Abstract

Spider orb-web building is a captivating, rare example of animal construction, whose neural
underpinnings remain undiscovered. An essential step in understanding the basis of this behavior is a
foundational mapping of the spider's neuroanatomy, which has thus far been primarily studied using
non-web building species. We created a three-dimensional atlas for the hackled orb-weaver, *Uloborus*
diversus, based on immunostaining for the presynaptic component, synapsin, in whole-mounted spider
synganglia. Aligned to this volume, we examined the expression patterns of neuronal populations
representing many of the classical neurotransmitter and neuromodulators, as well as a subset of
neuropeptides – detailing immunoreactivity in an unbiased fashion throughout the synganglion,
revealing co-expression in known structures, as well as novel neuropils not evident in prior spider works.

This optically-sliced, whole-mount atlas is the first of its kind for spiders, representing a substantive
addition to knowledge of brain anatomy and neurotransmitter expression patterns for an orb-weaving
species.

Introduction

Brain atlases are essential tools for neuroscience in model organisms – ranging from neuropil
annotations (*1*), to neuronal subtype and transcriptional expression pattern atlases (*2*), to ultrastructural
connectivity maps (*3, 4*). In recent years, three-dimensional atlases of major neuropil structures have
also been created for non-canonical arthropod study species, including a number of insects (*5–7*) and
spiders (*8, 9*).

The hackled orb-weaver spider, *Uloborus diversus* (*10*), is an emerging model system for the study of
orb-web building in spiders (*11, 12*), whose central nervous system has yet to be investigated. To date,
the majority of studies of the spider central nervous system have been performed in one, *de facto*
model species, *Cupiennius salei (C. salei)*, a cursorial spider which hunts without building webs for prey
capture (*13*). While isolated anatomical treatments exist for orb-weavers and other web-based spiders
(*9, 14–21*), the preponderance of *C. salei* literature is even starker when considering examinations
beyond general neuronal stains, where *C. salei* is essentially the only spider species in which the

expression pattern of more than a single neurotransmitter has been mapped (*14, 22–32*). Furthermore,
the current understanding of spider brain anatomy is almost exclusively based on tissue slice analysis,
which can provide exceptional detail, but has the disadvantage of being often limited in completeness
by the planes which authors chose to exhibit.

Given that the substantial behavioral adaptation of web-building may be reflected in the presence of
necessary brain structures or their proportionality, and certainly in distinct underlying neuronal circuitry,
an important step in understanding the basis of this behavior is to have a foundational architecture of a
nervous system which generates it. We created a three-dimensional immunofluorescence atlas of major
neurotransmitter and neuromodulator populations for *U. diversus*, using whole-mounted synganglia.
Using immunostaining against the presynaptic marker, synapsin, we assembled a standard, full volume
of *U. diversus* synganglion onto which specific neurosignaling molecule expression patterns were
aligned. These include markers for classical neurotransmitters (GABA, acetylcholine), neuromodulators
(dopamine, serotonin, octopamine/tyramine) and several neuropeptides (AllatostatinA, Proctolin, CCAP,
FMRFamide). These volumes provide comprehensive and comparable detail throughout the
synganglion, in both undifferentiated and established regions – such as the arcuate body, whose layers
become distinguishable through the use of neurosignaling molecule co-stains. We further identify
several previously undescribed neuropils in the supraesophageal ganglion, and the neuronal subtype
populations whose specific expression demarcates them.

Results

The central nervous system of spiders is distinctive among arthropods for its compressed nature.
Residing within the prosoma, the synganglion is a fusion of two major ganglia, named in reference to the
esophageal passage running between them – the subesophageal ganglion, comprised primarily of motor
and sensory interneurons and comparable to the ventral nerve cord in insects, and the supraesophageal
ganglion, considered the brain proper, containing the higher-order integration centers (Fig. 1a).

Consistent with general arthropod nervous system morphology, the neuronal somata are arranged
superficially around the synganglion (Fig. 1b,c), while all the internal tissue is neuropil. An averaged
volume of anti-synapsin immunostaining (for neuropil) and DAPI stain (for nuclei), reveals that a
substantial proportion of somata are found on the ventral side of the subesophageal ganglion, with
some nuclei found laterally, but little to any on the dorsal surface of the subesophageal ganglion. A clear
patch is also present on the posterior aspect adjoining the opisthosomal neuromere. Nuclei are found
completely throughout the ventral-dorsal plane of the anterior side of the synganglion, with populations
also seen on the lateral sides (Fig. 1b,d).

In the supraesophageal ganglion as well, nuclei are not present on the posterior side, except for at the
dorsal-most end, where a cap of DAPI-positive staining enveils the posterior, anterior, lateral, and dorsal
aspects of the supraesophageal ganglion, beginning approximately at the level of arcuate body (Fig
1b,c).

Within the subesophageal ganglion there are a limited number of conspicuous neuropils, which are
evident from the exterior, and have been previously described in other species (*8, 9, 13*). Most ventrally,

a bulk of the subesophageal ganglion is comprised of four leg ganglia (or neuromeres) per hemiganglia,
corresponding to the eight legs of the spider (Fig. 2a-e).

Supplying these neuropils, as well as others and founding the longitudinal connections between the
major ganglia, are a series of major nested fiber tracts, having a stacked organization in both the medio-
lateral and ventro-dorsal planes. A chiasm structure is visible at the midline (Fig. 2c,d) with the
synaptically-negative circular openings assumed to be tracheal passageways. Throughout these same
planes, the pedipalpal neuropil appears anteriorly (Fig. 2b-e).

Further dorsally (Fig. 2f,g), the tract pattern takes on a ladder appearance, which correspond to an
arcade of finer commissures, not visible in this representation. These commissures connect all major
neuropils of the subesophageal ganglion. The courses of these tracts are most comprehensible when
followed by studying individual neurosignaling molecule stains, as exemplified by anti-tyrosine
hydroxylase immunofluorescence, discussed below.

The opisthosomal neuromere, supplying the hind compartment of the spider body, starts to emerge
(Fig. 2f, g), and will reach its full width in a shared plane with the esophageal passage (Fig. 2h,i) before
diminishing more dorsally after the esophageal passage closes (Fig. 2j,k). Within the opisthosomal
neuropil, a ladder-like appearance of medio-laterally running tracts can also be appreciated (Fig. 2g-i).
Posteriorly travelling tracts also diverge laterally to follow the circumference of the opisthosomal
neuropil (Fig. 2i).

At the level of the esophageal passage, an anterior-lateral neuropil begins to form, wrapping medially
to form the cheliceral neuropil (Fig. 2g-i), as medially the esophageal passage begins to close. The
esophageal passage is bridged at the anterior side by a region named the stomodeal bridge (Fig. 2j) (8).
A bridge structure also exists at the posterior end, where additional undifferentiated synaptic density is
flanking. Within this plane (Fig. 2j), the protocerebral tract is essentially parallel to the ventro-dorsal
axis, and appears as twin, dense nodes rising in the central burgeoning supraesophageal ganglion.

Subesophageal ganglion features and expression patterns:

Explorations of neurosignaling population innervation in the subesophageal ganglion have generally
been less detailed than within the supraesophageal ganglion. Certain neuropeptides were either only
briefly shown to be immunoreactive (such as AllatostatinA (8)) or not presented on in the
subesophageal ganglion (e.g. CCAP (28)). We find that all neuropeptidergic antisera, as well as the
others, examined in this study have robust expression throughout the subesophageal ganglion. One
observation which does not appear to be previously noted is that there is a roughly equal
anterior/posterior division in the leg neuromeres. Whereas some immunostains reveal equal
innervation of the halves (α-TH), others show divergent patterns (α-TDC2), or predominant expression in
only one compartment (α-AstA). Based on select examples where the origin of innervation is
discernable, the posterior and anterior compartments of the leg neuropils may be supplied by neurites
from different tracts within the interior of the subesophageal ganglion.

The opisthosomal neuropil is a section of the subesophageal ganglion which has received relatively less
attention. The preeminent reference for major tracts within the spider synganglion is the treatment in *C.*
salei (*13*), but despite a detailed annotation throughout the synganglion, the trajectories within the

opisthosomal ganglion were not diagrammed. A more recent expansion of this anatomical knowledge to
further cursorial as well as web-based species of spiders (9) likewise did not comment on the
opisthosomal neuropil. A depiction from Hanström (33), shows that longitudinal tracts run parallel to
the midline, as well as more laterally, and that there are crossing branches between them, forming a
ladder-like architecture. This bears a resemblance to the pattern revealed by specific antisera in *U.*
diversus, confirming the central tracts, perimeter defining tracts, as well as crossing fibers within the
opisthosomal ganglion – though whether they cross completely from midline to periphery was not
apparent. In certain cases we observed a ladder structure as well as a ring-like central structure with
neurites projecting like spokes. Immunoreactivity within the opisthosomal ganglion was variable
between target neurosignaling molecules. One additional subesophageal feature previously identified in
C. salei is the Blumenthal neuropil (34), which is innervated by afferents from the thermoreceptive and
hygroreceptive tarsal organ. Although we also see a paired, synapsin-density close to the midline in the
approximate anterio-ventral subesophageal location as described for *C. salei*, we cannot be confident
that this is the same structure – a question which will benefit from tracing techniques.

Acetylcholine:

In order to visualize acetylcholinergic populations and their expression patterns, we employed antisera
for choline acetyltransferase (ChAT). To our knowledge, the only previous study of cholinergic neurons
in the spider CNS was done in the wandering spider, *Cupiennius salei* (30).

Beginning ventrally, numerous ChAT+ somata are seen in the dense field of neurons located medially
from the leg neuromeres along the midline of the hemiganglia (Fig. S1a). Cholinergic neurons are also
present between leg neuromeres in the anterior-posterior direction, and for both cases, there is a
diversity of both size and staining intensity. The interspersed presence of more intensely ChAT-
immunoreactive neurons within the subesophageal ganglion was also observed in *C. salei* (30). At
approximately the level of the pedipalp ganglia (Fig. S1b, arrows) there are 3-4 relatively smaller,
strongly immunoreactive somata.

GABA:

GABAergic neurons can be identified with antisera to γ-aminobutyric acid (GAD) and have been studied
in the CNS in *C. salei* (26, 29) as well as the barn spider, *Araneus cavaticus* (15) and *Achaearanea*
tepidariorum (also known as *Parasteatoda tepidariorum* (17). GABAergic neurons are the most populous
subtype that we have visualized in *U. diversus*, with a large portion of these cells residing on the ventral
surface in the subesophageal ganglion (Fig. S2a-b), with presence posteriorly as well, ventral to the
opisthosomal neuropil (Fig. S2c). While used coincidentally with other successful antibodies by our
standard preparation, GAD antisera unfortunately exhibited poor signal penetration in the interior of
the tissue, limiting our analysis to the presence of GAD+ somata, as well as a number of neuropil
features which happened to be closer to the surface of the tissue, such as the opisthosomal neuropil
(Fig. S2d).

Dopamine:

In contrast to all other neurosignaling molecules, dopaminergic innervation of the spider brain has not
been investigated in *C. salei*, but rather in the wolf spider, *Hogna lenta*, and the jumping spider,
Phidippus regius, where it was interrogated using antisera to core synthesizing enzyme, tyrosine
hydroxylase (*35*).

We found this antibody to be effective in *U. diversus*, staining both cell bodies and projections with
enough clarity to follow the innervation patterns of many individual dopaminergic neurons. Associated
with each of the leg neuromeres are 7-8 TH+ neurons (Fig. S3a). The positioning of these is somewhat
variable, but it appears that they form two subgroups – a cluster of 5-6 smaller neurons (Fig. S3a –
arrowheads), typically with a couple being less intensely immunoreactive to TH, and the remaining 1-2
larger neurons which are spaced further from the rest (Fig. S3a – arrows). Dopaminergic projections
clearly trace each of the 4 leg neuromere commissures, as well as two anterior commissures (Fig. S3e).
The smaller subset appears to give rise to the leg neuromere commissures, as well as supplying some
innervation within the neuromere. The projections of the more populous cluster are more difficult to
follow, but presumably contribute to the neuromere pattern. Each leg neuromere is evenly filled by a
mesh network of dopaminergic varicosities (Fig. S3b).

Medio-ventral to the pedipalp neuromere are a cluster of 2-3 TH+ neurons per hemiganglia in the
anterior field of somata (Fig. S3c, d - arrows). The projections of these neurons can be traced through
the pedipalp and cheliceral commissures, suggesting that they are supplying both of the respective
neuropils. The posterior of these commissures (pedipalp) is subdivided into two tracts which mingle at
the midline. Posterior to these neurons is an area of denser immunoreactivity continuous with the
strongly labelled anterior-most arching commissure of the dorsal-tract (as referred to by Auletta et al
(*35*), for the same antibody).

178
Serotonin:

To visualize serotonergic populations we used an antibody raised directly against serotonin. The
patterning of serotonergic innervation has been studied throughout the synganglion in *C. salei* –
although only a literal description has been accessible to us (*22*) – and briefly shown for the arcuate
body in the wolf spider, *Pardosa* (*36*). Matching what has been reported for *C. salei* (*22*), a cluster of ~5
serotonin-positive cells are evident adjacent to each leg neuromere (Fig. S4a).

Most notably in the neuromeres of Legs I (anterior), the serotonergic innervation in the limb
neuroarchitecture appears to be supplied in two roughly equal halves, filling the periphery and leaving
an area dark of immunoreactivity within (Fig. S4b – brace). The anterior half of the innervation appears
to be supplied from the medial branch of the "dorsal-most tract" (as referenced by Auletta et al. (*35*)).
Several 5-HT+ neurons are seen ventral to the pedipalp neuropil (Fig. S4c – arrows), which has
serotonergic immunoreactivity on the medial portions flanking the midline. Ventral to the opisthosomal
neuromere are clusters of serotonergic somata which project into a robust tract travelling medially (Fig.
S4d – arrows).

193
Octopamine/Tyramine:

The antisera which we screened for individual octopaminergic and tyraminergic populations were not
found to be effective. Tyrosine decarboxylase 2 (TDC2) is an enzyme the catalyzes the conversion of
tyrosine to tyramine, which is subsequently necessary for octopamine metabolism, meaning that TDC2
is present in both neuronal subtypes in invertebrates. We found a *Drosophila melanogaster* antibody to
TDC2 to be effective in *U. diversus.*

Given that TDC2-immunoreacitivty should include both octopaminergic and tyraminergic neurons, we
might expect that potentially more positive somata would be seen in *U. diversus* than in *C. salei*, where
octopamine was stained for directly (*24*), assuming the relative population sizes in the species are equal.
Instead in the subesophageal ganglion we find a cluster of 5-6 TDC2+ somata per leg neuromere (Fig.
S5a), which is fewer than for C. salei (*24*). Unlike the uniform mesh-like innervation of each leg
neuromere produced by dopaminergic neurons, or the more or less symmetrical pattern for serotonin,
the pattern in TDC2 staining is notably different. The anterior side of each neuromere contains a patch
of continuous, diffuse, and more lightly stained immunoreactivity, while on each posterior side there is a
swath of brightly reactive, sparse puncta (Fig S5b).

All subesophageal ganglion tracts and commissures which were revealed by fine dopaminergic
projections are likewise labelled with TDC2-immunoreactivity. We also observed somata ventral to the
opisthosomal neuromere (Fig. S5c – arrows), but did not see any such gargantuan cell bodies as seen in
this vicinity in *C. salei* (*24*). There is substantial TDC2-immunoreactivity in the pedipalpal (Fig. S5c) and
cheliceral neuromeres (Fig. S5d).

TDC2-immunoreactivity displays an intricate pattern within the opisthosomal neuromere. At the ventral
anterior end two triangular formations of puncta (Fig. S5d – brace) abut the input of a string of
varicosities on each lateral side, which then becomes heavier and continues to outline the boundary of
the opisthosomal neuromere (Fig. S5d – arrow). An approximately mirrored pair of immunoreactive
triangles are found with their apex pointing posteriorly, at the posterior end of this neuromere. Within
the interior of the opisthosomal neuromere, fibers resembling spokes emanate to a ring-like midline
where there is a small chiasm, and a thicker bridge structure joining lateral segments which travel in the
anterior-posterior direction.

AstA:

The earlier work in *C. salei* (*28*) did not comment on AstA-immunoreactivity outside of the dorsal
supraesophageal ganglion, but an image from the jumping spider, *Marpissa muscosa*, confirms that
AstA-immunoreactive expression is present throughout the synganglion (*8*). In the far ventral portion of
the subesophageal ganglion where there is a complete covering of somata, there are paired clusters of 3
– 4 large AstA+ somata located on the posterior side (Fig. S6a – arrow). In a similar plane, there are two
smaller somata located along the midline (Fig. S6a). AstA-immunoreactivity has a distinctive pattern
within the leg neuromeres, showing robust varicosities but only the posterior portion of neuromere (Fig.
S6b,c). This innervation appears to be supplied from the lateral branches of the centro-lateral tract.
232
233 Similar to what has been described for *M. muscosa* as the stomodeal bridge, the area adjacent to the
234 esophagus on the anterior side of the subesophageal ganglion is prominently immunoreactive to
235 allatostatin (Fig. S6d – brace), although the actual bridge which crosses the midline is more modest than

236 in other stains, having only a few neurites, and thin representation in the posterior commissure (Fig. S6e
237 – arrow). Faint somata are also seen closely anterior to this region.
238

Proctolin:

Proctolin expression patterns were previously explored in *C. salei* both throughout the CNS (*26, 32*), as
well as in a focused manner in the protocerebrum, as a means to reveal arcuate body layering (Loesel et
al., 2011). Beginning in the subesophageal ganglion, proctolin-immunoreactive somata were found in
clusters of multiple somata along each neuromere ((*37*) citing Duncker et al., 1992), as well as many
other weakly labelled Proc+ cells (*32*). Curiously, in *U. diversus* we see a single bright Proc+ soma
associated with each of the 8 leg neuromeres in the subesophageal ganglion (Fig. S7a). These neurons
are found approximately at the same area as clusters for other populations, such as the aforementioned
monoamines. They are generally posterior and medial to the bulk of the respective leg neuromere.
Smaller and faintly immunoreactive Proc+ neurons are also seen in the vicinity and it is possible that our
sensitivity to weakly-labelled somata is lesser than in stained slices.
250

Medial to the emerging pedipalp neuropils are 2-3 Proctolin+ somata projecting a neurite into the
strongly staining anterior zone, also highlighted by serotonergic innervation (Fig. S7b – arrow). Likewise
in this plane, densely labeled somata are present in the field ventral to the opisthosomal neuromere (Fig.
S7b – arrowhead). A circular form of saturated proctolin-immunoreactivity is seen at the posterior end of
an oval shaped synapsin-density (Fig. S7c – arrow), suggesting that it is a subset of a major tract bundle.
In dorsal planes this immonreactivity morphs into lateral moving strands of varicosities becoming
difficult to trace. Such an appearance is not found in the other neurosignaling molecule stains, even
those with profound subesophageal expression.
259

260 The fine neurites projecting to the center of the opisthosomal neuropil as seen for TDC2 are also
261 apparent for proctolin-immunoreactivity (Fig. S7d).
262

CCAP:

Despite its name alluding to function in the heart, CCAP has considerable immunoreactivity throughout
the sub- and supraesophageal ganglia in *U. diversus*. The one prior investigation of CCAP in *C. salei*
presented CCAP expression patterns only for the brain (*28*). In our volumes, a cluster of ~5 intensely
immunoreactive neurons is seen around the Leg IV neuromere (Fig. S8a), and positive somata are also
associated with the opisthosomal neuromere (Fig. S8c – arrow). CCAP-immunoreactive neurons are
present in a more dispersed fashion within the ventral subesophageal ganglion (Fig. S8b).
Immunoreactivity within the leg neuropils is predominantly in the posterior halves, where sparse puncta
are evenly distributed (Fig. S8b).
272

FMRFamide:

At the ventral end of the synganglion, FMRFamide+ neurons are numerous and dispersed throughout the
width of the ventral field of somata (Fig. S9a). Unlike other neuropeptides and monoamines, these
immunoreactive somata cannot be readily attributed to clusters corresponding to individual
neuromeres. A concentration of FMRFamide neurons are present in the somata field ventral to the
opisthosomal neuromere (Fig. S9b – arrows), which was also found for *C. salei* (*30*). Ample FMRFamide

signal is seen within the opisthosomal neuromere (Fig. S9c-e). FMRFamide+ neurons are also prevalent
around the cheliceral neuromeres in the area of the stomodeal bridge (Fig. S9d – arrows).
281
Supraesophageal ganglion features:

Within the supraesophageal ganglion reside a number of dense neuropil regions which are discernible
from their surroundings. These include major recognizable structures such as the mushroom bodies (Fig.
2m-o) and arcuate body (Fig. 2q-t), as well as some previously undescribed structures, made evident by
the present image volumes.

The protocerebral tract can be followed further dorsally (Fig. 2j-l). The protocerebral tract dissipates,
and the protocerebral commissure (PCC) appears centrally (Fig. 2l). In this plane, the brightest lateral
structures are the hafts, the ventral-most reaches of the mushroom bodies. The neuropil directly
anterior to the PCC, paired and adjacent to the midline, forms a distinct landmark, which we refer to it
as the 'hagstone' neuropil, given its pendular and pierced form (Fig. 2m). Continuing dorsally (Fig. 2n),
the bulk of the mushroom bodies is present, the hagstone neuropil persists, and a faintly arching,
umbrella-like density is visible at the posterior side of the supraesophageal ganglion. The mushroom
body bridge and head is found dorsally (Fig. 2o), and centrally, an ovoid neuropil coalesces (Fig. 2p-r),
which has not been apparent in previous anatomical investigations (tonsillar neuropil, Fig. 2q). The
arcuate body lobes are present on the posterior side of the dorsal supraesophageal ganglion (Fig. 2 q-t),
while anterio-laterally a previously uncharacterized banded neuropil structure is visible (protocerebral
bridge (PCB) neuropil, Fig. 2S-t).

299
Mushroom bodies

The mushroom bodies (MBs) (or corpora pendunculata) are a paired neuropil structure whose size,
shape and mere presence are substantially variable across not only chelicerates, but arthropods in
general. Their fundamental morphological attributes are a stalk and head region reflecting their
namesake structure, and their mirrored distribution in the hemiganglia. Best characterized in insect
model species, and while sharing in anatomical and molecular characteristics (*38*), the evolutionary
relationship of insect MBs to those of chelicerates and other arthropods, and particularly spiders, has
been a continuing debate (*9, 38–40*).

The mushroom bodies of *U. diversus* (Fig. 3a,b) tend to show the most robust synpasin-
immunoreactivity of all structures in the supraesophageal ganglion (Fig. 3c, maximum intensity
projection), indicating a great degree of synaptic density. While web-building species have been
reported to have simplified (*9*) or even entirely absent mushroom bodies (*9, 20, 33*), these structures
are present in *U. diversus* and retain the complete form seen in more visually-reliant species (*8, 9*), even
if they are smaller relative to the supraesophageal ganglion as a whole (Fig. 3a,b,c).

U. diversus MBs display a haft, body and head region, with the two hemiganglion pairs connected by a
bridge (Fig. 3a-c). Synapsin-immunoreactivity is modest within the bridge region, whose true thickness is
better visualized with staining for βTubulin3 (Fig. 3d). Despite the strong synapsin-immunoreactivity in
the MBs, we surprisingly did not see co-expression with most of our specific neurosignaling molecule
antibodies. This pattern is also reflected in the extant spider literature, with a single study showing
immunoreactivity in the mushroom bodies of *C. salei* for anti-GAD and anti-proctolin staining (*26*). In our

hands, only anti-AllatostatinA staining showed co-immunoreactivity throughout the mushroom body
(Fig. 3e). Although difficult to trace the source far, it appears the hafts are innervated from the posterior
side (Fig. 3f). By βTubulin3-immunoreactivity, we observe two tracts which straddle the MB hafts as they
descend from the dorsal somata layer (Fig. 3g). Finer neurites are not distinguishable in the βTub3-
immunoreactivity, but it seems plausible that the AstA+ neurites entering the MB hafts might stem from
the medial of these two tracts.

Babu and Barth (1984) described the protocerebro-dorsal tract as providing input to the hafts of the
mushroom bodies. The connection of this tract to the MB hafts is not apparent by our synapsin stains in
U. diversus, which was likewise the case with silver staining for *P. amentata*, *M. muscosa*, *A. bruennichi*,
and *P. tepidariorum* (*9*).

The antero-dorsal input to the MB heads, representing the secondary eye pathway (*39*), is much more
conspicuous and has received considerable treatment within the literature. The mushroom body heads
are sometimes referred as the third-order visual neuropil in this pathway, with the ample parallel fibers
which give this structure its shape arising from globuli cells which cap the mushroom body head.

The globuli cells are not distinguishable from the surrounding nuclei by DAPI signal, but can potentially
be discerned through specific neurosignaling molecule immunostains. We find the cluster of cells closely
associated with the MB heads are revealed by ChAT-immunoreactivity, and to a lesser extent by GAD-
immunoreactivity, suggesting they represent cholinergic and GABAergic populations, respectively (see
Acetylcholine and GABA subsections, below). Globuli cells in *C. salei* have previously been shown to be
ChAT+ (*30*). By βTubulin3 staining, we also observed a trident of tracts feeding into the dorsal aspect of
the mushroom body head (Fig. 3g).

Visual System

U. diversus, like many orb-weavers, builds its web in the night and can do so in essentially complete
darkness in laboratory conditions, suggesting that vision is expendable to much of the spider's
behavioral repertoire (*41*). Web-building spiders are considered to have poorer vision than spiders
which depend on sight to capture prey, which is reflected in their diminished optic neuropils and tract
pathways (*9, 21*).

Relative to cursorial species (*8, 9, 13*), in *U. diversus* the anterior extensions of the protocerebrum
containing the first and second-order optic neuropils are considerably thinner and not as extensively
fused with the continuous neuropil of the supraesophageal ganglion, and are prone to separating during
dissection. Consequently, neither the primary or secondary visual pathway neuropils appear reliably
enough in the anti-synapsin volumes to be apparent in the averaged standard brain representation, but
nevertheless these structures are exhibited in various individual preparations. The optic neuropils in *U.*
diversus tended to show weaker synapins-immuoreactivity, but were clearly seen with antisera to HRP
(Fig. 4a).

As in other species, the secondary pathway is larger (Fig. 4b), lifting away anteriodorsally to the zone of
the MB heads. This continuity can be inferred from the sliced three-dimensional maximum intensity
projection of synapsin (Fig. 4b). The primary pathway is diminutive in *U. diversus*, and emerges as a
bulbous shape at the dorsal-most end of the brain through a field of somata (Fig. 4a).

Previous reports have used GABA (*26*), histamine (*23*), dopamine (*35*), CCAP (*28*), and FMRFamide (*26*)
to reveal the successive neuropils of the visual pathways. As noted above, the only features within the
optic pathway for which we observed neurosignaling molecule immunoreactivity were the globuli cells
with GAD and ChAT staining. It is possible that targets for which we could not acquire an effective
antisera, such as histamine, could be revelatory of the optic lamellae and other visual pathway
structures, as they have been for *C. salei* (*14*, *23*). Specific compartments of the pathways, such as the
medulla or lamellae could not be discerned with any preparation.

Arcuate body:

The arcuate body is a prominent neuropil structure found in all spider species whose central nervous
system anatomy has been examined closely to date. Residing in the dorso-posterior aspect of the supra-
esophageal ganglion, this solitary crescent-shaped structure has been recognized as having at least two
broad divisions, the ventral and dorsal lobes (*8*, *28*, *33*).
373

Additional layers have been noted by synapsin staining in the dorsal arcuate body (*8*). The precise
number of layers varies within the literature, and it is unclear to what extent authors distinguish
between the gross lobes of the AB, and sublayers which may be found within. This is also complicated by
the fact that slices are not always made in a consistent orientation. In absence of a whole-mounted
example or a seamless stack of slices, an oblique slice may over- or underestimate the size of a layer,
depending on the angle taken. Additionally, the degree of layering may also reflect a true difference
between species, independent of methodology.
381

In *U. diversus*, at the grossest level, we likewise observe two lobes of the arcuate body, which we will
refer to as the ventral (ABv) and dorsal (ABd) (Fig. 5a,b). Though largely coincident in the dorso-ventral
axis, the ventral arcuate body somewhat envelopes the dorsal arcuate lobe, hence appearing first from
the ventral direction and lingering posteriorly on the dorsal side, with only a smaller part of the dorsal
arcuate body protruding independently beyond the ABv at the dorsal end (Fig. 5b).

Each lobe (ABv and ABd) can be further subdivided into two sub-lobes or layers – a posterior (posABv
and posABd) and anterior (antABv and antABd) section, making a total of four units (Fig. 5c). The
sublayers of the arcuate body lobes are distinguishable by immunostaining for specific neuronal
subpopulations which differentially innervate the layers (Fig. 5d, Fig. 6). By examining these expression
patterns, another tier of complexity can be appreciated, as each of these sublayers (posABv, antAbv,
posABd, antABd) can be further subdivided into 2 or even 3 aspects, depending on the antisera used.

There is a diversity of layering patterns (Fig. 6), but some basic motifs emerge. Innervation can be
partial, as in filling a single sublayer (anterior or posterior) of a lobe, or complete throughout the lobe,
taking on a saturated appearance, a meshwork of neurites, or a sparse field of puncta. The space
between marked sublayers may at times have finer neurite connections which have been described as
palisade-like (*28*). Most commonly at the dorsal end of the ventral arcuate body (ABv), heavy garland-
like varicosities may form, in certain examples (α-Proctolin, α-TDC2, α-FMRFamide, Fig. 6) appearing as
disjointed units, suggestive of an undergirding column. More prevalently in the dorsal arcuate, a robust
networking of thicker immunoreactive fibers weave between roughly trapezoidal signal-negative areas

(α-5-HT, α-TDC2, Fig. 6), resembling a flagstone pathway. Detailed descriptions of arcuate body layer
projection patterns (Fig. 6) and comparisons to other spider species are found below in the respective
subsections for each neurosignaling molecule.

The innervation pattern of a given neuronal subpopulation in a layer of the arcuate body is not a general
delineation of the structure of that layer, as different transmitter populations can display distinct
expression patterns within the same layer. An example is the dorsal arcuate body (ABd), where TDC2-
immunoreactivity shows a prominent columnar, flagstone innervation, while proctolin has a sparse field
of fine puncta in the same layer (Fig. 5f).

Posterior to the arcuate body is crest of somata which has been previously referred to as the posterior
cell layer (PCL) (30). Neurons of the PCL send their projections anteriorly through the ventral arcuate
layers, as revealed by immunostaining for βTubulin3 in conjunction with synapsin (Fig. 5e). The fibers
successively run medially as one progresses further dorsally in the arcuate lobes, with certain tracts
being thicker than others. Hill noted the presence of tracts running through the arcuate body to join the
PCDt in jumping spider, *P. johnsoni* (*42*).

Acetylcholine:

In the arcuate body, cholinergic signal is predominantly found in the ventral arcuate body lobe (Fig. 6 -
α-ChAT, ventral, Fig. S1 h,i). Within the ventral side of this lobe, cholinergic signal forms fine puncta
which completely fill the anterior sub-layer of this lobe. Toward the dorsal end of this lobe, the punctate
immunoreactivity forms heavier beaded varicosities. Midway there are faint column-like expression
patterns joining from a thin layer within the posterior ventral AB (pABv). A single layer is sparsely
innervated on the anterior side of the dorsal lobe (Fig. 6) (Fig. 6 - α-ChAT, dorsal). Cholinergic
innervation within the layers of the arcuate body has yet to be described for any other spider species.

GABA:

In the ventral lobe of the arcuate body are several layers of faint GAD-immunoreactivity (Fig. S2g, Fig. 6 -
α-GAD). At the edge of the posterior layer, GAD+ somata of the adjacent posterior cell layer are seen,
anterior to which there is wider layer fine signal (Fig. 6 - α-GAD, ventral). Moving anteriorly, this is
followed by a very thin layer of puncta which may be connected through minute projections to the next
layer which is as thick as the first. The anterior-most layer of the ventral lobe appears empty of
immunoreactivity. Apart from a haze which is difficult to disentangle from bleedthrough or background,
the same can be said of the dorsal arcuate body lobe. However, in the dorsal arcuate body lobe we see a
clear illustration of how neurites stemming from the somata of the posterior cell layer extend through
the arcuate body layers (Fig. 6 - α-GAD, ventral). The pattern in *C. salei* (*26, 29*) is similar for the first
layers beginning from the posterior side, but diverges at the anterior-most arcuate body section, where
the thickest and most densely stained layer appears to be in what would be the anterior dorsal arcuate
body layer, where we see little to no signal.

Dopamine:

Within the arcuate body, TH-immunoreactivity occupies a single layer in the posterior aspect of the
dorsal lobe (Fig. 6 - α-TH, dorsal), supplied by thin and sparse neurites stretching from the anteriorly
located tracts (Fig. S3k). This single layer of punctate terminals with anteriorly branching projections is
consistent with both *H. lenta* and *P. regius* (*35*), but otherwise the *U. diversus* dopaminergic arcuate

body layering appears simpler and more comparable to the jumping spider, *P. regius*, due to lacking the
additional wispy immunoreactivity in anterior layers as in *H. lenta*.

For the wolf spider, *H. lenta*, TH labelling reveals densely stained first and second-order optic neuropils
(*35*). In contrast we see a stark lack of immunoreactivity in anterior regions which would be expected to
contain the comparable neuropils in *U. diversus*.

Serotonin:

Immunostaining against 5-HT in the social huntsman, *Delana cancerides* shows two gross levels of
immunoreactivity in the arcuate body; a wide diffuse layer of puncta, and a thinner layer bordered by
dense puncta on each side, with columnar-like expression in between (*36*). Taken together as two
adjacent layers, this pattern is remarkably similar to that seen for our model species. In U. diversus,
serotonergic-immunoreactivity shows a faint layer in the posterior ventral arcuate lobe, and an anterior
ventral actuate sublayer broadly flush with minutely fine fibers (Fig. 6 - α-5-HT, ventral, Fig. S4k). The
dorsal arcuate lobe displays a robust and wide immunoreactive pattern resembling flagstone-pavement,
hinting at a columnar structure (Fig. 6 - α-5-HT, dorsal). This layers innervation greatly resembles that
seen for TDC2 in the same lobe (Fig. 6 - α-TDC2, dorsal).

Octopamine / Tyramine:

Both anterior and posterior sublayers of the ventral arcuate body exhibit TDC2 immunoreactivity (Fig. 6 -
α-TDC2, Fig. S5l,m). The posterior layer of this sublayer is saturated with diffuse puncta with the anterior
side showing faint minute columnar arrangement. The anterior sublayer has denser, garland-like
varicosities. In the dorsal arcuate body lobe, TDC2 immunoreactivity appears only in the anterior
sublayer (aABd), where it fully fills the span of this layer with robust staining resembling a series of
keystone-shaped columnar-like elements. Octopaminergic expression has been reported in the arcuate
body (labelled 'central body' in source) (*24*) of C. salei, where a parasagittal section shows strong
immunoreactivity in the ventral portion of both arcuate body lobes. We must imagine the respective
horizontal view, but it would appear by the gaps in immunoreactivity that a dorsal horizontal slice in C.
salei should show three general layers of AB staining, which is essentially what we see from a dorsal
plane in U. diversus.

AllatostatinA:

The pattern of arcuate body innervation by AstA+ neurons is in general agreement with findings from C.
salei and M. muscosa (*8*, *28*) where signal is prominent in the ventral arcuate lobe (ABv), with little to no
staining in the dorsal arcuate (ABd). Concerning the sublayers of the ventral arcuate lobe, AstA-
immunoreactivity is seen on the anterior aspect of the posterior ventral arcuate (posABv), and fully
encompasses the anterior ventral arcuate (antABv) (Fig. 6 - α-AstA). In a given sample, a series of
discernible units of immunoreactivity are seen in the posABv layer, suggesting the columnar organization
which is present, but generally obscured by the density of staining (Fig. S6k – arrowheads).
477
Proctolin:

Proctolin immunoreactivity is evident in all lobes and layers of the arcuate body (Fig. 6 - α-Proctolin, Fig.
S7l,m). In the ventral arcuate body (ABv), at the posterior ABV a line of intense terminals, underlayed by
diffuse puncta. Towards the dorsal end of the ventral arcuate body (ABv), the proctolin-immunoreactivity
in the posterior-most layer transforms into heavy garland-like columnar varicosities extending at an

anteriodorsal angle. This is in complete correspondence to the varicosities seen for this layer in *C. salei*
(*28*). In the anterior ventral arcuate (antABv), the anterior and posterior sublayers take on an intricate
mesh-like form, also with smaller flagstone formations. Between these two layers are fine palisade
neurites. Both sublayers of the dorsal arcuate (ABd) are also filled, but with a sparse field of fine puncta.
487
CCAP:

CCAP expression is strong in the posterior ventral AB layer with a fine mesh, punctate appearance which
seemingly contours the columnar structures on the anterior and posterior boundaries of this layer. The
anterior and posterior sublayers of the ventral AB are highlighted, with a decrease in staining within the
area between the sublayers (Fig. 6 - α-CCAP, ventral, Fig. S8h). In the anterior ventral AB, the anti-CCAP
expression is slightly finer and more punctate than in the preceding description. The staining appears
singular unlike in the posterior ventral AB – this might be reflective of expression in the area between
sub-layers within anterior ventral AB. Within the dorsal AB (Fig. 6 - α-CCAP, dorsal), only the posterior
layer has appreciable expression, showing a single, finely innervated but moderately thick layer hugging
the posterior boundary of the dorsal AB. CCAP-immunoreactive layers in U. diversus are comparable to
C. salei (*28*), as for both species the thickest staining layer is the most posterior one (ventral arcuate
body lobe), followed anterio-dorsally by a lesser layer, and with a thinner strand of intensely
immunoreactive boutons running through the more anteriorly located dorsal arcuate body lobe.
501
FMRFamide:

From both *C. salei* (26) and the giant house spider, *Tegenaria atrica* (18), a basic structure of the
FMRFamidergic arcuate body layers emerges, where the entire dorsal arcuate body lobe is suffused with
immunoreactivity, there is a sharp strand of garland-like varicosities giving way to the typical columnar
arrangement in the posterior dorsal arcuate body layer (posABd), and more diffuse, punctate
immunoreactivity in the anterior dorsal arcuate body layer (antABd). This pattern is approximately what
we see in *U. diversus*, with additional details made clear by access to a continuous stacked image
volume (Fig. 6 - α-FMRFamide).

510
It appears that the saturated signal within the ventral arcuate lobe is actually the result of an
innervation pattern which is stronger in the wall of each tubular-like sublayer, and weaker in the
interior. This can be seen from several specific planes which slice longitudinally through both sublayers,
revealing four layers, each being the boundary of one of the sublayers (Fig. 6 - α-FMRFamide, ventral). In
the dorsal arcuate body, the immunoreactivity is primarily in the posterior sublayer, having the heavy
varicosities at the ventral aspect, and keystone column pattern more dorsally (Fig. 6 - α-FMRFamide).
Relative to other examined spiders, the punctate pattern in the anterior sublayer is weakly present. The
arcuate body layering pattern of FMRFamide immunoreactivity is similar to that of CCAP.

Tonsillar neuropil

Within the historically non-descript central supraesophageal ganglion, we observed a synaptically dense
neuropil structure in *U. diversus*. Beginning in the planes dorsal to the mushroom bodies, this paired
structure is positioned directly on either side of the midline, and is centrally located, being medial to the
perimeter of the supraesophageal ganglion from both the lateral as well as anterior and posterior limits.

The half in each hemiganglion has an approximately ovoid appearance, particularly at the anterio-dorsal
end, while bridged at the posterior aspect. Between the two halves, at the midline, is a furrow which is
negative for synapsin-immunoreactivity, giving this neuropil, in conjunction with the synapsin-negative
zone, a likeness to tonsils when viewed from the horizontal optical planes (Fig. 7a, c – α-synapsin).

In individual anti-synapsin stains, a fiber tract traveling laterally adjoins this neuropil in the more dorsal-
posterior portions. By tubulin-immunoreactivity, it appears to bifurcate the structure below the bridge
in the dorsal portion (Fig. 7b). As evidenced by at least octopaminergic/tyraminergic co-staining, this
tract may be supplying input from yet another hitherto undescribed neuropil, the protocerebral bridge,
to be discussed below.

A subset of antisera for specific neuronal populations are instrumental in confirming this neuropil, as
their immunoreactivity is circumscribed by its boundaries, with little neighboring signal to obscure the
distinction (Fig. 7c). Most representative among these is serotonergic-immunoreactivity, exhibiting fine
varicosities which neatly fill the area. TDC2+ signal, indicating innervation from octopaminergic and
tyraminergic neurons, are also prominent in this neuropil. The relatively heavier terminals appear
stronger on the periphery, and when viewed in alignment with the 5-HT channel, resemble a division of
compartments, most notably in the ovoid regions where serotonin is found in an internal, core pattern,
with octopaminergic/tyraminergic signal as a shell (see Octopamine/Tyramine subsection).

There may also be a division in the anterior-posterior dimension as AllatostatinA-immunoreactivity is
more pronounced in the posterior bridging region, and sparsely punctated in the anterior ovoid zones
(Fig. 7c – α-AstA), while proctolin-immunoreactivity is limited to the posterior region (Fig. 7c – α-
Proctolin). FMRFamide immunostaining is diffusely present, particularly in the anterior-dorsal portions
of the tonsillar neuropil, but this is amidst broadly saturated signal from this antibody throughout the
supraesophageal ganglion.

Protocerebral bridge

Originating anterio-laterally and progressing posterior-medially through the ascending dorsal planes of
the supraesophageal ganglion is a banded neuropil structure which we will designate as the
protocerebral bridge. Wider in the lateral aspect, the structure tapers towards the medial end with the
thinnest, midline-crossing component only being apparent in specific neuronal subpopulation stains.
This is the dorsal-most neuropil seen in the interior of the supraesophageal ganglion before reaching the
dense cap of somata (Fig. 8a,b).

As with the previous neuropil, only a subset of antisera show immunoreactivity within this neuropil. The
most filling is GABAergic-immunoreactivity (by anti-GAD stain) which defines a nearly complete swath of
the neuropil with dense signal (Fig. 8b - α-GAD). Comparing further neuronal-subtype preparations
reveals that the protocerebral bridge has a layered structure. TDC2-immunoreactivity is pronounced
throughout the length of the protocerebral bridge, displaying heavy chains of puncta on the posterior
edge of the bridge (Fig. 8b - α-TDC2). Proctolin-immunoreactivity forms a tight, thinner band, primarily
at the medial end of the neuropil, comprised of fine puncta and is centrally located among the layers
(Fig. 8b - α-Proctolin). The acetylcholinergic pattern is a distinct thin layer on the anterior and posterior

edge, most clearly visible on the lateral portion of protocerebral bridge (Fig. 8b - α-ChAT). A faint section
of AstA-immunoreactivity was also seen (Fig. 8b - α-AstA).

Posterior and ventral to the protocerebral bridge is an arching string of varicosities which reaches its
apex just before the appearance of the dorsal arcuate body layer. We refer to this as the dorsal
protocerebral commissure (dPCC) (Fig. 8b – arrows) and the neuronal subtype populations which show
protocerebral bridge expression tend to also innervate this commissure. The strongest of these are
octopaminergic/tyraminergic neurons (anti-TDC2) and proctolinergic neurons (anti-Proctolin) (Fig. 8b -
α-TDC2, α-Proctolin). This pathway separates from the posterior-lateral contour of the protocerebral
bridge, where there is an approximately triangular expansion of immunoreactivity before travelling
medially, and passing just posterior to the edge of the tonsillar neuropil. A similar pattern, though of
relatively lesser staining intensity is also seen for allatostatinA (Fig. 8b - α-AstA). Cholinergic-innervation
is also apparent in the posterior arch, but is more subtle and in a single layer in the anterior domain,
being less comparable to that of TDC2, Proctolin and AllatostatinA.

Additional supraesophageal observations:
579
580   *Acetylcholine*:
581
582   The most strongly ChAT-immunoreactive neurons are found in a 6-7 neuron cluster in the anterior col-
583   umn, medial to the cheliceral ganglia and just ventral to where the esophagus closes with the esophage-
584   al bridge (Fig. S1d).
585
The nature of this antibody, along with the abundance of this population made it not possible to de-
scribe the contribution of these individual populations to the immunoreactivity patterns within the
neuropil. ChAT-immunoreactivity forms dense puncta abundant throughout the supra- and
subesophageal ganglia (Fig. S1b-f). Compared to other immunostains in our study, the relatively uniform
immunoreactivity throughout the neuropil, apart from a couple exceptions, does not clearly highlight
specific structures.
592
The aforementioned globuli cells are visible anterio-dorsally to the level of the MB heads (Fig. S1g). Dor-
sal still to these appear two bright clusters, each containing two ChAT+ neurons (Fig. S1h). The anterior
medial cluster are more typically sized (Fig. S1h - small arrow), while the lateral pair are the largest
ChAT+ neurons we observed in *U. diversus* (Fig. S1h - large arrow). A concentrated line of cholinergic
somata (~16-20) are present on the thinner band of cell bodies posterior to the arcuate body (Fig. S1h -
small arrowheads), and at the far dorsal end a roughly equal amount are dispersed medially (Fig. S1i).
599
600   Two strings of ChAT+ varicosities arc with their zenith at the posterior midline, before the arcuate body.
601   The posterior arc has stronger immunoreactive puncta and travels ventrally to the dorsal arcuate body
602   (ABd). The wider anterior arc is made of fine parallel fibers and appears to comprise a part of the
603   protocerebral bridge-like neuropil (Fig. 8b, Fig. S1i – arrows).
604
605   *GABA*:
606
GAD-immunoreactive neurons are also found abundantly throughout the anterior side of the brain,
within the deep furrow of somata (Fig. S2d,f). One feature which is visible with this antibody is the

protocerebral bridge neuropil, which is robustly innervated by GAD-immunoreactivity. This signal aligns
with the full breadth of synapsin-immunoreactivity corresponding to this neuropil (Fig. S2g). A bulbous
shape is outlined by GAD-immunoreactivity, and overlays with the apex of the mushroom body heads in
the standard brain volume (Fig. S2e - arrow), suggesting that the globuli cells contain GABAergic innerva-
tion. Anterior to the tonsillar neuropil there is a sharp band of GABAergic cell bodies arranged in the
medio-lateral direction (Fig. S2f). Further in the dorsal subpraesophageal ganglion, there is a distinctive
ascending column of GAD+ somata on each of the hemiganglia which stand out due to not being imme-
diately flanked by other GABAergic neurons to each side (Fig. S2g). Such a grouping also seems present
in *C. salei* (*37*) and *P. tepidariorum* (*43*).
618
619   *Dopamine*:
620
Continuing dorsally, the next clusters of TH+ neurons are at the level of and dorsal to the closure of the
esophagus. The dorsal cluster is a tandem pair of two neurons each (Fig. S3f – arrows), posterior to
which are seen a band of neurites and adjoining immunoreactivity on each side, representing the
stomodeal bridge (STb, as per (*44*), Fig. S3f – asterisk). These tandem neurons match well to the posi-
tioning of "Group 3" neurons in the wolf spider, *H. lenta* (*45*). Similarly, to the "Group 3" members, the-
se neurons appear to contribute substantially to the stronger immunoreactivity surrounding the esoph-
ageal bridge.
628
The opisthosomal neuromere is supplied by a grouping of neurons found in the somata ventral to it, and
the lateral borders of this structure are highlighted by intensely staining tracts of TH-immunoreactivity,
while the interior has a mesh of varicosities, including its own fine commissures (Fig. S3f - brace). Just
dorsal to the neurons in the vicinity of the bridge, are the second cluster comprised of 5 TH+ somata
(Fig. S3g – arrows). These appear to be a similar population to "Group 2" neurons in *H. lenta*, which are
more numerous, but share the description of projecting posteriorly and slightly dorsally to the edge of
the supraesophageal ganglion (*45*).
636
The final cluster of the ventral end of the supraesophageal ganglion appear laterally as 4 neurons per
hemiganglia (Fig. S3g, h – arrow). This is approximately at the level where the "ventral-most TH-ir tract"
(using terminology in (*45*)) joins in an arch above the esophagus (seen clearer medially in Fig. S3g), the
third and most posterior bridging of that channel. These neurons are likely the counterpart to those la-
belled "Group 1" in *H. lenta* (*45*). As for *H. lenta*, these neurons contribute heavily to the tracts running
briefly posteriorly, and then medially to course through the protocerebro-dorsal tract (PCDt), ventral to
the arcuate body. Interestingly, a subset (potentially 2 of the 4) of these lateral subpraesophageal neu-
rons also produce descending projections (Fig. S3f – arrowhead), which join the "intermediate TH-ir
tract" (as defined in (*45*)). In short, the TH+ somata of the ventral supraesophageal ganglion are remark-
ably similar in organization and projection patterns to those reported in the wolf spider, with the only
discrepancy being fewer neurons found for each cluster in *U. diversus*.
648
About the level of the arcuate body there are a doublet and singlet (Fig. S3i,j – arrowhead and arrow,
respectively) of TH+ neurons, totaling three per side, which are present on anterior facing somata field.
These neurons, and particularly the lone medial ones (Fig. S3i,j – arrow), form extensive projections
within this sector of the supraesophageal ganglion. The doublet population forms a wide arc laterally
and ventrally, which melds into the PCDt, wherein its individual fibers can no longer be discerned. The
single neurons project slightly dorsally, also contributing to the PCDt, the looped and crossed portion
visible at the posterior midline (Fig. S3i), and appear to also be the source of innervation to the arcuate
body layer appearing dorsally (Fig. S3k). In *H. lenta*, a 'triad' of neurons is described at this area, with a

subset projecting to the arcuate body layer and the others connecting with the PCDt (*45*). Apart from
the closer clustering in this spider, the description and number, down to the division of targets matches
our findings for the described neurons in *U. diversus.*
660
A final, dorsal-most cluster of 2 – 3 neurons appears medially (Fig. S3k), anterior to the arcuate body.
Despite very close confirmation of the preceeding somata, these neurons were not reported in either *H.*
lenta or *P. regius* (*45*), and therefore may be particular to *U. diversus*. The projections of these neurons
are more difficult to follow due to the mass of neurites which they overlap through just ventrally, but it
appears that at least the most prominent of their neurites actually continue to descend ventrally, cross-
ing below the PCDt in the posterior direction before turning sharply to continue into the ventral
supraesophageal and potentially even the subesophageal ganglion. At this same dorsal plane as these
somata, densely fine varicosities are evident in an area positioned correctly to potentially overlap with
the protocerebral bridge neuropil (Fig. S3k), but this has not been confirmed with a reliable alignment.
670
671 *Serotonin*:
672
5-HT-immunoreactivity is prominent in the posterior bridging area dorsal to the esophageal passage, as
well as the laterally adjacent tissue (Fig. S4e), and not as apparent in anterior stomodeal bridge. Sero-
tonergic fibers form a distinctive circular tract pattern around the midline of the supraesophageal gan-
glion (Fig. S4f), not as clearly seen with any other neuronal-subtype stain. Bright puncta are also visible
at several points surrounding the intensely synapsin-immunoreactive protocerebral tract, suggesting
that serotonergic projections are running among this fiber bundle (Fig. S4f). The semi-circular tracts
bending medially (Fig. S4g), before a chiasm of seemingly all three directions is seen immediately dorsal
(Fig. S4h). On the posterior end is a diffuse umbrella-like band of varicosities (Fig. S4h, i).
681
682 Continuing dorsally from this point, the innervation spreads to fill a kidney shaped structure which is
683 pierced by a circular spot lacking synapsin-immunoreactivity (Fig. S4i – brace) – with such internal
684 synapsin-negative areas assumed to be tracheal passageways or potentially glia. It is difficult to ascertain
685 to what degree the innervation in this region is continuous with that of dorsally located features.
686
A pair of strongly immunoreactive 5-HT neurons (one for each hemiganglion) (Fig. S4j – arrows) are
found medially, at the plane of the MB heads, and appear to send a neurite into a varicose-filled region
pinned in by the MB bridge to the posterior and lateral sides, and the cell body furrow anteriorly (Fig.
S4j). Ventrally this region leads to the aforementioned hagstone structure. Dorsally, the
immunoreactivity can be followed until the very strikingly defined contours of the tonsillar neuropil,
which has been described (Fig. 7).
693
694 For *C. salei* (*46*), additional clusters of serotonergic neurons were reported in the dorsal
695 supraesophageal ganglion, but apart from a given cluster (Fig. S4k – arrows) we have not been able to
696 reliably distinguish groupings within the dorsal somata.
697
698 *Octopamine/Tyramine:*
699
In the anterior wall of somata spanning from the frontal plane at the level of cheliceral neuropil to the
fusion of the esophageal bridge are atleast 15-20 TDC2+ neurons, of varying size and staining intensity
(Fig. S5f,g). This number corresponds closely to the counts for *C. salei* in the same region (*47, 48*). TDC2-
immunoreactivity is prominent in the stomodeal bridge and adjacent areas, and at this plane two lateral

bands of immunoreactivity appear which do not correspond to a clear demarcation in the synapsin
channel.
706
A variant of the subesophageal tract arrangement is reprised in the opisthosomal neuropil, where in-
tense boutons line a tract running parallel to the midline between hemiganglia to close a loop at the
posterior end (Fig. S5f, g – arrow), while also giving rise dorsal and laterally to a concentric ladder-like
structure with tracts laying in the anterior-posterior direction (Fig. S5h – brace).
A diagram from C. salei points to octopaminergic expression in the interior supraesophageal ganglion, as
a frontal slice indicates two areas of octopaminergic-immunoreactivity, both referred to as
"protocerebral neuropil" – suggesting the use of this term to be a general placeholder for non-descript
areas within the supraesophageal ganglion (*48*). We find TDC2-immunoreactivity strongly in the umbrel-
la-like posterior region also innervated by 5-HT (Fig. S5i), and sparser puncta within the bounds of the
hagstone neuropil. Dorsally, the signal remains strong within the interior, and prominent in an anterio-
medial stretch hemmed in by the mushroom bodies, as well as thin strands which run along the lateral
periphery (Fig. S5j). TDC2-immunoreactivity is also found in the tonsillar central neuropil, where it is
substantial throughout, but particularly strong in a peripheral type of shell pattern, especially when
aligned to 5-HT staining which respectively forms the core (Fig. S5k).
721
We have described above how TDC2-immunoreactivity heavily marks the protocerebral bridge, as well
as a commissure connecting posterio-dorsally (Fig. 8, Fig. S5l). Seyfarth and colleagues (*48*) report
octopamine-immunoreactivity revealing "fine varicose fibers in protocerebral bridge". As this references
a single cropped micrograph, it is difficult to orient and draw a comparison with confidence to the
neuropil which we are describing as the protocerebral bridge. A final detail of interest concerns a string
of puncta which extend from the protocerebral bridge to the tonsillar neuropil (Fig. S5l and inset) –
which could correspond to tract highlighted by tubulin-immunoreactivity (Fig. 7b) – revealing a putative
pathway between these neuropils.
730
Interestingly, earlier reports indicated no octopaminergically immunoreactive somata within the
protocerebrum in *C. salei* ((*47*) reprinting table from Dunker 1992, (*49*)). In *U. diversus,* a series of TDC2+
neuronal cell bodies are visible in the anterior half of the far dorsal cap of somata covering the
supraesophageal ganglion, with some TDC2+ somata also being present in the thinner layer of cells pos-
terior to the arcuate body (Fig. S5m – arrow). Given that TDC2 also should be present in tyraminergic
neurons which can be octopamine-negative, these findings may be consistent with the picture for *C.*
salei, or alternatively may reveal that *U. diversus* has octopaminergic populations which are lacking in
the wandering spider.
739
740 *AllatostatinA*:
741
742 In *U. diversus*, strong AstA-immunoreactivity is present on the posterior side of where the esophagus
743 closes, where a commissure is also seen crossing (Fig. S6f). Moving dorsally, this gives way to even more
744 synaptically dense areas, eventually highlighting the circular structure circumnavigated by thin projec-
745 tions, and forming an umbrella-like structure at the posterior side (Fig. S6g)– which is more comprehen-
746 sibly illuminated by anti-5-HT staining (Fig. S4g).
747
Heavy AstA-immunoreactivity was noted in the central/medial supraesophageal ganglion, for which
names of distinct regions and neuropils have been lacking (*50*). The best view of staining in this region is
a coronal slice, making a direct alignment to our images challenging, but the fact of substantial AstA-
immunoreactivity within the interior of the supraesophageal ganglion is consistent in *U. diversus* (Fig.

S6h). Within this plane the MB hafts are innervated, as previously detailed (Fig. 3), and ~7 AstA+ neurons
are present in the anterio-medial channel (Fig. S6h – arrows).

One structure that we identify are the tonsillar neuropils, the form of which AstA-immunoreactivity
abundantly fills out, resembling similar patterns as seen with 5-HT and TDC2 (Fig. S6i, Fig. 7c). A pair of
large, intensely stained AstA+ neurons are present alongside the neuropil, deep and medial within the
furrow of somata, and whose neurites enter the anterior aspect of the adjoining tonsillar neuropil (Fig.
S6i). The most dorsal AstA+ somata are a pair found laterally once the arcuate body emerges (Fig. S6j).

Contrary to the jumping spider (51), we did not see AstA-immunoreactive somata in the posterior cell
layer adjacent to the arcuate body. This region is prone to damage during preparation, but nevertheless,
AstA+ neurons were not seen here in any of our samples.

Proctolin:

On the posterior edge of the STb there is a thin Proc+ commissure while the anterior edge of the STb is
highlighted by a bolder vein of varicosities (Fig. S7e). Medial to the synapsin-negative channel through
which the protocerebral tract rises, there is a band of proctolin-immunoreactivity which occupies a
space that is not thoroughly labelled by any other target of this study (Fig. S7f).

A cluster of small, brightly immunoreactive proctolin+ neurons are evident at the level of the MB hafts
(Fig. S7g), with less immunoreactive but larger somata appearing dorsally around the MB heads (Fig. S7i
– arrow). Posterior to the cup-shaped synaptic-density formed by the MB hafts continuing with the rest
of the MB is a crescent of Proc-immunoreactivity (Fig. S7h), which also appears present in *C. salei* (52).
Here there is signal in the posterior, midline-spanning umbrella structure observed for 5-HT and TDC2,
as well as fine varicosities in the hagstone neuropil.

Just dorsally past the level of the MB heads, a strand of varicosities forms anteriolaterally (Fig. S7j –
brace) travelling into the center and splitting into a delta with one branch pointing medially, while the
other posteriorly (Fig. S7k). Dorsal still, this strand disappears and is overlayed at the delta by the arch-
ing varicosities which will form the dorsal posterior protocerebral commissure (Fig. S7l), as has been de-
scribed above.

At the plane of the protocerebral bridge Proc+ expression, 3-4 proctolin neurons are seen anteriorly,
near the midline (Fig. 8 – α-Proctolin, dorsal). Dorsal to this neuropil in the cap of somata, another 10 or
so clearly Proctolin-immunoreactive somata are dispersed centrally and laterally (Fig. S7m).

CCAP:
In general, CCAP-immunoreactivity resembles anti-ChAT staining in the sense that CCAP signal in the
supraesophageal ganglion is composed of intense but isolated puncta, showing expression in many are-
as, but generally lacking concentration in any given area (Fig. S8d,e). CCAP-immunoreactivity highlights
the ventral trajectory of the PCDt more prominently than other immunostains (Fig. S8f – arrow).

CCAP+ somata are numerous in the dorsal supraesophageal ganglion. They are found clustered posteri-
orly as well as directly dorsal to the ventral AB. A number of other CCAP+ somata which are spaced sin-
gularly apart from each other are present medially and anterior to the level of the dorsal arcuate body
(Fig. S8h). While CCAP expression has been identified in pre-optic neuropil (50), we could not discern
optic pathway expression reliably above background.

800
FMRFamide:

FMRFamide-immunoreactivity is saturated throughout the supraesophageal ganglion, making the
boundaries of individual features difficult to ascertain (Fig 17F, G). A similarly immunoreactively-dense
appearance was presented from slice work in *C. salei* (*52*). At the apex of the protocerebral commissure,
ventral to the dorsal arcuate body (ABd), is an approximately rectangular FMRFamide-immunoreactive
band (Fig. S9g – brace), representing a pattern of immunoreactivity which was not salient for any of our
other immunostained targets.

FMRFamide+ neurons are numerous and fairly evenly dispersed at the dorsal cap of the
supraesophageal ganglion (Fig. S9h). They are found in the area posterior and dorsal to the arcuate body
layer, as well as somewhat larger somata present in the anterior portion of the tissue. Again, while the
fainter FMRFamide+ neurons may not be fully apparent to us, the bright ones are comparable to the
number and distribution reported for *C. salei* (*53*).

815
816
Discussion:

Almost the entirety of spider CNS literature has been studied from tissue slices, with few examples of
whole-mounts (*8*, *9*, *23*, *35*). Our ability to observe novel structures and make comparisons between
innervation patterns was aided by whole-mount preparation and averaged brain alignment.
Furthermore, imaging and alignment of many neurosignaling molecule stains in a single species was
clarifying for the identification of novel structures, as a subset of stains crystalized putative boundaries.
While nine spider species have been the subject of examination for the expression pattern of an
individual neurosignaling molecules (*8*, *14*, *15*, *17*, *35*, *36*) the wandering spider, *C. salei,* is essentially
the only species prior to the current work to have had multiple targets annotated. Given the utility of
specific stains for understanding of neuropil structures, tracts and other features, this atlas provides a
rich source for comparative anatomy in an orb-weaving spider, *U. diversus*, while also extending
knowledge of a number of different neurosignaling pathways for spiders at large.

Mushroom bodies

As evident from synapsin volumes, the mushroom bodies of *U. diversus* are the most salient feature in
the central supraesophageal ganglion. The *U. diversus* MBs have a complete appearance, exhibiting an
attached haft region similar to visually-dependent spiders (*9*), and to which we find evidence of
innervation, albeit from an unknown origin. Historically, the MBs have at times been referred to as the
third-order visual neuropil, and have been discussed in the context of the visual pathways, which form
the subject of a substantial portion of the spider nervous system literature (*8*, *9*, *21*, *39*, *42*, *54*). The
optic neuropils of *U. diversus* are diminutive, which is consistent with hunting through
mechanosensation on a web. While we employed several neurotransmitter stains which have identified
upstream optic pathway elements (e.g. medulla, lamellae) in other species, these first and second-order
structures were not evident even in preparations where the labile tissue of the secondary pathway was
intact. The diminished nature of the optic pathways, but simultaneous presence of a distinct mushroom
body structure in *U. diversus* raises an incongruence concerning the role of the mushroom body. A
growing literature is suggestive of a deeper complexity, as examples of both cursorial and web-based

spiders can be found which either have or lack MBs (*9, 20*). The fact such synaptically dense structures
persist in spider species whose visual capacities seem all but irrelevant to their lifestyle indicates the
sensory input to the mushroom bodies may differ between species. The mushroom bodies of insects, as
most granularly understood in *Drosophila melanogaster*, were originally considered to be olfactory
integration centers, and while remaining the most apparent input, subsequent studies have shown this
center to also process multiple sensory modalities and influence behaviors not directly related to
olfaction (*55*). Evolutionary pressures on certain species may also force a 'modality switch', as evidenced
by the whirlygig beetle, *Dineutus sublineatus*, which has lost antennal lobes and instead have mushroom
bodies supplied by the optic lobe, displaying a transition from olfactory to visual processing (*56*). An
alternative hypothesis would be that mushroom bodies in web-building species may integrate other
sensory information, such as mechanosensation, relevant for web activities – which may also necessitate
learning and memory processes. Closer identification and annotation of the innervation patterns of non-
visual sensory streams leading to the MBs would strengthen such a viewpoint.

858
859 **Arcuate body**
860
The arcuate body, being unmistakable and consistently present among species, is perhaps the best
detailed structure in the spider brain, particularly in regards to innervation by neurotransmitter subtype
populations. By aligning volumes to a common reference, the present methodology allowed for
disambiguation of the layers innervated by specific signaling molecules and understanding of where
these patterns overlap. In *U. diversus*, we confirmed two broad lobular divisions, which each contain an
additional two major layers, supporting a number of structural motifs. Generalizing for the arcuate body
innervation patterns in *U. diversus* of specific neuronal populations, as compared to *C. salei* and a few
other species, one can conclude that there is a great degree of similarity, in the relative arrangement of
the gross layers, and even in certain fine structural details. In comparative studies, the arcuate body has
been found to compose a roughly proportionate percentage of the brain across the species examined –
be they web-builders or visually-based hunters (*19, 57*). It is thus assuredly involved in various spider
behaviors, and it will be illuminating to unravel how this conserved circuitry is harnessed for different
ethological needs. The arcuate body lobes have been previously compared to the two nested neuropils
known generally in insects as the upper and lower central bodies (*28, 36, 58*) and the architecture of *U.*
diversus supports these observations, showing obvious layering intersected by perpendicular neurites
and columnar-like patterns.

877
878 **Novel neuropils**
879
Structures which are conspicuous in our orb-building model spider but potentially not in hitherto
studied cursorial species may be indicative of areas which are important for web-building. Nevertheless,
it is not currently clear whether similar neuropils are absent in other species, or if they were simply not
apparent by prior techniques. Apart from the mushroom bodies and arcuate body, neuropil structures
within the interior of the supraesophageal ganglion have not been well distinguished. Multiple works
refer to a "central" or "protocerebral neuropil" seemingly in regards to the undifferentiated mass of the
supraesophageal ganglion as a whole. The image volume produced by aligning whole-mounted
synganglia immunostained against synapsin instead reveals an intricacy of structures, beyond those
described here. Two of the most conspicuous neuropils found in the dorsal supraesophageal ganglion
are the protocerebral bridge and the tonsillar (central) neuropils.

Our description and multi-target staining of the protocerebral bridge provides the clearest
demonstration of such a structure in the spider to date. The use of this name has a precedent within the
spider literature (*24*), although whether the referent structure in *C. salei* is the same as in our model
species will require additional clarification. Whether or not the authors chose this name in order to draw
a parallel to the insect protocerebral bridge is likewise ambiguous. The protocerebral bridge is a core
constituent of the insect central complex (*59*), but demonstrations in non-insect arthropods are scarcer.
Examples have been found in crustaceans, such as the crayfish *Cherax destructor* (*60*), as well as rock
slater *Ligia occidentalis* and sidestriped shrimp *Pandalopsis dispar*, the latter of which shows widely
arching, layered structure, stopping short of the midline (*61*). We find such an anterior midline structure
in *U. diversus*, possessing layers as revealed by antisera to neurotransmitter populations, and having a
thinning (to absent) midline crossing, reminiscent of disjointed PCBs in certain insects including
cockroaches and moths (insectbraindb.org). A columnar pattern is not as of now forthcoming in the *U.*
diversus protocerebral bridge, which may be a consequence of density, as columnar structures can be
difficult to see by immunohistochemistry (*59*), demonstrated by the fact that the PCB is no more
evidently columnar in cockroach than in the sidestriped shrimp when visualizing with the same antisera
to TRP (*61*).
906
A final undescribed neuropil which was apparent in the supraesophageal ganglia was the centrally
located, tonsillar neuropil. Based on the ovoid form, paired appearance close to the midline, and close
proximity to the unpaired midline neuropil(s) (arcuate body- ABv and Abd), the tonsillar neuropil bears a
general resemblance to the noduli, a smaller constituent of the central complex of pterygote insects
(*59*). To our knowledge, an analogous structure to this region has not been documented in non-insect
arthropods. Unlike the arcuate body and protocerebral bridge, neither a columnar nor layered
architecture is apparent in the tonsillar neuropil, although specific neurosignaling molecule stains
concentrate in certain domains, including a potential core and shell, as well as an anterior/posterior
division. Noduli in insects also contain compartments, and the presence of layering is species-dependent
(*59*).
917

A spider central complex?

Based on gross morphology, it is tempting to speculate that these novel neuropils, when considered
along with each individual lobe of the arcuate body may form an equivalent to a central complex in *U.*
diversus (Fig. 9). The central complex of insects is innervated and interconnected by tangential,
columnar and pontine neurons in insects, forming a consistently identifiable relationship between
neuropils across species (*62*). Apart from the crayfish (*60*), where neurons supplying the protocerebral
bridge also appear to innervate the central body, knowledge of intra-complex connectivity is lacking in
non-insect arthropods. A detailed study of the Onychophoran (velvet worm, sister to arthropods) brain
revealed several brain structures that appeared anatomically similar to those observed in arthropods
(*63*). However, whether these ganglia are functionally homologous is a matter of debate. Mushroom
body anatomy varies greatly across arthropods (*38*). While the Onychophoran central body is thought to
be truly homologous to the insect central body (and arcuate body in chelicerates), the frontal body
(which has gross similarities to the insect protocerebral bridge) appears to lack columnar organization
and lacks an obvious connection to the central body. No noduli were observed in the Onychophoran
brain, nor have they been observed in arthropod brains outside of insects. The tonsillar neuropils we
observe appear to share connectivity with the protocerebral bridge, but no clear connectivity with the
arcuate body. Since noduli have not been observed in non-insect arthropods (*59*), the anatomy of the

tonsillar neuropils may be coincidental, or convergently evolved to execute functions relevant to the
protocerebral bridge.

Given that many of the antisera used in this study do not consistently trace neurites, the connectivity
patterns between the neuropils of *U. diversus* supraesophageal ganglion require clarification. Future
investigations employing techniques capable of isolating the ramification patterns of individual neurons
within the context of the present neuropils in *U. diversus* will be essential to defining whether these
currently disparate structures are truly members of a complex, and to what extent the connectivity is
comparable to better studied arthropods. As a unit, the modules of the central complex integrate a
variety of information including present orientation with respect to a salient environmental feature,
memory of a heading goal, and speed – which can accomplish tasks such as path integration, migration,
and other goal-directed movements relevant to particular species (*64*). While occurring in a much more
spatially constrained context, these informational components could likewise be vital for organizing
movements during the process of web-building, as well as maintaining a conception of the 360-degree
web space as the spider strikes out to capture prey and subsequently return to the resting position at
the hub. In such a scenario for *U. diversus* and other orb-weavers, updates to present heading would
likely be provided by mechanosensation, rather than optic flow, which has been shown to contribute
even in insects which otherwise predominantly employ vision (*65*). The columnar segments of the
central bodies maintain a representation of the flies orientation within the environment in regards to a
given feature (*66*). Although the exact number of columnar elements in the spider arcuate body lobes
has not been established, they are numerous (with some suggestions in the thousands (*58*)), which
could support a much more refined representation of the animal's radial self-made realm, underlying
the often-stunning speed and precision with which the spider builds and navigates.

Materials and Methods:

Animals

Adult female *Uloborus diversus* spiders were used for all neuroanatomical preparations. Spiders were
housed freely in a green house, or as 1 – 4 individuals in acrylic habitats within the lab, under 12:12 light
dark cycles.

Immunohistochemistry

Spiders were anesthetized with carbon dioxide, and rapidly dissected in HEPES-buffered saline (HBS)
with 0.1% TritonX, and prepared for immunostaining following the methodology described by Ott
(2008). Samples were fixed overnight in ZnFA (2%) at 4° C. The following day samples were washed 3 x
10 minutes in HBS + 0.1% TritonX on a nutator. Samples were dehydrated in 80% methanol/20% DMSO
for 1 hour and 30 minutes, followed by 30 minutes in 100% methanol. A series of 5 minute incubations
in 90%, 70%, 50%, 30%, and 0% methanol in 0.1 M Tris was applied and the samples were blocked in 5%
normal goat serum, 1% DMSO, in PBS with 0.1% Triton (PBST) for at least 1 hour. Primary antibodies
were incubated for 3-5 days on a nutator at 4° C, before being washed with PBST for 3 x 15 minutes.
Secondary antibodies were applied in blocking solution and incubated for 2-3 days on a nutator at 4° C.
Secondary antibodies were washed off with 3 x 15 minutes washes with PBST, including DAPI (1:1000) in
one of the wash steps. The sample was dehydrated for mounting through a glycerol series of 2%, 4%,
8%, 15%, 30%, 50%, 70%, and 80% glycerol in 0.1 M Tris for 20 minutes each. Nutation was performed
for 2% through 15%, but only occasional hand agitation for the remaining steps. The sample was
protected from light. Following 30 minutes of washing with 100% ethanol, most of the ethanol was
pipetted off and the sample was underlayed with methyl salicylate, and allowed to sink, where it was
stored in the dark at room temperature until mounting.

For anti-TH staining, samples were dissected in Millonig's buffer with 0.1% TritonX, and fixed in 4% PFA
in PBS for 45 minutes at room temperature while nutating. Immunostaining proceeded as described by
Auletta et al., (2019). Samples were dehydrated and mounted in methyl salicylate by the steps used
above for all other antibodies.

Imaging

U. diversus synganglia were balanced upright, by placing samples subesophageal ganglia-side down in a
well of methyl salicylate. Wells were constructed by adhering nested metal washers to a glass coverslip
or slide using cyanoacrylate glue. A coverslip was also adhered to the top of the outer washer. Samples
were imaged using a Zeiss LSM700 or LSM880 confocal microscope, with a LD LCI Plan-Apochromat
25x/0.8 Imm Corr DIC M27objective (set to oil immersion), or a W Plan-Apochromat 20x/1.0 DIC D=0.17
M27 75mm water immersion objective, respectively.

Volume alignment

Alignment of confocal image volumes was performed using Elastix 5.0.1 (Klein et al., 2010, Shamonin et
al., 2014). Registration was performed first by a rigid method using an affine transform with an adaptive
stochastic gradient descent optimizer for 20000 iterations, with 40000 spatial samples at 5 resolution
levels. This was followed by a non-rigid registration using a bspline transform with a standard gradient
descent optimizer for 200000 iterations at 5 resolution levels and using the
AdvancedMattesMutualInformation metric. This was followed by a non-rigid registration using B-spline
transform with a standard gradient descent optimizer for 200000 iterations with 40000 spatial samples
at 5 resolution levels and using the AdvancedMattesMutualInformation metric. Transformation matrices
were established using the anti-synapsin stain as a registration channel. A preliminary subset of synapsin
volumes were mutually transformed onto each other, and the brain sample for which the most
satisfactorily aligned pairings resulted was selected as the reference brain, onto which all other
subsequent image volumes were aligned. The standard brain depicted in the figures above is an
averaged composite of 6 aligned synapsin volumes. The final transformation matrix generated by
registration of the synapsin channel, was then applied to other channels present for each sample image
volume (the neurosignaling target immunostains).

In limited cases, no satisfactory image volume alignment could be obtained based on the Elastix
parameters specified previously. In these cases, we manually applied a small correction to the Elastix

output (the "moving image") using radial basis function (RBF) interpolation. First, several location
correspondences were manually annotated in the reference and moving image. An additional N^3
regularly spaced location correspondences were automatically created where no manual annotation
was present within a 100-pixel distance, with N=ceil[Image Axis Length / 100]. The moving image
coordinates were subsequently transformed using RBF interpolation with a thin plate spline kernel.

Visualization

Annotations of neuropils were drawn using ImageJ and Napari (napari.org), and 3D renderings created
using Imaris 10.1 (Oxford Instruments). Renderings of z-planes on to the 3D synapsin volume were
created using VisPy (vispy.org)

Figure 1: Synganglion of *Uloborus diversus*.

(**A.**) 3D rendering of *U. diversus* (female) synganglion from averaged α-synapsin volume, oblique
posterior-lateral (left) and oblique anterio-lateral (right) views (**B.**) 3D rendering of α-synapsin (green)
and DAPI stained (blue) synganglion, posterior, lateral and anterior views (**C.**) Sequence of horizontal
optical slices from averaged α-synapsin (gray) volume with averaged DAPI stains (blue), from ventral
subesophageal ganglion (left) to dorsal end of supraesophageal ganglion (right). Compass abbreviations:
A = anterior, P = posterior, D = dorsal, V = ventral, L = lateral, M = medial.

1274

Figure 2: Overview of averaged α -synapsin immunoreactivity in whole-mount synganglion.

Sequence of optical horizontal sections from averaged α-synapsin volume, with top-right insets showing
position of respective slice in a 3D full volume rendering (**A. – I.**) Subesophageal ganglion, beginning
ventrally (**A.**) and progressing dorsally until (**I.**). Notable features include the leg neuromeres (LN1-4, for
respective legs 1-4), pedipalpal neuropil (PdN), cheliceral neuropil (ChN), opisthosomal neuropil (OpN,
which is still visible until (**L.**)), and the esophageal passage. (J. – T.) Supraesophageal ganglion, with
marked features including the stomodeal bridge (STb), protocerebral tract, protocerebral commissure
(PCC), hagstone neuropil (HsN), mushroom body (haft, body, and head), tonsillar neuropil, arcuate body
(ventral and dorsal lobes, ABv and ABd, respectively), and protocereral bridge (PCB).

1284

Figure 3: Mushroom bodies.

(**A.**) 3D rendering of mushroom body neuropil as annotated from averaged α-synapsin volume, dorsal
(top) and oblique posterior (bottom) (**B.**) Maximum intensity projection of averaged α-synapsin volume,
showing the mushroom bodies to be the most strongly immunoreactive structure in the
supraesophageal ganglion (**C.**) Optical sections of the supraesophageal ganglion from an averaged α-
synapsin volume (ventral (top) to dorsal (bottom). The haft, body and head regions of the MB are
labelled (**D.**) α-βTubulin3 (magenta) immunoreactivity aligned with α-Synapsin volume (gray) (compare
to bottom portion of previous subfigure) showing the arching form of the mid-line spanning mushroom
body bridge (**E.**) AllatostatinA immunoreactivity (α-AstA, green) present in the MB haft (pink dotted line
marking location of α-synapsin immunoreactivity) with arrows pointing to innervation from the
posterior side (**F.**) α-βTubulin3 (magenta) and α-Synapsin (green) immunoreactivity in the
supraesophageal ganglion at the plane where the mushroom body hafts appear (round, intensely
immunoreactive). Arrows mark a fiber tract flanking the haft which could be the origin of the
innervation in the preceding subfigure (**G.**) Tripart tract entering at the mushroom body head to fuse
with the tract descending through the MB.

1300

1301 **Figure 4: Visual pathways.**

1302 (**A.**) Immunostaining for α-HRP (magenta) for neuropil and use of DAPI (blue) for nuclei, arrows show the
1303 primary (▢) and secondary (▢▢) visual pathway extensions from the bulk of the supraesophageal tissue
1304 (**B.**) 3D renderings of synpasin-immunoreactivity in the dorsal supraesophageal ganglion, with tissue of
1305 the primary (▢) and secondary (▢▢) visual pathway visible.

1306

Figure 5: Arcuate body.

(**A.**) 3D rendering of arcuate body neuropil as annotated from averaged α-synapsin volume, posterior oblique, posterior, and anterior oblique views, left to right, respectively (**B.**) Individual 3D rendering of the ventral arcuate body lobe (ABv, dark green) and dorsal arcuate body lobe (ABd, light green), with magenta envelope representing space which would be occupied by the missing lobe in each image. Top row images are dorsal views, bottom row are oblique posterior (**C.**) Optical horizontal slices of α-synapsin immunoreactivity from the dorsal supraesophageal ganglion. Top image is relatively ventral to the bottom, and shows the ventral arcuate body lobe (ABv), while the bottom image features both the ventral and dorsal arcuate body lobe (ABd). Each lobe contains an anterior (ant.) and posterior (pos.) section, marked with yellow dashed lines (**D.**) Ventral (top) and dorsal (bottom) views showing aligned image volumes of Proctolin (α-Proctolin, yellow), Crustacean Cardioactive Peptide (α-CCAP, cyan) and FMRFamide (α-FMRFamide, red) immunoreactivity, demonstrating distinct structures as well as overlapping innervation of the arcuate body layers (**E.**) α-βTubulin3 (magenta) and α-Synapsin (green) immunoreactivity in the arcuate body (ventral to dorsal as top to bottom, respectively), with arrows marking where pronounced fiber tracts pass through the arcuate body layers (**F.**) Dorsal view of arcuate body showing layering in ABv and ABd (brace), for Proctolin (α-Proctolin, yellow) and Octopaminergic/Tyraminergic (α-TDC2, magenta) immunoreactivity which have overlapping but distinct innervation patterns in the anterior ABd.

1325

Figure 6: Arcuate body layers revealed by staining for specific neurosignaling populations.

Ventral (left column) and dorsal (right column) horizontal optical section views of the arcuate body (perimeter of whole arcuate body marked by dashed line) for GABAergic (α-GAD), Cholinergic (α-ChAT), Dopaminergic (α -TH), Serotonergic (α -5-HT), Octopaminergic/Tyraminergic (α-TDC2), AllatostatinA (α-AstA), Proctolin (α-Proctolin), Crustacean Cardioactive Peptide (α-CCAP), and FMRFamide (α-FMRFamide) immunoreactivity.

1332

Figure 7: Centrally-located, tonsillar neuropil.

(**A.**) 3D rendering of tonsillar neuropil as annotated from averaged synapsin immunovolume with posterior oblique, anterior oblique, and dorsal views, left to right (**B.**) Oblique horizontal optical section of supraesophageal ganglion with α-Synapsin (green) and α-βTubulin3 (magenta) immunoreactivity. The tonsillar neuropil is seen centrally, with the arrow denoting a fiber tract which passes medially across it (**C.**) Ventral and dorsal views of the tonsillar neuropil, as demarcated by dotted lines. Synapsin (gray), Serotonergic (α-5-HT, green), Octopaminergic/Tyraminergic (α-TDC2, magenta), Proctolin (α-Proctolin, yellow), AllatostatinA (α-AstA, green) and FMRFamide (α-FMRFamide, red) immunoreactivity.

1341

Figure 8: Protocerebral bridge neuropil.

(**A.**) 3D rendering of protocerebral bridge neuropil as annotated from averaged synapsin immunovolume. (**B.**) Ventral and dorsal views of the PCB, as demarcated by dotted lines. Synapsin (gray), GABAergic (α-GAD, red), Octopaminergic/Tyraminergic (α-TDC2, magenta), Proctolin (α-Proctolin, yellow), Cholinergic (α-ChAT, cyan) and AllatostatinA (α-AstA, green) immunoreactivity. Arrows point to posterior protocerebral commissure.

Figure 9: A potential central complex in *U. diversus*

(**A.**) 3D renderings of averaged U. diversus synganglion with annotations of potential central complex constituents in shades of green (protocerebral bridge, arcuate body lobes, tonsillar neuropil), also showing the mushroom body (purple) (**B.**) 3D neuropil renderings from of neuropils of the central complex as found in the insects *Rhyparabia maderae*, *Scarabaeus lamarcki*, and *Manduca sexta* (images from insectbraindb.org)

Fig. S1: Cholinergic population expression pattern (α-ChAT immunoreactivity)

α-ChAT (cyan) and α-synapsin (gray) immunoreactivity across the synganglion, top part of image is posterior and bottom is anterior (**A.**) ventral subesophageal ganglion displaying medially located ChAT+ somata of various sizes and staining intensity, as well as somata between leg neuromeres (**B.**) further dorsal slice in the subesophageal ganglion showing abundant staining throughout, arrows mark small intensely ChAT+ somata just ventral to the pedipalpal neuropil (**C.**) overlay with synapsin-immunoreactivity in the subesophageal ganglion (**D.**) anteriorly located cluster of the most intensely ChAT+ somata in proximity to the esophageal passage closure (**E.**) plane dorsal to esophageal closure, with immunoreactivity in the stomodeal bridge, opisthosomal neuropul and protocerebral tract (**F.**) supraesophageal ganglion expression at the plane of the mushroom bodies (**G.**) plane just dorsal to the mushroom body heads, showing putative globuli cells (arrows) within the protrusion of the secondary visual pathway, DAPI stain (red) (**H.**) further dorsal supraesophageal slice, large arrow marks a couple of very large, strongly stained ChAT+ neurons, smaller arrow shows medially located smaller ChAT+ somata, and arrowheads point to string of ChAT+ somata in the posterior cell layer (**I.**) far dorsal end of supraesophageal ganglion showing dispersed ChAT+ somata in the dorsal cap. Arrows indicate arcs of immunoreactivity part of the protocerebral bridge.

Fig. S2: GABAergic population expression pattern (α-GAD immunoreactivity).

α-GAD (red) and α-synapsin (gray) immunoreactivity across the synganglion, top part of image is posterior and bottom is anterior. Lack of signal in interior of tissue is due to poor penetrance of this antibody (**A.**) GAD-immunoreactive somata in the far ventral subesophageal ganglion (**B.**) in a more dorsal plane (**C.**) GAD+ somata ventral to the opisthosomal neuromere (**D.**) GAD-immunoreactivity at the level of the stomodeal bridge, showing ample somata anteriorly, and innervation of the opisthosomal neuropil (**E.**) split views of GAD and synapsin immunoreactivity at the level of mushroom body heads, with arrow indicating a (**F.**) supraesophageal ganglion view at the level of the tonsillar neuropil showing a grouping of GAD+ somata appearing in the medio-lateral axis (**G.**) dorsal supraesophageal ganglion view revealing columns of GAD+ somata on the anterior side as well as

1383 dispersed somata along the arcuate body, immunoreactivity of the protocerebral bridge centrally, and
1384 faintly visible neurites crossing perpendicular to the arcuate body layers.

1385

Fig. S3: Dopaminergic population expression pattern (α-TH immunoreactivity).

α-TH (green) immunoreactivity across the synganglion, top part of image is posterior and bottom is
anterior (**A.**) TH+ somata in the ventral subesophageal ganglion, with brightened view on right. The
approximate boundary of the tissue marked by the dotted line. Each leg neuropil is associated with a
cluster of somata made of a smaller, more numerous population (arrowheads), and 1-2 larger neurons
(arrows) (**B.**) maximum projection focus on the mesh-like filling of leg neuropils by TH varicosities,
dotted line showing perimeter of leg neuropil 2, as an example (**C.**) Fibers of the ventral-most tract
travelling parallel to the midline and showing commissures. Arrows mark a cluster of somata ventral to
the pedipalpal neuropil which project to the pedipalpal and cheliceral commissures (**D.**) further dorsal
view of the subesophageal ganglion, the thicker medial tracts running in the anterio-posterior axis are
part of the intermediate-tracts (as defined by Auletta et al., 2019(*4*)), the thinner lateral tract (left side)
is part of the ventral-most tract (**E.**) fully visible intermediate-tract, containing a chiasm is seen medially,
the ventral tract fibers are lateral and also give rise to 6 major midline crossing commissures,
representing the 4 leg neuropils and pedipalpal and cheliceral neuropils. Somata ventral to the
opisthosomal neuropil are seen posteriorly (**F.**) Tandem clusters of two pairs of TH+ somata (arrows)
adjacent to the closure of the esophageal passage, with immunoreactivity visible in the stomodeal
bridge (asterisk) just posteriorly. Arrowhead marks the descending projection of the 4 lateral neurons,
presented in the next two subfigures. Opisthosomal neuropil immunoreactivity (brace) shows thick
tracts on the perimeter, and crossing fibers internally, as well as somata on the lateral aspect. (**G.**)
maximum projection of ventral supraesophageal, arrows marking an additional cluster of 5 TH+ somata,
dorsal to the preceeding subfigure. (**H.**) Four neuron lateral cluster (arrow) giving rise to projections
joining within the protocerebral dorsal tract as well as a subset descending to the intermediate-tract of
the subesophageal ganglion (**I. – J.**) Max projection views of the dorsal supraesophageal ganglion where
a single (arrows) and doublet (arrowheads) contribute substantially to the TH immunoreactivity in this
region, with the doublet population arching laterally to join the PCDT, and single medial neuron also
contributing, while innervating the arcuate body layer seen in (**K.**) where a cluster of 2 or 3 TH+ somata
are found centrally, which do not have a counterpart in previously examined species.

1413

Fig. S4: Serotoninergic population expression pattern (α-5-HT immunoreactivity).

α-5-HT (green) and α-synapsin (gray) immunoreactivity across the synganglion, top part of image is
posterior and bottom is anterior (**A.**) ventral subesophageal ganglion where clusters of ~5 somata
positive for 5-HT are seen at the medial aspect of the leg neuropils (**B.**) further dorsal subesophageal
ganglion plane showing pattern of neuropil innervation (brace) comprised of a posterior and anterior
half, leaving a dearth of signal in the center of the neuropil (**C.**) 5-HT+ somata present anteriorly
(arrows), ventral to the pedipalpal neuropil, pathways of the ventral-tract appear internally (**D.**) 5-HT
immunoreactive somata (arrows) with thick neurites found ventral to the opisthosomal neuropil (**E.**)
beginning planes of the supraesophageal ganglion showing a bridging commissure on the posterior side,
with pronounced immunoreactivity in the adjacent region (**F.**) multiple strong 5-HT+ puncta adjoin the

protocerebral tract synapsin densities suggesting 5-HT fibers are a part of this tract. A distinctive circular
structure forms (**G.**) through arches of innervation travelling medially to midline varicosities (**H.**) which
all intersect, beginning innervation just anteriorly of the hagstone neuropil. In the posterior
supraesophageal ganglion at this plane an umbrella-like structure of fine varicosities appears (**I.**)
Continuation of the umbrella-like structure found posteriorly, with expanding immunoreactivity in the
hagstone neuropil (brace) found aside the midline (**J.**) strongly immunoreactive 5-HT neurons near the
plan of the mushroom body head, whose neurites innervate the area found laterally to the somata. (**K.**)
faint evidence of 5-HT+ populations in the far dorsal supraesophageal ganglion, 5-HT immunoreactivity
in layers of arcuate body seen posteriorly.

1433

Fig. S5: Octopaminergic/Tyraminergic population expression pattern (α-TDC2 immunoreactivity).

α-TDC2 (magenta) and α-synapsin (gray) immunoreactivity across the synganglion, top part of image is
posterior and bottom is anterior (**A.**) ventral subesophageal ganglion horizontal optical slice showing
medial clusters of TDC2+ somata corresponding to each leg neuropil (**B.**) maximum intensity projection
of ventral subesophageal ganglion demonstrating an anterior/posterior division in innervation pattern
within each leg neuropil, with sparse heavy puncta posteriorly and denser but diffuse patterning
anteriorly (**C.**) Bright TDC2+ somata (arrows) ventral to the opisthosomal neuropil, TDC2+
immunoreactivity in the medial fiber tracts and pedipalpal neuropil (**D.**) horizontal optical slice showing
opisthosomal neuromere posteriorly, and anteriorly the region ventral to the closure of the esophageal
passage. Anteriolaterally, TDC2+ immunoreactivity is seen in the cheliceral neuropil. A triangular
strucuture (brace) is formed as strings of puncta travel posteriorly to become heavier on the lateral
perimeters of the opisthosomal neuropil. Interiorly there is a ring-like structure and chiasm with fine
spoke neurites connecting to it (**E.**) the same view as preceeding but overlayed onto α-synapsin
immunoreactivity (**F.**) maximum intensity projection encompassing a span from the level of the
esophageal passage to the appearance of the bridge, where a cluster of 15-20 TDC2+ somata are found
(arrows). The opisthosmal neuropil displays strings of immunoreactivity along the borders, roughly
parallel to the midline, as well as travelling laterally across the halves of the neuropil (**G.**) TDC2+
immunoreactivity is present in the stomodeal bridge, seen immediately posterior to the somata clusters.
In the opisthosomal neuropil, pronounced tracts run along the length of the midline, with a fine arching
commissure at the posterior end (arrow). (**H.**) maximum intensity projection of planes just dorsal to the
preceeding figure demonstrate a lateral nested pathway of longitudinal puncta, and an additional strand
positioned in the medial-lateral direction (brace) (**I.**) supraesophageal ganglion plane at the level of the
MB hafts displays ample TDC2+ immunoreactivity, with presence in the umbrella-like structure at the
posterior side, sparser puncta within the bounds of the hagstone neuropil, and signal found anterio-
medially to the mushroom body (**J.**) which continues in these areas dorsally to the level of the
mushroom body heads, where strands of immunoreactivity also follow the contours of the lateral edges
of the supraesophageal ganglion (**K.**) α -TDC2 (magenta) and α -5-HT (green) immunoreactivity overlaps
in the centrally located tonsillar neuropil, showing TDC2+ signal in a peripheral pattern, with more 5-HT+
immunoreactivity at the center of the neuropil. (**L.**) subesophageal ganglion plane at the level of the
arcuate body and protocerebral bridge, with magnification focusing on a series of puncta (arrows) which
might be indicative of innervation to or passage by the tonsillar neuropil (**M.**) Further dorsal maximum
intensity projection from supraesophageal ganglion, with TDC2+ somata (arrow), and innervation
patterns of the ventral and dorsal arcuate body lobes visible posteriorly.

1467

Fig. S6: AllatostatinA population expression pattern (α-AstA immunoreactivity).

α-AstA (green) and α-synapsin (gray) immunoreactivity across the synganglion, top part of image is
posterior and bottom is anterior (**A.**) ventral subesophageal ganglion slice with clusters (arrow) and
individual AstA+ somata (**B.**) maximum intensity projection of planes in the subesophageal ganglion
revealing AstA+ varicosities in the posterior halves of the leg neuropils (**C.**) AstA+ immunoreactivity in
lateral branches of the centro-lateral tract, supplying the leg neuropils (**D.**) a section of AstA+
immunoreactivity is visible adjacent to the esophagus (brace) with (**E.**) thin neurites at the crossing of
the stomodeal bridge (arrow). Paired longitudinal strands of puncta are seen extending into the
opisthosomal neuromere, posteriorly (**F.**) a more robust commissure and appreciable immunoreactivity
is seen on the posterior side of the ventral supraesophageal ganglion (**G.**) Medially-arching circular
pattern of AstA+ immunoreactivity in the posterior supraesophageal ganglion, similar to 5-HT signal in
the same region (**H.**) Plane of supraesophageal ganglion at the level of the mushroom body hafts,
showing strong expression on the posterior side, AstA+ immunoreactivity encompassing the umbrella-
like form seen in other stains (5-HT, TDC2). A cluster of ~7 AstA+ somata are visible in the anterior field
(arrows) (**I.**) a pair of large, intensely AstA+ somata are present deep within the furrow of the anterior
somata field, sending neurites into the immediately posterior tonsillar neuropil, whose shape is
distinguishable (**J.**) Just dorsally, the centrally located tonsillar neuropil is still visible, as the arching
posterior protocerebral commissure is visible laterally and posteriorly. A pair of AstA+ somata are
present laterally. (**K.**) AstA+ innervation of the posterior side of the ventral arcuate body (ABv), with
circular units of immunoreactivity visible on the posterior edge (arrowheads), suggestive of columnar
structure.

1489

Fig. S7: Proctolin population expression pattern (α-Proctolin immunoreactivity).

α-Proctolin (yellow) and α-synapsin (gray) immunoreactivity across the synganglion, top part of image is
posterior and bottom is anterior (**A.**) maximum intensity projection of ventral subesophageal ganglion
showing a single brightly Proctolin+ neuronal cell body per each leg neuropil. More faintly labelled
Proctolin+ somata are also visible (**B.**) Optical plane in the subesophageal ganglion at the level of the
pedipalpal neuropil, showing a cluster of Proctolin+ somata (arrow) and a concentration of signal in the
immediately posterior-medial vicinity. Small Proctolin+ somata are also seen in the field ventral to the
opisthosomal neuropil (arrowheads). (**C.**) further dorsal view of the subesophageal ganglion at the level
of commissures of the major dorsal tract. Densely-immunoreactive pair of roughly circular shapes
(arrow) represent a tract which is rising directly dorsally (**D.**) Proctolin+ immunoreactivity is present in
the opisthosomal neuropil, covering similar trajectories as other immunostains (e.g. TDC2), but in a
more fragmentary manner (**E.**) Optical section at the level of the stomodeal bridge, featuring Proctolin
immunoreactivity crossing the midline on the anterior and posterior bounds of the bridge. Proctolin
immunoreactivty is also seen concentrated adjacent to the midline on the posterior side of the emerging
supraesophageal ganglion, which is seen further dorsally (**F.**) in addition to immunoreactivity in a patch
medial to the synapsin-negative channel through which the protocerebral tract travels, a zone not
obviously present with other immunostains. (**G.**) Proctolin+ somata become visible in the anterior
somata field beginning at the level of the mushroom body hafts, where Proctolin immunoreactivity is
concentrated posteriorly about the midline, and the hagstone neuropil is also highlighted. (**H.**) Further

dorsally as the mushroom body develops, crescents of Proctolin immunoreactivity are nested within the
cup-shape structure formed by the mushroom body hafts and body, which is also a distinctive feature of
α-Proctolin staining. Somata continue in the anterior furrow, likewise (**I.**) further dorsally where faint
Proctolin+ somata (arrow) are present at the level of the mushroom body heads (**J.**) At this level too, as
shown in a maximum intensity projection of the neighboring planes, a strongly immunoreactive strand
of varicosities begins anterio-laterally (brace) (**K.**) continuing posterior-medially, to bifurcate into a
medial and posterior facing branch (brace). Proctolin immunoreactivity is seen centrally in the posterior
aspect of the tonsillar neuropil. (**L.**) maximum intensity projection spanning planes in the previous
subfigure as well as dorsal ones overlays a dorsal strand of immunoreactivity which we describe as a
dorsal posterior protocerebral commissure, crossing the midline just anterior to the arcuate body (**M.**)
maximum intensity projection of planes of far dorsal supraesophageal ganglion showing Proctolin+
somata distributed centrally and laterally, layering pattern of the ventral and dorsal arcuate body lobes
is also visible posteriorly.

1522

Fig. S8: Crustacean cardioactive peptide population expression pattern (α-CCAP immunoreactivity).

α-CCAP (red) and α-synapsin (gray) immunoreactivity across the synganglion, top part of image is
posterior and bottom is anterior (**A.**) maximum intensity projection of ventral supraesophageal ganglion
showing clustering of CCAP+ somata (**B.**) further dorsal plane showing sparsely located CCAP+ somata,
as well as the immunoreactivity pattern within the leg neuropils made of a evenly-spaced distribution of
bright puncta but only in the posterior portion of each neuropil (**C.**) CCAP immunoreactivity is visible
anteriorly around the pedipalpal neuropil, and faint CCAP+ somata are also seen in the area ventral to
the opisthosomal neuropil (arrow). (**D.**) Horizontal optical slice at the plane of the stomodeal bridge
showing where CCAP immunoreactivity is present. Dense staining is also apparent in the opisthosomal
neuropil (**E.**) Supraesophageal ganglion plane at the level of the mushroom bodies where CCAP
immunoreactivity is punctate broadly across the tissue, with some concentrations in the posterior
umbrella-like structure and the anterior bounds of the hagstone neuropil (**F.**) Supraesophageal ganglion
plane at the emergence of the ventral arcuate body lobe, with arrow marking the ventral trajectory of
the PCDt (**G.**) maximum intensity projection of planes in the vicinity of the ventral arcuate body lobe,
showing clustering of CCAP+ somata deep and medial in the anterior furrow of neuronal cell bodies (**H.**)
dispersed CCAP+ somata at the dorsal end of the supraesophageal ganglion, with abundant CCAP
innervation of all layers of the arcuate body seen posteriorly.

1540

Fig. S9: FMRFamide population expression pattern (α-FMRFamide immunoreactivity).

α-FMRFamide (red) and α-synapsin (gray) immunoreactivity across the synganglion, top part of image is
posterior and bottom is anterior (**A.**) ventral subesophageal ganglion showing distribution of
FMRFamide+ somata (**B.**) FMRFamide immunoreactivity in the leg neuropils and somata present among
the cell bodies ventral to the opisthosomal neuropil (arrows) (**C.**) a dorsal subesophageal plane at the
level of the major neuropil commissures showing FMRFamide immunoreactivity (**D.**) FMRFamide+
somata in the anterior cell body wall (arrows), with immunoreactivity around the cheliceral neuropil.
FMRFamide innervation of the opisthosomal neuropil is also apparent (**E.**) continuing dorsally, at the
plane of the stomodeal bridge (**F.**) FMRFamide immunoreactivity is extensive across the

supraesophageal ganglion, as seen for the plane of the mushroom body (**G.**) as well as further dorsally
where the arcuate body emerges. An approximately rectangular pattern of immunoreactivity (brace) is
seen posterior to the tonsillar neuropil, which is distinctive to FMRFamide immunoreactivty. FMRFamide
signal is seen posteriorly in both sublayers of the ventral arcuate body (**H.**) while a pronounced layer of
FMRFamide immunoreactivity appears in the posterior aspect of the dorsal arcuate body layer.
FMRFamide+ somata are abundantly distributed across the dorsal end of the supraesophageal ganglion.
