analysis were performed using either Mann-Whitney, t-test, Fisher exact test or Chi-square tests.

Table 1: Primary and secondary antisera used within this study.

Primary Antibody	Host Species	Dilution	Catalogue Number	Supplier
Calbindin D28k	Rabbit	1:1200	CB38	Swant
CART (55-102)	Rabbit	1 :1000	H-003-62	Phoenix Pharmaceuticals
ChAT	Goat	1:150	AB144P	Merck Millipore
NPY	Rabbit	1:500	Ab10980	Abcam
TH	Chicken	1:500	Ab76442	Abcam
tdTomato	Rabbit	1 :300	600-401-379	Rockland
Tuj1	Rabbit	1 :200	Ab52623	Abcam

Secondary Antibody				
Anti-chicken (FluoProbe594)	Donkey	1:300	FP-SD1110	Interchim
Anti-goat (AF488)	Donkey	1:300	A-11055	ThermoFisher Scientific
Anti-rabbit (AF647)	Donkey	1:300	A-31573	ThermoFisher Scientific

Results

Neurochemical properties of calbindin neurons.

Within the neurochemical diversity of mouse cardiac neurons, our group previously discovered that neurons expressing the calbindin-D28K protein constitute 46% of the total population [21]. However, until now there has been no information available regarding the neurochemical and electrophysiological properties of this neuronal subpopulation. In order to further advance the investigation of this neuronal population, we opted to employ a Cre-Lox strategy to selectively label these neurons with the tdTomato fluorescent protein. Initially, we confirmed the presence of these neurons in the Calb1-IRES2-Cre-D mice model.

Immunolabelling of both cholinergic and calbindin neurons within cardiac ganglia (Figure 1A) reveals that calbindin neurons constitute a significant portion of ganglionic neurons. Interestingly, calbindin positive projections can form multiple pericellular baskets surrounding neuronal somata (Figure 1A, arrows). These findings align with our previous observations [21].

Therefore, we utilized this mice model to specifically label calbindin neurons, facilitating further investigation into their neurochemical and electrophysiological properties. Through AAV1-Flex-tdTomato viral transduction of Calb1-IRES2-Cre-D mice, we achieved specific expression of tdTomato in calbindin neurons (Figure 1B). This approach resulted in significant expression of the fluorescent reporter in 59 ± 8 % of calbindin-D28K positive neurons (n = 332), leveraging this expression to assess the overall distribution of calbindin neurons within all cardiac ganglia using the iDISCO protocol. Figure 1C shows no preferential localization of these neurons

within the cardiac ganglion plexus. Additionally, tdTomato expression is observed in fibers connecting different ganglia suggesting that calbindin neurons could participate in inter-ganglionic communication (Fig1C b,c).

To unravel the neurochemical profile of calbindin neurons, we conducted immunohistochemistry experiments onto tdTomato expressing hearts. This enabled the identification of calbindin neurons by fluorescence, thereby avoiding crossreaction between antibodies. Immunodetection of the cholinergic marker ChAT confirmed that almost all the calbindin neurons are cholinergic (>99%), consistent with previous findings [21]. Among the phenotypic diversity previously identified in cardiac neurons expressing Tyrosine Hydroxylase (TH), Cocain and Amphetamin Related Transcript peptide (CART) and Neuropeptide Y (NPY) represent significant neuronal populations in mice [21]. We therefore aimed at evaluating the proportion of expression of these markers within the calbindin neuronal population. 36.5 % of calbindin neurons co-express TH (Figure 2 A. a-c and B.). This proportion is significantly lower (25.9%, p<0.01) in neurons without tdTomato expression referred as "non calbindin neurons" in this study. CART peptide, a neuronal marker expressed in 60% of cardiac neurons [21] is expressed in a similar proportion in calbindin neurons (56.9 %) which is comparable to that observed in "non calbindin neurons" (62.4%, p>0.05). However, while the majority of "non calbindin neurons" also express the NPY (70.7%), this proportion was significantly lower (30%, p<0.0001) in calbindin neurons.

Immunofluorescence experiments reveal that calbindin neurons form a relatively dense network of projections innervating the atrial stage, without being associated with any particular ganglionic zone. This neuronal population exhibits heterogeneity in their neurochemical phenotype, with the co-expression of several markers. However, it is characterized by a slightly higher proportion of TH and a much smaller proportion of NPY expressing neurons.

Morphological properties of calbindin neurons.

The morphological characteristics of calbindin neurons were investigated by examining isolated cells following neuronal dissociation.

Regarding the size of these neurons, calbindin neurons exhibit a larger soma compared to non calbindin neurons (Figure 3, Table 2). This quantification was conducted by measuring the perimeter and area of the soma of isolated neurons (Figure 1A, B). Both parameters are significantly larger in calbindin neurons compared to non calbindin neurons (p<0.01 and p<0.05 respectively for area and perimeter). Hence, calbindin neurons display a soma area (1305.2 ± 120 µm², n=27) that is 53% higher than non calbindin neurons (845.1 ± 76.7 µm², n=24). This distinction is further confirmed when comparing the membrane capacitance measured during the whole-cell patch-clamp experiments on these cells. Indeed, cell membrane capacitance is an electrical parameter dependent on the total membrane surface of the cell, thus, reflecting cell volume and size. We observed that calbindin neurons exhibit a significantly higher membrane capacitance (42.3 ± 2.7 pF, p<0.01) increased by 31% compared to non calbindin neurons (32.3 ± 2.3 pF, Figure 3C, Table 2).

We also examined the neurite length of calbindin neurons compared to other neurons. Since most of neurons lose their neurite during cellular dissociation, this parameter was assessed in isolated neurons maintained in culture for 24 hours before fixation and immunolabelling by using β-tubulin III (Figure 3D). These experiments indicate that calbindin neurons exhibit a significantly shorter neurite length (1261 ± 120 µm, n=23, p<0.001) compared to other neurons (2175 ± 262 µm, n=31).

From a morphological perspective our results suggest that calbindin neurons exhibit a larger soma and a shorter neurite length compared to other neurons.

Table 2 Morphological and electrophysiological properties of non calbindin and calbindin neurons.

	Non calbindin (n=24)	Calbindin (n=27)	Statistical comparison
Cell surface area (μm^2)	**845.1 ± 76.7**	**1305.2 ± 120.0****	**P<0.01 (Mann-Whitney test)**
Perimeter (μm)	**66.3 ± 4.6**	**83.7 ± 3.4****	**P<0.01(Mann-Whitney test)**
Membrane capacity (pF)	**32.3 ± 2.3**	**42.3 ± 2.7****	**P<0.01(t test)**
Input resistance (MΩ)	1520.2 ± 144.0	1481.5 ± 126.1	n.s (t test)
RMP (mV)	-60.1 ± 1.3	-60.5 ± 0.9	n.s (t test)
Rheobase (pA)	**56.3 ± 9.5**	**86.7 ± 9.9*****	**P<0.001 (Mann-Whitney test)**

In bold: significantly different properties. AP: Action Potential, RMP: Resting Membrane Potential, AHP: Afterhyperpolarization, n.s: not significant, # only calculated for neurons displaying AHP.

Excitability and action potential properties of calbindin neurons.

The electrical membrane properties of isolated neurons were assessed using the current clamp mode of the patch clamp technique in whole cell configuration. Calbindin neurons were identified via tdTomato fluorescence and their electrophysiological properties are summarized in Table 2. Regarding passive membrane properties (Figure 4 B, C), the input resistance did not exhibit a significant difference between calbindin (1481 ± 126 MΩ, n=27) and non calbindin neurons (1520 ± 144 MΩ, n=24). Similarly, calbindin neuron displayed a resting membrane potential of -60.5 ± 0.9 mV (n=27), which did not significantly differ from the resting membrane potential of non calbindin neurons (-60.1 ± 1.3 mV, n=24).

Neuronal excitability (Figure 4 D, E) was evaluated through incremental depolarizing current injection of 500 ms duration. Our findins revealed that calbindin neurons exhibit a significantly higher rheobase (86.7± 9.9 pA, n = 27) compared to non calbindin neurons (56.3 ± 9.5 pA, n=24, p<0.0001). This lower excitability was associated with a reduced discharge capacity of calbindin neurons compared to other neurons. Specifically, regardless of the injected current, 48.15 % of calbindin neurons displayed phasic behaviour, discharging only 1 action potential, in contrast to other neurons where this proportion is significantly smaller (12.5%, p<0.001).

We then sought to determine whether calbindin neurons exhibit specific single AP properties. This was assessed by 2 ms suprathreshold current injections. Similar to the rheobase findings, APs of calbindin neurons are triggered by significantly higher current injection (1142 ± 82 pA, n=27) compared to other neurons (832 ± 74 pA, n=24, p<0.01 Mann-Whitney). Additionally, calbindin neurons are predominantly composed of APs without a hyperpolarization phase (neurons without AHP: 19/27 (calbindin) versus 10/24 (non-calbindin)) (figure 5 A, B,

p<0.05). For neurons exhibiting a hyperpolarization phase, the duration and amplitude of this phase were similar for both groups of neurons studied (Table 2). For other parameters of action potential, no significant difference is observed between calbindin and non calbindin neurons in terms of AP amplitude, duration, depolarization and repolarization kinetics (Figure 5 C-F).

In conclusion, these findings demonstrate that calbindin neurons exhibit a distinct electrophysiological profile marked by a lower excitability, a predominantly phasic firing patterns coupled with a decreased proportion of APs displaying a hyperpolarization phase.

Calcium current of calbindin neurons.

Voltage-gated calcium channels are key players in neuronal excitability [32, 34]. In the context cardiac physiology, inhibition of N-type calcium channels notably leads to an increase in rheobase coupled with a reduction in AP discharge capacity [20, 34]. Since calbindin neurons differ from other cardiac neurons in their low excitability and reduced discharge capacities, we aimed to investigate whether the voltage-dependent calcium currents differed in calbindin neurons. These currents were examined using voltage-clamp techniques with barium as charge carrier.

Under our experimental conditions, depolarization of cardiac neurons triggers an inward current starting at -35 mV and reaching a maximum amplitude around -20 mV in both neuronal populations (Figure 6A). However, the current density is significantly reduced in calbindin-D28K-expressing neurons for potentials between -30 mV and -20 mV (p<0.05). Therefore, we sought to investigate on the same cells the effect of ω-conotoxin, a specific blocker of N-type calcium channels. The perfusion of 1 µM ω-conotoxin results in a marked reduction of current amplitude indicating a significant presence of N-type calcium channels in cardiac neurons (Figure 6B). The ω-conotoxin resistant current of calbindin neurons appears smaller compared to other neurons although this difference was statistically significant only for -20 mV. Hence the ω-conotoxin sensitive current was estimated by the subtraction of the ω-conotoxin resistant current to the global calcium current recorded in the same cell (Figure 6C-D). The N-type current is significantly smaller in calbindin neurons compared to non calbindin neurons with respectively a current density measured at -25 mV of -12.6 ± 3 pA/pF (n=15) and -24.6 ± 3.9 pA/pF (n= 12, p<0.05).

Calbindin neurons exhibit a reduced voltage-dependent calcium current density, involving a lower N-type calcium current density. This diminution could account for the less excitable nature observed in these neurons.

Discussion

In this study, through the utilization of a Cre/loxP-dependent system for expressing specific fluorescent proteins, we present for the first time an elucidation of the relationship between the neurochemical phenotype, the morphological and electrophysiological properties of cardiac intrinsic neurons. Specifically, our investigation into calbindin-D28k expressing neurons unveils a novel association: That is a minority of these neurons express NPY, featuring enlarged soma with shorter neurite extension, correlated with decreased excitability and a reduced N-type calcium current density. Calbindin-D28K, a calcium-binding protein regulated by vitamin D [1, 2, 7], has

served as a marker to distinguish between neuronal subtypes within both the central and peripheral nervous system [10, 11, 15, 28]. However, the cardiac population of calbindin neurons has been relatively understudied, with only one investigation conducted in rats [25] and a prior examination from our team identifying this population in mice [21]. Our current findings align with those of Richardson *et al.* [25] indicating a lack of specific distribution patterns of calbindin neurons across different regions of the ganglionated plexus. Notably, calbindin neurons exhibit both intra- and interganglionic projections, demonstrating the capacity to form pericellular baskets around neuronal somata. These findings suggest that these neurons play a significant role in local circuits. In our investigation, we observed that approximately 70% of non calbindin neurons express the NPY, while this proportion decreased to 30 % within the calbindin population. Since the calbindin population constitutes 45% of the global population in the mouse [21], the proportion of neurons co-expressing NPY/calbindin in our study falls within a similar range as observed in rats [25]. However, in contrast to our results, nearly all neurons, including those within the calbindin population, expressed NPY in rats. This disparity may stem from species differences. In mice, this neuronal population exhibits heterogeneity as evidenced by the fact that the expression of TH, CART and NPY is not strictly confined to either calbindin or non calbindin neurons. Nevertheless, the proportion of TH and NPY is significantly dependent on the presence of calbindin in neurons, suggesting a distinct neurochemical profile for this population.

The morphological profile of calbindin neurons also exhibit notable distinctions compared to other neuronal subtypes. Specifically, they feature a larger soma, as quantified through direct measurements of both area and perimeter, as well as through assessment of membrane capacitance conducted during patch-clamp experiments on the same neurons.

Although this parameter has not been previously explored in calbindin neurons within the heart, a study conducted in the rat stellate ganglion noted larger somas in neurons co-expressing both calbindin-D28K and NPY [24]. Similarly, in the rat myenteric plexus, calbindin-positive neurons were found to have a larger soma area compared to neurons lacking calbindin-D28K immunoreactivity [22]. Our study corroborates these findings, demonstrating that the larger size of calbindin neurons is associated with a reduction in neurite length among cultured neurons. This result was derived from a 24 hours culture period subsequent to neuronal dissociation, a necessary step to facilitate neurite outgrowth, as the mechanical dissociation process typically disrupts most neuronal projections. Consequently, the assessment of neurite length under our experimental conditions indicates a reduced capacity for neurite outgrowth among calbindin neurons compared to non calbindin neurons. One plausible explanation is that calbindin-D28k, functioning as a calcium-binding protein, might influence calcium homeostasis, a crucial factor governing axonal growth. [29, 33].

In addition to their unique neurochemical and morphological characteristics, calbindin neurons, also demonstrate specific electrophysiological properties in our investigation. In a previous study, we delineated four distinct neuronal profiles in mice based on their AP properties [21]. These profiles included phasic neurons with a higher rheobase in comparison to adapting neurons as well as neurons with or without an AHP. In the present study, the majority of the calbindin neurons fall into the phasic profile, characterized by a single AP with a rheobase significantly higher than that of non calbindin neurons. This was also associated with the absence of AHP in the majority of calbindin neurons. This marks the first instance where the neurochemical profile of a cardiac neuronal population has been linked to its excitability properties. Despite calbindin neurons not constituting a homogenous

group, the expression of calbindin is evidently linked to reduced excitability. Additionally, the N-type calcium current density is also significantly lower in this population, potentially accounting for this distinction. Previous studies have associated N-type calcium current with the excitability of cardiac neurons, albeit without discerning between different populations [20, 34, 35].

Exploring the correlation between calbindin expression and neuronal excitability, as well as ion channel expression, has been a focus in various cellular models. For example, it has been shown that dentate granule cell excitability is increased in a calbindin-D28K knockout mouse model [17], an effect attributed to a reduction in voltage-gated potassium currents. Similarly, calbindin-D28K expression in a rat beta-cell line results in a reduction of voltage-gated calcium currents [18]. These findings are in alignment with our observations and suggests that the disparities observed in cardiac neurons may directly stem from the presence of calbindin-D28K protein. This underscores the potential role of calbindin in modulating ion channel activity and, consequently, neuronal excitability.

The findings regarding the properties of cardiac calbindin neurons uncovered in our study hold particular interest with respect to their potential involvement in cardiac physiopathology. Notably, these neurons exhibit an enlarged soma size coupled with a reduced excitability with a lower N-type calcium channel expression. Such characteristics bear resemblance to those observed in cardiac neuronal remodeling associated with conditions such as heart failure and type II diabetes. Indeed, previous studies have noted comparable features in cardiac neurons from patients with heart failure, wherein a hypertrophied cell body was observed in contrast to neurons from healthy hearts [27]. Corresponding observations have also been documented in this study in animal models of heart failure. Because of the expanded membrane surface area observed, Singh's group [27] suggested that this hypertrophy might contribute to a decrease in neuronal excitability and potentially elucidating the parasympathetic dysfunction linked with heart failure. Indeed, in a rat model of chronic heart failure, cardiac neurons displayed reduced excitability, attributed to a decrease in the N-type calcium channel expression [30]. This electrical remodeling of intracardiac neurons has been linked to increased susceptibility to ventricular arrhythmias [34, 36]. Such insights underscore the intricate interplay between neuronal remodeling and cardiac dysfunction in pathological conditions like heart failure.

Similarly, in a rat model of type II diabetes, arrhythmia susceptibility was correlated with reduced N-type calcium currents, resulting in decreased neuronal excitability [20, 35]. This remodeling mirrors the characteristics observed in cardiac calbindin neurons, prompting an important inquiry into whether changes in calbindin expression could underlie these pathologies. Furthermore, calbindin D28K expression is known to be dependent on vitamin D3 [1, 2, 7]. Since vitamin D deficiency has been associated with type 2 diabetes, heart failure, and atrial fibrillation [9], investigating calbindin expression in cardiac neurons within this context holds considerable interest. Such exploration could potentially uncover novel insights into the role of calbindin in the pathophysiology of these conditions and its implications for neuronal function in the heart

Limitation of the study

In our experimental setup, AAV1-Flex-tdTomato viral transduction in Calb1-IRES2-Cre-D mice, leads to an expression of the tdTomato in approximatively 60% of calbindin positive neuron. This implies that, while all

tdTomato neurons are calbindin positive, there remains a proportion of neurons lacking tdTomato expression (estimated at around 25%) that are still calbindin-positive. Consequently, the discrepancies observed in our study are inevitably underestimated due to this incomplete labeling of calbindin-positive neurons.

Conclusion

Our current investigation characterizes for the first time the electrophysiological properties of a particular cardiac neuronal population delineated by its neurochemical phenotype. Calbindin neurons exhibit distinct morphological and excitability traits consistent with cardiac neuronal remodeling observed in conditions like type II diabetes and heart failure. Given these parallels, it is imperative to explore further this specific neuronal subset within the context of such pathologies. By doing so, we may gain deeper insights into the complex mechanisms underlying cardiac dysfunction and potentially uncover novel therapeutic avenues.

Ethical standards

Animals studies have been approved by the appropriate ethics committee "COMETHEA" and have therefore been performed in accordance with the ethical standards laid down in the 1964 Declaration of Helsinki and its later amendments. All authors gave their informed consent prior to their inclusion in the study.

Statements and Declarations

The authors declare that they have no conflict of interest.
