Abstract

The ability to determine how much the environment can be controlled through our actions has long been viewed as fundamental to adaptive behavior. While traditional accounts treat controllability as a fixed property of the environment, we argue that real-world controllability often depends on the effort, time and money we are able and willing to invest. In such cases, controllability can be said to be *elastic* to invested resources. Here we propose that inferring this elasticity is essential for efficient resource allocation, and thus, elasticity misestimations result in maladaptive behavior. To test these hypotheses, we developed a novel treasure hunt game where participants encountered environments with varying degrees of controllability and elasticity. Across two pre-registered studies (N=514), we first demonstrate that people infer elasticity and adapt their resource allocation accordingly. We then present a computational model that explains how people make this inference, and identify individual elasticity biases that lead to suboptimal resource allocation. Finally, we show that overestimation of elasticity is associated with elevated psychopathology involving an impaired sense of control. These findings establish the elasticity of control as a distinct cognitive construct guiding adaptive behavior, and a computational marker for control-related maladaptive behavior.

Introduction

Taking action requires us to invest resources, such as time, money, and effort, and is thus only
sensible if our actions have the potential to change the environment to our advantage. Accurate
estimation of this potential – that is, of the environment's controllability[1-4] – enables us to make
informed decisions as to whether to engage in action[5-7]. Misestimations of controllability thus
result in maladaptive behavior, and contribute to mental health disorders such as depression,
anxiety, and obsessive-compulsive disorder[8-12].

The degree of control we possess over our environment, however, may itself depend on the
resources we are willing and able to invest. For example, the control a biker has over their
commute time depends on the effort they are willing and able to invest in pedaling. Likewise, the
control a diner in a restaurant has over their meal may depend on how much money they have to
spend. In such situations, controllability is not fixed but rather *elastic* to invested resources (i.e.,
in the same sense that supply and demand may be elastic to changing prices[13]). Importantly, high
controllability need not imply high or low elasticity. Controllability can be high, yet inelastic to
invested resources – for example, when choosing among equally priced bus routes to work
(Figure 1).

Figure 1. Examples of inelastic vs elastic control: Top – Choosing one of three equally priced public transport routes provides inelastic control over commute time, whereas the control of biker over commute time is elastic to the effort they invest in pedaling. **Middle –** A diner has either inelastic or elastic control over their lunch depending on whether the restaurant offers a fixed-price lunch deal, or a standard menu where dishes vary in price. **Bottom –** the probability of winning in blackjack is inelastic to money, as it only depends on whether one hits or stands, whereas when playing roulette, one can increase the probability of winning by investing more coins to cover more possible outcomes. Importantly, most real-world scenarios lie on a spectrum between these illustrative extremes, such that controllability is partly elastic and partly inelastic.

Knowing the elasticity of control is necessary for deciding whether and how to act. Failing to
achieve one's goal, for example, should only lead one to invest more resources in an elastic
environment. Critically, in many real-life domains (e.g., studying for an exam), we must use our
experiences to infer the degree to which we can improve our outcomes by investing more
resources[16-20]. Failure to do so is bound to result in maladaptive behavior, and may thus
contribute to mental health disorders. Depressed patients, for instance, are less willing to expend
their resources to obtain control[21,26-27], which could result from an underestimation of elasticity.
Conversely, the repetitive actions that characterize obsessive compulsive disorder patients[24]
could indicate that such patients overestimate elasticity, believing that the additional efforts they
invest will yield progressively better outcomes. Ultimately, not having a good grasp of how
one's additional efforts influence outcomes is bound to undermine one's sense of agency [14-15].

Thus, here we ask whether and how people infer the elasticity of control over their environment.
We hypothesize that individual differences in elasticity inference lead to a mismanagement of

one's resources when attempting to control the environment, and are thus associated with
psychopathologies involving a distorted sense of control[21-23].

Experimental paradigms to date have tested elasticity and controllability as coupled, such that
controllability was either low or elastic[16-20]. Elasticity, however, must be dissociated from
controllability to accurately diagnose mismanagement of resources. A given individual, for
instance, may tend to overinvest resources because they overestimate controllability – for
example, exercising due to a misguided belief that this can make one taller. Alternatively, they
may do so because they overestimate the elasticity of control – for example, a chess expert
practicing unnecessarily hard to win against a novice. In this latter example, the amount of effort
the expert chooses to invest would not change their level of control over the match's outcome.
Diagnosing the former source of mismanagement of resources requires a manipulation of
controllability, whereas diagnosing the latter requires manipulating the elasticity of control.

Therefore, here we dissociate elastic and inelastic controllability using a novel treasure-hunt
game where participants encountered three distinct environments: The first offered *high elastic*
controllability, where a high level of control can only be attained by investing extra resources.
The second offered *high inelastic controllability*, where control is attainable with any level of
resource investment. And the third offered *low controllability*, where control was not attainable
despite any level of resource investment. In each environment, participants were allowed to
invest various amounts of resources to pursue reward or to altogether forgo pursuing reward.
Examining how participants adapted their resource investment to observed outcomes enabled us
to determine whether and how participants inferred each environment's controllability and its
elasticity.

Across two pre-registered studies (N = 514), we establish that people do indeed infer the
elasticity of control. We present a computational model that explains how people make this
inference, and identify individual biases in its implementation. We thus show that elasticity
overestimation leads to an overinvestment of resources and is associated with elevated
psychopathology involving an impaired sense of control. These findings establish the elasticity
of control as a distinct inference guiding adaptive behavior, and a computational marker of
control-related psychopathology.

Results

We had online participants (first study = 264, replication study = 250, ages =18-45, Mean 33 ±
.6) play a novel treasure-hunt game set across multiple planets. On each trip (trial), participants
attempted to travel from an initial location ('desert' or 'fountain') to a treasure (worth 150 coins),
located at either the house or the mountain (Figure 2A). Participants could exercise control by
boarding the train to reach the house, or the plane to reach the mountain (right-side Figure 2B).
The present planet's controllability determined the probability that participants would succeed in
boarding the vehicle they selected. In high-controllability planets, participants consistently
boarded their preferred vehicle, enabling them to reliably reach their destination. Conversely, in
low-controllability planets, participants frequently failed to board and were thus forced to walk
to the nearest location, where the treasure was located in only 20% of trials.

To investigate elasticity learning, we allowed participants to invest different amounts of resources in attempting to board their preferred vehicle. Specifically, participants could purchase one (40 coins), two (60 coins), or three tickets (80 coins) or otherwise walk for free to the nearest location. We defined inelastic controllability as the probability that even one ticket would lead to successfully boarding the vehicle, and elastic controllability as the degree to which two extra tickets would increase that probability. Participants were informed that a single ticket allowed them to board the vehicle only if it stopped for them at the station, but that they may be able to increase their chances of boarding by purchasing extra tickets. Each additional ticket awarded participants an attempt to jump onto the moving vehicle after it had already left the main platform (Figure 2C). At the end of each trip, participants were shown where they arrived at, enabling them to infer whether they successfully boarded their vehicle.

To dissociate elasticity from inelastic controllability, each participant visited three randomly sampled planets. In the first planet, controllability was high and inelastic, meaning that no matter how many tickets you purchased, you had a good chance of making your ride (sampled from green area in Figure 2D). In the second planet, controllability was high and elastic, meaning that you needed to purchase two extra tickets to have a good chance of making your ride (Figure 2D, blue). And in the third planet, controllability was low, meaning that no matter how many tickets you purchased, you did not have a good chance of making your ride (Figure 2D, red).

Importantly, the order of these planets was randomized, and participants did not know in advance which planet they were visiting. Thus, they could only infer a planet's controllability and elasticity from the outcomes of their actions. Moreover, to increase sensitivity to individual biases, we had all participants visit a fourth planet where purchasing any number of tickets (0, 1, 2, 3) was equally optimal (Figure 2D, black circle). We also homogenized participants' initial learning experiences by giving them three free tickets for the first five visits to every planet. As we shall see below, this latter measure also helped dissociate between different models of how participants solved the task.

Figure 2. Experimental design: (A) **Goal.** On each trip to a planet, participants' goal was to reach a treasure located either at the house or the mountain (B) **Transition rules.** Participants could exercise control by boarding either the plane or the train to a destination of their choice, whereas missing the ride sent the participant walking to the nearest location (which happened to be the treasure location in only 20% of trials). (C) **Trip structure.** At the beginning of each trip, participants selected whether to purchase 1, 2, or 3 tickets to attempt to board their vehicle of choice, or walk for free to the nearest location. If the participant purchased at least one ticket, they were allowed to choose between the plane and the train. Then, for each additional ticket purchased, the participant was given an opportunity to increase their chances of boarding the vehicle. Specifically, the chosen vehicle appeared moving from left to right across the screen, and the participant attempted to board it by pressing the spacebar when it reached the center of the screen. At the end of the trip, participants were shown where they arrived at, allowing them to infer whether they successfully boarded the vehicle. (D) **The space of possible planets.** Planets varied in inelastic controllability – the probability that even one ticket would lead to successfully boarding the vehicle – and in elastic controllability – the degree to which two extra tickets would improve the probability of successfully boarding the vehicle (one extra ticket provided half the benefit). The color corresponds to the optimal number of tickets (0, 1 or 3) in each planet. The darker the color the higher the advantage in expected value gained by purchasing the optimal number of tickets relative to the second-best option. Each participant made 30 consecutive trips in one planet from the green area, one planet from the blue area, one planet from the red area, and one planet with identical characteristic across all participants (black circle).

People adapt to the elasticity of control

To determine whether participants inferred elasticity, we first examined how they adapted their
resource investment across planets. We found that participants were more likely to purchase
tickets ('opt in') in more controllable planets, whether controllability was elastic (Initial and

Replication studies, $p<.001$; mixed logistic regression) or inelastic (Initial and Replication
studies, $p <.001$; Figure 3A&C). Conversely, participants purchased more extra tickets only in
planets with high elastic controllability (Initial $p =.01$, Replication $p=.004$; mixed probit
regression; Figure 3B&C). Although substantial individual differences were observed in this
regard (Figure 3D), these results show that most participants successfully adapted to the
controllability and elasticity of the environments they visited.

Figure 3. Participants adapted to the elasticity of control: Results from initial (N = 264) and replication (N = 250) studies. (A) **Opt-in percentage across all planets.** Participants opted-in more frequently on controllable planets (outlined in blue and green) than on uncontrollable planets (outlined in red) (B) **Extra tickets purchased across all planets.** Participants purchased more extra tickets in planets with high elastic controllability (outlined in blue). An average of 11 to 12 participants visited each planet in each of the studies. (C) **Effect of elastic and inelastic controllability on opting in and the purchasing of extra-tickets.** Bars show estimated fixed effects and 95% CIs from mixed logistic (opt-in) and probit (extra tickets) regressions. (D) **Individual differences.** Distribution of participants by opt-in rate (top) and average number of extra tickets purchased (bottom) across both studies, shown separately for planets with low controllability (red), high inelastic controllability (green), and high elastic controllability (blue).

People infer the elasticity of control

That participants adapted to elasticity does not necessarily mean they inferred elasticity.
Successful adaptation may also be achieved merely by treating each possible level of resource
investment as a separate course of action. One could thus learn the degree of control afforded by
each course of action (i.e., purchasing 1, 2, or 3 tickets), and then choose the one that affords the
highest expected value considering its cost. This simple strategy could achieve optimal
performance given unlimited experience. However, it would not be as efficient as a strategy that
employs elasticity inference, because it does not make use of the dependencies that exist between
different levels of resource investment in the degrees of control they afford. Thus, upon failing to
board a vehicle despite purchasing 3 tickets, the simpler strategy would need to purchase 1 or 2
tickets to know these options would fail as well, whereas an agent equipped with the concept of
elasticity would conclude that controllability is low, and it is thus best to opt out. Conversely,
upon succeeding to board with 3 tickets, the simpler strategy would tend to favor purchasing 3
tickets, over 1 or 2 tickets, even if the extra tickets confer no benefit, whereas an agent that infers
elasticity would not favor 3 over 1 or 2 tickets because it received no evidence that
controllability is elastic (i.e., that the extra tickets help).

To determine which of these models best describes the way participants solved the task, we
formalized the simpler strategy as the 'controllability model', and an elasticity-inferring strategy
as the 'elastic controllability model' (pre-registration: https://aspredicted.org/CHW_12H). Both
models use beta distributions, characterized by parameters *a* and *b,* to represent the probability of
boarding when purchasing different numbers of tickets, but only the elastic controllability model
learns latent elasticity estimates. Specifically, in the 'controllability model', three beta
distributions represent the expected level of control from purchasing 1, 2, or 3 tickets. Thus, the
parameters of these distributions ($a_n, b_n, n \in \{1, 2, 3\}$) accumulate the number of times each
number of tickets led (a_n) or did not lead (b_n) to successful boarding. Conversely, in the 'elastic
controllability model', the beta distributions represent a belief about the maximum achievable
level of control ($a_{control}, b_{control}$) coupled with two elasticity estimates, specify the degree to
which successful boarding requires purchasing at least one ($a_{elastic \geq 1}, b_{elastic \geq 1}$) or specifically
two ($a_{elastic2}, b_{elastic2}$) extra ticket. Figure 4 shows schematically how the two models differ in
updating their estimates in response to different types of outcomes. Both models similarly use
these estimates to compute an expected value for purchasing 0, 1, 2, or 3 tickets, and accordingly
choose between these options (see Methods, pg. 20-23, for model equations).

Figure 4. Computational models: Illustration of the learning rules of the *controllability* and *elastic controllability* models. The width of the colored region represents the estimated control, shown as a percentage of absolute control (gray area) along with the update rules based on each outcome.

(A) **Controllability model:** This model treats the purchase of 1, 2, and 3 tickets as distinct actions. It accumulates evidence for the effectiveness (a) or lack of effectiveness (b) of each action based solely on whether or not the action led to successful boarding, illustrated by changes in the width of the shaded region corresponding to each ticket amount.

(B) **Elastic Controllability model:** Represents beliefs about maximum control (black outline) and the degree to which at least one or specifically two extra tickets are necessary to obtain control. These are combined in calculating the expected control with 1, 2, and 3 tickets, demonstrated by the bars. The arrangement of the bars illustrates that, only in the elastic controllability model, controllability offered by extra tickets is added up on top of what is offered by a single ticket. The model updates its beliefs as follows: **Top** – Successfully boarding with one ticket provides evidence of high maximum controllability ($a_{\text{control}} + 1$; expanded shaded region) and reduces the perceived need to purchase extra tickets ($b_{\text{elastic}\geq1} + 1$), increasing expectations of purchasing 1, relative to 2 or 3, tickets (light green expanded). A failure to board does not change estimated maximum controllability, but rather suggests that 1 ticket

might not suffice to obtain control ($a_{\text{elastic}\geq1} + 1$; light green diminished). **Middle** – Successfully boarding with 2 tickets provides evidence of high maximum controllability ($a_{\text{control}} + 1$; expanded shaded region), and reduces the perceived need to purchase two extra tickets ($b_{\text{elastic2}} + 1$), increasing expectations of purchasing 1 or 2, relative to 3, tickets (light & dark green expanded). Here too, a failure to board does not change estimated maximum controllability, but rather suggests that 2 tickets might not be sufficient ($a_{\text{elastic2}} + 1$; light & dark green diminished). **Bottom** – Successfully boarding with 3 tickets provides evidence of high maximum controllability ($a_{\text{control}} + 1$; expanded shaded region), but offers no insight about whether fewer tickets would suffice to obtain it. Failure to board with 3 tickets provides evidence of low controllability ($b_{\text{control}} + 1$; diminished shaded region).

Examining the predictions of both models, each simulated using the parameter setting that best
fit participants' choices, showed that the elastic-controllability model was better than the
controllability model at opting-out in low controllability planets (elastic-controllability model %
opt in = 49% $\pm$ .01, controllability model % opt in = 63% $\pm$ .01; Figure 5C, top panel). Most
importantly, this higher level of performance closely matched participants' behavior (% opt in =
47%, $\pm$.02). Furthermore, the elastic controllability model was also better at not purchasing
extra tickets in low-controllability (elastic controllability extra tickets = .49$\pm$.01 controllability
extra tickets = .65$\pm$.01) and inelastic-controllability (elastic controllability extra tickets =
.58$\pm$.01 controllability extra tickets = .66$\pm$.01) planets, and this too was more closely aligned
with participant behavior (low-controllability extra tickets = 51$\pm$.02, inelastic-controllability
extra tickets = 53$\pm$.02; Figure 5C, bottom panel).

Beyond these general aspects of task behavior, having participants start on every planet with free
3-ticket trips also enabled us to examine their response to succeeding or failing with 3 tickets,
prior to any other experiences on the planet (Figure 5D). As noted above, failure with 3 tickets
makes the controllability model favor 1 and 2 tickets over 3 tickets, whereas success with 3
tickets makes it favor 3 tickets over 1 and 2 tickets. Critically, neither the participants nor the
simulation of the elastic controllability model showed these effects. Upon failing with 3 tickets,
both participants and the elastic model primarily favored to opt out. Conversely, if they
succeeded with 3 tickets, they did not become less likely to purchase 1 or 2 tickets.

In fact, failure with 3 tickets even made participants favor 3, over 1 and 2, tickets. Presumably,
failure resulted in increased uncertainty about whether it is at all possible to control one's
destination, and thus, participants who nevertheless opted in invested as much resources as they
could to resolve this uncertainty. This directly contradicts the controllability model, but also goes
beyond the behavior exhibited by the elastic controllability model. To capture this aspect of
participants' behavior, we modified the elastic controllability model (elastic controllability*)
such that it would increase its elasticity estimates when controllability is reduced. Model
comparison consistently supported this modification (Initial study: log Bayes Factor = 143
Replication study: log Bayes factor = 155). More importantly, both the original and modified
elastic controllability models explained participants' behavior better than the controllability
model (Initial: log Bayes Factor $\geq$ 270, Replication: log Bayes Factor $\geq$ 148; Figure 5E). These
results establish that people infer the elasticity of control, and thereby adapt their resource
allocation to the environment's controllability and its elasticity.

Figure 5. Model simulations: (A) **Opt-in.** Proportion of opt-in by the controllability and elastic controllability models across all planets. Each region is outlined by the color corresponding to the optimal ticket strategy (Blue: 3 tickets, Green: 1 ticket, Red: opt-out). (B) **Extra ticket purchases.** Extra tickets purchased by the controllability and elastic controllability models across all planets. Here too, each region is outlined by the color corresponding to the optimal ticket strategy. (C) **Comparison of opt-in rates and extra ticket purchases made by models and participants. Top -** Proportion of opting-in as a function of overall controllability. **Bottom -** The number of extra tickets purchased for each level of inelastic controllability when elasticity did not warrant purchasing extra tickets (i.e. below 30%). (D) **Resource investment following free 3-ticket trips.** The distribution of resource investment choices made immediately following the free 3-ticket trips, as a function of the outcomes of those trips. Results are shown for the two studies (Initial, Replication), the controllability model, and the original and modified variant of the elastic controllability models. (E) **Model comparison.** Consistency of each model with participant behavior is shown as log Bayes factor compared to a null model wherein participants have distinct preferences among different number of tickets to purchase but no latent controllability estimates.

Individual elasticity biases explain misallocation of resources

To determine whether the elastic controllability* model could identify individual biases in
elasticity inference, we fitted the model to participants' choices and thus derived each
participant's beliefs about controllability ($\gamma_{\text{controllability}}$) and elasticity ($\gamma_{\text{elasticity}}$) prior to
visiting a given planet. $\gamma_{\text{controllability}}$ is used to initialize the model's belief about the maximum
available control (a_{control}, b_{control}), with higher values reflecting stronger prior beliefs that
planets are controllable. $\gamma_{\text{elasticity}}$ is used to initialize the model's elasticity estimates (a_{elastic},
b_{elastic}), with higher values reflecting stronger prior beliefs that control is elastic (see Methods,
pg. 22). The stronger the belief, the greater its influence on choices to opt in ($\gamma_{\text{controllability}}$) and
purchase extra tickets ($\gamma_{\text{elasticity}}$) regardless of observed outcomes. In addition to these two
model parameters, we examined four additional parameters that directly influence opting-in and
the purchase of extra tickets. These include an inverse temperature parameter (β), which
specifies the stochasticity with which expected values affect resource investment choices, and
baseline-preference parameters for purchasing 1, 2, or 3 tickets (α1, α2, α3). Across both
samples, shared variance among parameters never exceeded 14% (Supplementary Figure S1),
and was particularly low for the controllability and elasticity priors (Initial study: 5%,
Replication study: 3%). Thus, a tendency to assume the environment is controllable did not
imply a tendency to assume that control is elastic, establishing elasticity and controllability
inferences as distinct facets of individual differences.

To examine the variance in resource investment explained by each of the parameters, we
regressed participants' opt-in rates and extra ticket purchases on their fitted model parameters
(Figure 6A). We found that a higher controllability bias (higher $\gamma_{\text{controllability}}$) was associated
with more opting in (Initial study $p<.001$, Replication study $p<.02$; logistic regression) and more
extra tickets purchased (Initial $p<.001$, Replication $p<.001$; probit regression) on low-
controllability, as compared to high-controllability, planets. Thus, a prior assumption that control
is likely available was reflected in a futile investment of resources in uncontrollable
environments.

In contrast, a higher elasticity bias was associated with the purchasing of more extra tickets on
planets with inelastic, as compared to elastic, controllability (Initial study: $\beta = .18, 95\% \text{ CI} =$
$[0.03, \ 0.34], \text{p} = .02$; Replication study: $\beta = .15, 95\%\text{CI} = [0.02 \ 0.28], \text{p} = .02$; linear
regression). Thus, a prior assumption that control is likely elastic was primarily reflected in a
needless investment of extra resources in environments where control could be obtained more
cheaply.

Other parameters were also associated with individual differences that are consistent with the
parameters' roles in the model. Specifically, the inverse temperature parameter (β) was
associated with a more optimal allocation of resources, all three baseline preference parameters
(α1, α2, α3) were associated with opting in, and α2 and α3, in particular, were also associated
with the purchasing of more extra tickets (Figure 6A).

In sum, participants differed in how they allocated their resources across environments, with
prior beliefs about controllability explaining misallocation of resources in uncontrollable

environments, and prior beliefs about elasticity explaining misallocation of resources in
environments where control was inelastic.

Individual elasticity biases are associated with psychopathology

To examine whether the individual biases in controllability and elasticity inference have
psychopathological ramifications, we assayed participants on a range of self-report measures of
psychopathologies previously linked to a distorted sense of control (see Methods, pg. 24). We
then ran a canonical correlation analysis (CCA) to examine the relationship between the self-
report measures and the model parameters underlying individual biases in task behavior. CCA is
a useful method of characterizing relationships between two sets of variables, by assigning a
canonical loading to each variable that maximizes the correlation between the linear
combinations of each set of variables. The canonical loading of each measure thus indicates the
contribution of that variable to the overall correlation. We assessed statistical significance
against a null distribution obtained by permuting the model parameter relative to the
psychopathology scores. This showed that the canonical correlation was significant in both the
Initial (p=.01) and the Replication (p=.02) studies.

To obtain more robust estimates of the CCA loadings, we next ran a canonical correlation
analysis on both datasets combined (Figure 6C, ρ=.33, p=.004). On the side of model parameters,
the elasticity prior parameter ($\gamma_{\text{elasticity}}$) received the highest loading. By comparison, the
controllability prior parameter received a lower loading with the opposite sign. A further
permutation test showed that the contribution of the elasticity prior parameter to the parameter-
psychopathology correlation was itself significant (*p*=.04; Figure 6D).

Loadings on the side of psychopathology were dominated by an impaired sense of agency
(SOA), obsessive compulsive symptoms (OCD), and social anxiety (LSAS) – all symptoms that
have been linked to an impaired sense of control[22-25]. Conversely, depression scores (SDS)
received a negative loading, consistent with evidence of a lower willingness to expend one's
resources in depression[21,26-27]. This psychopathological profile also manifested in raw task
measures, since, like the elasticity prior parameter, it too was associated with the purchasing of
more tickets on planets where controllability was less elastic (Initial: $\beta = .19, 95\% \text{ CI} =$
$[.06, .32]$, p=.004; Replication: $\beta = .13, \; 95\% \text{ CI} = [.01, .25], \text{p} =$
$.03$; linear regression; Figure 6A). Thus, we found a distinct psychopathological profile
involving a distorted sense of agency associated with a bias in elasticity inference.
236

Figure 6. Individual biases in controllability and elasticity inference: (A) **Model parameters and task behavior.** Model parameters fitted to each participant's task behavior were used as predictors of opt-in (left; multiple logistic regressions) and extra ticket purchases (right; multiple probit regressions) separately for low controllability (red), high elastic controllability (blue) and high inelastic controllability (green) planets. In a separate analysis, participants' composite psychopathology scores (see panel C) were similarly used to predict opt-in (left; logistic regression) and extra ticket purchases (right; probit regression). Bars represent regression coefficients and 95% CIs. (B) **Model parameters and psychopathology.** Loadings from a Canonical Correlation Analysis (CCA) between model parameters and self-report psychopathology measures. Self-report measures were scored such that higher values reflect higher levels of psychopathology. Loadings are shown for the Initial (dark blue), Replication (light blue), and combined (gray bars) datasets. The magnitude of the loading reflects the degree to which each measure contributes to the correlation between parameters and self-reports. (C) **Model parameters and psychopathology composite scores.** For each participant, a composite psychopathology score was calculated by multiplying their self-report scores with their CCA-derived loadings, and a composite model parameter score was calculated by multiplying their parameter fits and corresponding loadings. Each dot represents an individual participant. Black line: group-level posterior slope. Gray shading: standard error. (D) **Significance testing.** p-values for the observed CCA correlation (circle) were computed against empirical null distributions (shaded area and bar showing 95% high-density interval). The top null distribution was obtained by shuffling the model parameter fits (top) relative to the psychopathology scores (top), and the bottom null distribution was obtained by shuffling only the elasticity prior parameter ($\gamma_{\text{elasticity}}$) while keeping all other parameters and self-report scores matched (bottom).

Discussion

Across two pre-registered studies, we demonstrate that humans infer the elasticity of control over
their present environment, and this informs their decisions of whether and how to act.
Accordingly, we found that a bias to overestimate elasticity leads to a mismanagement of
resources, and is associated with elevated psychopathology involving an impaired sense of
agency.

Unlike prior work that treated controllability and elasticity as coupled, our studies dissociated
elastic and inelastic controllability, revealing that individuals who typically assume that taking
action is worthwhile (overall controllability) do not necessarily assume that investing more
resources in taking action is worthwhile (the elasticity of control). In fact, elasticity and
controllability biases were oppositely related to psychopathology, revealing a psychopathological
profile that combines underestimation of control with overestimation of the degree to which
investing more resources is necessary to obtain control.

The observed elasticity biases across individuals are particularly striking given the simplicity of
the experimental task in comparison to real-life scenarios. Unlike the task, where successful
boarding directly determined a trip's outcome, in many real situations many actions may
contribute to a single outcome. In this regard, the present work introduces a new kind of credit-
assignment problem[28], which involves identifying not only which actions influenced the outcome
but also which of these actions was made more effective by investing more resources in its
execution. Moreover, whereas in the task elasticity increased linearly with the number of tickets,
resource investment in real life often exhibits non-linear effects. Specifically, further increases in
resource investment often result in diminishing returns, and beyond a certain point, even worse
outcomes (e.g. hiring too many employees, making the work less efficient). Additionally, real
life typically doesn't offer the streamlined recurrence of homogenized experiences that makes
learning easier in experimental tasks. These complexities introduce substantial additional
uncertainty into inferences of elasticity in naturalistic settings, thus allowing more room for prior
biases to exert their influences. The elasticity biases observed in the present studies are therefore
likely to be amplified in real-life behavior.

Our finding that elasticity biases are associated with agency-related psychopathologies raises
interesting questions for future research on the causal nature of this association. One possibility
is that biased elasticity inferences distort one's sense of agency by leading to maladaptive
resource allocation that results in consistently suboptimal outcomes. Another possibility is that
people who already have a reduced sense of agency, attempt to compensate for this feeling by
investing more resources despite minimal benefit, thus demonstrating an elasticity bias.
Importantly, these possibilities are not mutually exclusive. That is, elasticity biases and a
distorted sense of agency could reinforce each other in a cyclical manner. Longitudinal studies
tracking or manipulating elasticity beliefs while monitoring changes in real-life resource
investment and subjective sense of agency, could resolve how elasticity biases and
psychopathology influence each other.

Our operationalization of controllability aligns with previous work that defined controllability as
the degree to which actions influence the probability of obtaining a reward[3-4,6]. Other notable
studies defined controllability as the degree to which actions predict subsequent states,
independent of reward[1a]. Here we adhered to the former definition due to our present focus on
resource elasticity, since individuals are unlikely to invest resources to gain control if control
does not yield more reward. That said, we followed the latter work in ensuring that
controllability is not confounded with predictability[1b], in the sense that in planets with high
controllability, outcomes were not necessarily more predictable than in planets with low
controllability (See Methods). This enabled us to specifically assess individual inferences
concerning controllability and its resource elasticity.

In interpreting the present findings, it needs to be noted that we designed our task to be
especially sensitive to overestimation of elasticity. We did so by giving participants free 3 tickets
at their initial visits to each planet, which meant that upon success with 3 tickets, people who
overestimate elasticity were more likely to continue purchasing extra tickets unnecessarily.
Following the same logic, had we first had participants experience 1 ticket trips, this could have
increased the sensitivity of our task to underestimation of elasticity in elastic environments. Such
underestimation could potentially relate to a distinct psychopathological profile that more
heavily loads on depressive symptoms. Thus, by altering the initial exposure, future studies could
disambiguate the dissociable contributions of overestimating versus underestimating elasticity to
different forms of psychopathology.

Another interesting possibility is that individual elasticity biases vary across different resource
types. For instance, a given individual may assume that controllability tends to be highly elastic
to money but inelastic to effort. Future studies could explore this possibility by developing tasks
that compare individuals' elasticity beliefs across different resource types (e.g., money, time,
effort). This would clarify whether elasticity biases are domain-specific or domain-general, and
thus elucidate their impact on everyday decision-making.

Methods

Pre-registration

303 Both the Initial and Replication studies were pre-registered prior to data collection. The pre-
304 registrations included hypotheses, sample sizes, exclusion criteria, task design, analysis plans
305 (regressions, CCA), and computational models. Detailed pre-registration documents are available
306 at https://aspredicted.org/Q7M_BHR and https://aspredicted.org/CHW_12H.

Participants

We used the Prolific online platform (prolific.com) to recruit participants (Initial study N = 264,
Replication study N = 250). Participants were selected based on their demonstrated high
engagement levels in prior studies, fluency in English, and absence of psychiatric diagnoses. Due
to cultural differences in the perception of controllability[29] participants were recruited from
English speaking western countries. The average age of participants across both datasets was 33
years old (SE =.6), and 38% were female.

The sample size was determined using a power analysis as described below. Exclusion criteria
were applied to ensure data quality and participant engagement. Specifically, participants were
excluded if they demonstrated inattentiveness (defined as more than 8 mistakes on
comprehension quizzes during the instruction phase), displayed less than 90% accuracy in
selecting the correct vehicle corresponding to its pre-learned destination (indicating a lack of task
comprehension), or chose not to purchase any tickets in 90% or more of trials across all
experimental conditions (suggesting a lack of engagement with the task). These criteria led to the
exclusion of 22 participants (8.3% exclusion rate) from the initial study and 23 participants

(8.9% exclusion rate) from the replication study. Participants gave written informed consent
before taking part of the study, which was approved by the university's ethics review board
(approval number: 2022-06213). Participants were paid at a rate of 9 euros per hour.

Experimental Task

Participants were informed about the location of a treasure (150 coins, worth 15¢ of bonus
monetary compensation) and could exercise control by boarding the train to reach the house, or
the plane to reach the mountain. (see main text and Figure 2). Forgoing or failing to board
resulted in walking to the nearest location which happened to be where the treasure was located
20% of the time.

The first ticket (cost = 40 coins) allowed participants to select their desired vehicle, but it only
stopped for them at the platform some percentage of the time, corresponding to the inelastic
controllability of the planet. Participants could purchase up to 2 additional tickets (cost = 20
coins each) to attempt boarding the moving vehicle after it had left the platform. This improved
the probability of boarding in correspondence with the elastic controllability of the planet.

When participants purchased a second or third ticket, the chosen vehicle appeared moving from
left to right across the screen, and participants attempted to board it by pressing the spacebar
when it reached the center of the screen. The precision of each boarding attempt was quantified
as the absolute distance of the vehicle from the screen's center at the time of the press. Unless
elastic control was below 15%, boarding attempts with precision in the top 15 percentile relative
to the participant's prior performance automatically succeeded, and unless elastic control was
above 85%, those in the bottom 15 percentile automatically failed. For the remaining attempts,
the outcome was probabilistically determined such that the overall probability of successfully
boarding matched the elasticity of control on that planet. To verify that participants' pressing
ability did not bias their preference for purchasing extra tickets, we ran a mixed probit regression
of the number of extra tickets purchased on participants' average press precision. We found no
significant effect (p = .45).

At the end of each trip, participants were shown where they arrived, allowing them to infer
whether they successfully boarded their vehicle. Since this feedback is only interpretable if
participants knew each vehicle's destination, we only included participants in subsequent
analyses if they chose the vehicle corresponding to the destination of the treasure with at least
90% accuracy (Mean 97% ±2%, see first exclusion criteria).

To allow sufficient learning of each planet's elasticity and controllability, participants took 30
consecutive trips on each planet. This trip count was determined based on pilot data (N=19)
analyzing when participants' strategies stabilized. We examined the standard deviation in ticket
choices over the final 5 trips and found stabilization after around 15 trips (STD = 0.51). Based on
this, we provided an initial 15 trips for learning, then analyzed ticket choices starting from trip 16
onward per planet. This approach followed our pre-registered plan.

To homogenize learning experience across participants, we gave participants three free tickets
for the first five visits to every planet. However, only four of those trips were informative, since

on one of every five trips (randomly placed), the treasure was located in the nearby location,

making boarding inconsequential for reaching it.

Planet types

To study elasticity learning across all possible degrees of controllability and elasticity, 66 unique

planet conditions were generated by systematically varying inelastic controllability (the

probability of the chosen vehicle stopping at the platform if purchasing a single ticket) and

elasticity (the added probability of boarding from purchasing 2 extra tickets) from 0 to 100% in

10% increments. The treasure value (150 coins) and ticket costs (40 coins for the first ticket, 20

coins for extras) were chosen so that the optimal strategy, as determined by expected value

calculations (*equation 11*), was to purchase 0 tickets on 22 planets (low controllability

condition), 1 ticket on a different set of 22 planets (high inelastic controllability condition), and 3

tickets on the remaining 22 planets (high elastic controllability condition). Participants were

randomly assigned one planet from each condition, while ensuring they could earn roughly the

same total number of coins if they made optimal choices (Initial study= 45$\pm$.3, Replication study

46 $\pm$ .3). To address potential confounds between controllability and predictability[1b], we

designed the experiment such that high-controllability planets (where purchasing 1 or 3 tickets

was optimal) were not inherently more predictable than low-controllability planets. We

quantified predictability as the entropy of the probability distribution determining whether the

participant will or will not arrive at the rewarded location. For 60% of participants, purchasing

tickets on high-controllability planets decreased entropy (i.e., increased predictability) compared

to low-controllability planets, whereas for the other 40% it increased entropy (i.e., decreased

predictability). To increase sensitivity to individual differences, all participants first encountered

a planet where purchasing any number of tickets (0, 1, 2, or 3) yielded the same expected value

(EV = 30 coins).

Initial training

382   Prior to engaging in the task, participants completed 90 practice trials. These practice trials were

383   divided equally across planets with high inelastic controllability, high elastic controllability, and

384   low controllability. To reinforce participants' understanding of how elasticity and controllability

385   were manifested in each planet, they were informed of the planet type they had visited after

386   every 15 trips.

Power analysis

The sample sizes for both the initial and the replication studies were pre-registered before data
collection commenced. For the initial study, we derived the sample size of 264 participants using
a power analysis aiming to estimate with high accuracy (credible interval width < 0.1) the
likelihood that participants will opt-in for any combination of elastic and inelastic control (66
total combinations). For this purpose, we used Kruschke's (2014) procedure for Bayesian Power
Analysis[30]. Based on pilot data (N=19), we fitted a Bayesian Beta Binomial model to the
proportion of opt-ins in the planet with no optimal strategy (and therefore the highest variability
in behavior would be expected), and found that 12 participants were required for the credible

interval of the binomial proportion parameter to be lower than 0.1. Since each participant completes 3 combinations of elastic and inelastic control, we multiplied the required sample size by the total number of planets in each condition (22) which results in an estimate of n=264.

To examine whether this sample size is sufficient to detect significant effects of elastic and
inelastic controllability on opting in (analysis 1), and the purchasing of extra tickets (analysis 2;
see pg. 4-5), we used a bootstrap procedure whereby we sampled 264 participants from the pilot
data and ran the regression analyses on them. We repeated this procedure for 50 iterations, each
time recording $\beta_{elastic}, \beta_{inelastic}$, and their p-values. For analysis 1, we found that both
$\beta_{elastic}$ and $\beta_{inelastic}$ were significantly above 0 in all iterations, and for analysis 2, $\beta_{elastic}$ was
significantly above 0 in all iterations, thereby giving us >98% power to detect all of our effects
of interest. Confidence intervals were derived from a binomial test in which a positive significant
coefficient counted as a success.

For the replication study, we derived the sample size of 250 participants using a power analysis
aiming for 95% power to detect a significant (p <.05) canonical correlation between the model-
derived parameters and questionnaire scores (see analysis on pg. 12). For this purpose, we
sampled with replacement from the initial dataset (n=264) which had showed a significant
canonical correlation (p=.01; see results pg. 13), and calculated the p-value of a CCA in the
subsample. We repeated this procedure for 100 iterations, each time recording the calculated p-
value. To ensure our sample size was sufficient to detect significant effects in the regression
models predicting opt-in and extra ticket purchases from the composite psychopathology score
with over 95% power (described on pg. 13) we conducted another bootstrap analysis. We
sampled 250 participants with replacement each time calculating the composite score and ran the
regression analyses on that score, repeating this procedure 100 times. We found that $\beta_{composite}$
was significant (p<.05) in 95% of iterations (95% power).

Regression analyses
408
Mixed model regression analyses were performed using the "ordinal" package which fits
cumulative mixed models via Laplace approximations[31]. The model predicts the likelihood of
purchasing tickets (logistic model) and how many extra tickets are purchased (probit model) on
the last 15 trips on each planet. Predictors included fixed and random effects for elastic and
inelastic controllability and fixed and random intercepts per participant and planet number, with
the latter included to account for potential learning or fatigue effects. Statistical significance was
assessed using the Wald Z Test[32] with normality assessed using the Shapiro-Wilk Test[33].

Computational Modeling
416

To assess whether participants inferred elasticity or merely learned the control afforded by each
course of action separately, we fit two competing reinforcement-learning models
('*controllability*' and '*elastic controllability*'). Both models use beta distributions defined by
parameters (a , b), to form controllability beliefs for each ticket quantity n (n ∈ {1, 2, 3}), but
only the elastic controllability model leverages the dependencies that exist between different
levels of resource investment. Below, we expand on the computations underlying both models.
423

Controllability model

The controllability model accumulates the number of times that each ticket quantity n led to successful or unsuccessful boarding:

$a_n \leftarrow a_n + O$
$b_n \leftarrow b_n + (1 - O)$ *(equation 1)*

Where O=1 if boarding was successful and O=0 if not. The probability of boarding with 1,2 or 3 tickets on planet s is thus simply the expected value of that particular beta distribution:

$p(\text{boarding}|n, s) = \frac{a_n}{a_n + b_n}.$ *(equation 2)*

Here and in all subsequent models, learning only takes place when the treasure is not located on the nearby planet, which makes it possible to identify boarding success.

Elastic controllability model

The *elastic controllability model* explains ticket choices based on latent beliefs about the controllability and elasticity of each planet (see Figure 4). These beliefs are represented by three beta distributions, each defined by two parameters (a, b). The expected value of one beta distribution (defined by $a_{\text{control}}, b_{\text{control}}$) represents the belief that boarding is possible (controllability) whereas the expected value of the other two beta distributions represent the belief that successful boarding is added by purchasing at least one ($a_{\text{elastic}\geq1}, b_{\text{elastic2}}$) or specifically two ($a_{\text{elastic2}}, b_{\text{elastic2}}$), extra tickets (elasticity).

Thus, the parameter a_{control} accumulates the number of successful boarding attempts with any number of tickets, whereas b_{control} accumulates the number of failed boarding attempts despite purchasing the maximum number of tickets (3 tickets):

$a_{\text{control}} \leftarrow a_{\text{control}} + 1 \text{ if win with 1,2, or 3 tickets}$
$b_{\text{control}} \leftarrow b_{\text{control}} + 1 \text{ if lose with 3 tickets}$ *(equation 3)*

A failure to board with fewer tickets doesn't reduce the maximum controllability estimate but instead suggests that more tickets or the maximum number of tickets may be needed to obtain control:

$a_{\text{elastic}\geq1} \leftarrow a_{\text{elastic}\geq1} + 1 \text{ if lose with 1 or 2 tickets}$
$a_{\text{elastic2}} \leftarrow a_{\text{elastic2}} + 1 \text{ if lose with 2 tickets}$ *(equation 4)*

Conversely, successfully boarding with fewer tickets is evidence that obtaining controllability does not require maximal or any extra tickets:

$b_{\text{elastic}\geq1} \leftarrow b_{\text{elastic}\geq1} + \text{ if win with 1 ticket}$
$b_{\text{elastic2}} \leftarrow b_{\text{elastic2}} + 1 \text{ if win with 2 tickets}$ *(equation 5)*

To account for our finding that failure with 3 tickets made participants favor 3, over 1 and 2,
tickets, we introduced a modified elastic controllability* model, wherein purchasing extra tickets
is also favored upon receiving evidence of low controllability (loss with 3 tickets). This effect
was modulated by a free parameter κ:

$a_{more} \leftarrow a_{elastic1} + \kappa$ if lose with 3 tickets
$a_{elastic2} \leftarrow a_{elastic2} + \kappa$ if lose with 3 tickets   *(equation 6)*

The estimated controllability and elasticity, as characterized by the expected value of the three
beta distributions ($C_{total\ control}, C_{more}, C_{full}$), is used to derive the probability of boarding the selected
vehicle with 1, 2, or 3 tickets. Thus, the estimated probability of boarding with 1 ticket is an
estimate of inelastic control, that is, the percentage of the total control $C_{total\ control}$ that does not
require investing more resources:

$P(boarding|n = 1) = C_{total\ control} \times (1 - C_{more})$ *(equation 7)*

For 2 tickets, the added probability of boarding is an estimate of what percentage of total control
is elastic (C_{more}) but does not require investing maximal resources ($1 - C_{full}$):

$P(boarding|n = 2) = P_s(boarding|n = 1) + C_{total\ control} \times C_{more} \times (1 - C_{full})$ *(equation 8)*

Finally, since 3 tickets is the maximum resource investment, the estimated probability of
boarding with 3 tickets is equivalent to an estimate of total attainable control.

$P(boarding|n = 3, s) = C_{total\ control}$ *(equation 9)*

Models' resource investment

Because participants win 20% of the time even when they fail to board their selected ride, we
calculate the probability of arriving at the treasure with *n* tickets as:

$P(win|n) = P(boarding|n) + .2 \times (1 - P(boarding|n))$ *(equation 10)*

Then, taking the possible reward (R = 150) and ticket costs (C = {40,20,20}) into account, the
expected value for purchasing n tickets (n = {1,2,3}) tickets is:

$V(n) = (R - \sum_{i=1}^{n} C_i) \times P(win|n) - \sum_{i=1}^{n} C_i \times (1 - P(win|n))$ *(equation 11)*

One exception to this rule is the expected value of opting out, $V(0)$, which is similar across all
planets, and equals the potential reward (150) times the probability that walking will lead to the
reward (0.2).

The probability that a participant will purchase 0, 1, 2, or 3 tickets is calculated using the
SoftMax function such that:

$p(n) \propto \beta \times V(n) + \alpha_n + \rho \times I(n_{t-1} == n)$ *(equation 12)*

where β is an inverse temperature parameter, α_{1-3} are parameters that represent participants'
fixed tendencies to purchase 1, 2, or 3 tickets respectively, and ρ is a perseveration parameter
that represents participant tendency to purchase the same number of tickets as in the last trial
(n_{t-1}). A_0 is set to 0 to maintain parameter identifiability.
521
We compared the aforementioned models to a null model wherein participants have distinct
preferences among different number of tickets (α_{1-3}) and perseveration (ρ) but no latent
controllability estimates ($\beta = 0$ in equation 12). We also evaluated variants of both models that
replaced the SoftMax-based exploration (governed by inverse temperature β) with a decaying
epsilon-greedy approach. This epsilon-greedy variant, which begins with a fixed exploration rate
that decreases with the number of trials[57], performed significantly worse at explaining
participants' choices compared to the SoftMax-based models.
529
Prior controllability and elasticity beliefs
530
To capture prior biases that planets are controllable and elastic, we introduced parameters
$\gamma_{controllability}$ and $\gamma_{elasticity}$, each computed by multiplying the direction $(\lambda - 0.5)$ and strength
(ϵ) of individuals' prior belief. $\Lambda_{controllability}$ and $\lambda_{elasticity}$ range between 0 and 1, where values
above 0.5 indicate a bias towards high controllability and elasticity, and values below 0.5
indicate a bias towards low controllability and elasticity, whereas $\epsilon_{controllability}$, $\epsilon_{elasticity}$ ($\epsilon >$
0) capture the confidence in the bias. These parameters were thus used to initialize the beta
distributions representing participants' beliefs:
$a_{controllability} = 2 \times \epsilon_{controllability} \times \lambda_{controllability}$
$b_{controllability} = \epsilon_{controllability} \times (1 - \lambda_{controllability})$
$a_{more,full} = \epsilon_{elasticity} \times \lambda_{elasticity}$
$b_{more,full,} = \epsilon_{elasticity} \times (1 - \lambda_{elasticity})$ $\qquad$ *(equation 13)*
542
543 $a_{controllability}$ is multiplied by 2 so that in the absence of a bias, it would have equal preference
544 for purchasing 0 to 3 tickets (this requires that $C_{controllability} = \frac{2}{3}$, $C_{more,full} = \frac{1}{2}$).
545 For consistency, in the 'controllability model', the controllability estimates for each ticket
546 quantity are initialized for each ticket quantity n, where n={1,2,3}, as:
547
548 $a_n = \epsilon_n \times \lambda_n$
549 $b_n = \epsilon_n \times (1 - \lambda_n)$ $\qquad$ *(equation 14)*
550
551 Here, to ensure no preference between different ticket quantities in the absence of a bias, a_1 is
552 multiplied by 2 and a_2 is multiplied by $\frac{3}{2}$.

Model fitting
553
554
Reinforcement-learning models were fitted to participants' choices via an expectation
maximization approach used in previous work[34-36]. We generated random parameter settings
drawn from predefined group-level distributions and calculated the likelihood of observing the

participants' choices given each parameter setting. We then approximated the posterior estimates
of the group-level prior distributions for each parameter by resampling the parameter values,
weighted by their respective likelihoods, and refitted the data based on the updated priors. This
iterative process of resampling and refitting continued until no further improvement to model fit.
To determine the best-fitting parameters for each individual participant, we computed a weighted
average of the final batch of parameter settings, where each setting was weighted by the
likelihood it assigned to the individual participant's choices.
565
566 Model parameter β was initialized by sampling from a Gamma distribution ($k = 1$, $\theta = 1$), λ was
567 initialized by sampling from a Beta distribution ($\alpha = 1$ *and* $\beta = 1$), ϵ was initialized by sampling
568 from a Lognormal distribution ($\mu = 0$, $\sigma = 1$)., and all other parameters ($\alpha_{1-3}, \rho, \kappa$) were
569 initialized by sampling from a Normal distribution ($\mu = 0$, $\sigma = 1$).

570 **Validation of model fitting procedure**
571
     To validate the model fitting procedure, we simulated data using each model and using the model
     comparison procedure to recover the correct model (S1 table). Furthermore, we validated our
     parameter fits by simulating data using the best fitting parameters for each parameter and then
     recovering those parameters. The correlations for the parameters of interest were all equal or
     greater than $r = .74$ and at least .63 for all other parameters (see Table S2).

     Model comparison
572
To compare between models, in terms of how well each model accounted for participants'
choices, we employed the integrated Bayesian Information Criterion (iBIC)[37-38]. First, we
estimated the evidence for each model (L) by calculating the mean likelihood of the model given
200,000 random parameter settings sampled from the fitted group-level prior distributions.
Subsequently, we computed the iBIC by penalizing the model evidence to account for model
complexity, following this formula: iBIC = 2 ln L + k ln n, where k represents the number of
fitted parameters, and n is the number of subject choices used to compute the likelihood. Lower
iBIC values indicate a more parsimonious and better-fitting model.
581
582 **Model simulations**
583
To examine the predictions of the 'controllability' and 'elastic controllability' models, we
simulated choices using the best-fitting parameter settings obtained from participants' actual
choices. For generality, planets were randomized in the simulation as they were in the actual
experiment, such that a simulated participant did not visit precisely the same planets as the actual
participant. Furthermore, to avoid discrepancies between models, each planet was repeated the
same number of times for both models. 2000 simulations were performed with each model.
590
591 **Individual differences**
592
We examined individual biases in elasticity inference using participants' best-fitting parameters
for beliefs about controllability ($\gamma_{\text{controllability}}$) and elasticity ($\gamma_{\text{elasticity}}$). In addition to these

focal parameters, we also examined four other parameters that directly influence opt-in decisions
and extra ticket purchases: an inverse temperature/noise parameter (β) and three baseline
preference parameters (α_1, α_2, α_3).

We then regressed participants' actual opt-in (logistic regression) and extra ticket purchases
(probit regression) in each of the 3 controllability conditions on participants' parameters.
Regressions were performed in the lme4 package in R using Rstudio[39]. Statistical significance
was assessed using the Wald Z Test[32] with normality assessed using the Shapiro-Wilk Test[33].

Self-report measures

To assess trait-level agency beliefs and related psychopathologies, we administered the Sense of
Agency Scale (SOA)[40]. Additionally, we measured dysfunctional attitudes toward problem-
solving via the Negative Problem Orientation Questionnaire (NPOQ) [41], and temperamental
differences (five domains: hyperthymic, dysthymic, cyclothymic, irritable, and anxious) via the
Temperament Evaluation Questionnaire (TEMPS-A)[42-43].

Additionally, we incorporated a selection of questionnaires used by Gillan et al. (2016)[44], which
assess three factors—Anxious-depression, Compulsive behavior and intrusive thought, and
Social withdrawal—linked to goal-directed control deficits. These include the Apathy Evaluation
Scale[45] (AES), Eating Attitudes Test[46] (EAT), Alcohol Use Disorders Identification Test[47]
(AUDIT), Barratt Impulsiveness Scale[48] (BIS), Liebowitz Social Anxiety Scale[49] (LSAS), Self-
Rating Depression Scale[50] (SDS), Trait Subscale of the State-Trait Anxiety Inventory for
Adults[51] (STAI; Spielberger, 1983), and the revised Obsessive-Compulsive Inventory[52] (OCI-R).
We utilized abbreviated versions of these questionnaires following the methodology of Wise and
Dolan (2020)[53], who refined the questionnaires using a classifier to retain the items most
contributory to variance in the three factors without significant information loss.

As preregistered, we aggregated the scores of the selected items from each questionnaire
independently for inclusion in our CCA. Questionnaires were scored following the
corresponding scoring guide, but in such a way that larger scores always indicate greater
psychopathology. Based on best practice recommendations[54-55], participants were screened for
inattentive responding with infrequency items ('I competed in the 1917 Summer Olympic
Games') which resulted in the removal of 11 participants (Initial: 6, Replication: 5).

Directly using the scores from questionnaires of varying lengths in the CCA can give undue
influence to short questionnaires, whose scores are likely more noisy. To mitigate this problem,
we adjusted the standard deviation of each questionnaire's score proportionally to the square root
of its number of items before conducting the CCA (in accordance with the formula for standard
error). After performing the CCA on these weighted scores and normalized model parameters,
the resulting canonical loadings were transformed back to their original standardized scale,
ensuring that the reported loadings accurately reflected the original, unweighted scale of the
questionnaire scores.
631
632
633

Canonical Correlation Analysis (CCA)

Canonical correlation analysis was implemented using the robust CCA method based on
projection pursuit ('ccAPP' package;)[56]. We searched for the single canonical dimension that
maximizes the Spearman correlation between the model parameters and psychopathology scores.
Significance testing was conducted using a two-tailed permutation test with 1,000 iterations. In
each iteration, the model parameters were shuffled relative to the psychopathology scores, and
the canonical correlation was recalculated. The observed canonical correlation was then
compared to this null distribution to obtain a p-value. To evaluate the contribution of the
elasticity prior parameter ($\gamma_{\text{elasticity}}$) to the parameter-psychopathology correlation, we
performed an additional permutation test. In this test, only the elasticity bias estimates
($\gamma_{\text{elasticity}}$) were shuffled, while all other model parameters and self-report scores remained
constant.

To assess how the identified psychopathological profile manifests in raw task measures, we
calculated a composite psychopathology score for each participant. This score was derived by
multiplying individual participant scores by CCA-derived loadings, representing their position
on the psychopathology spectrum. We then used this composite score as a predictor ($\beta_{composite}$)
in a linear regression model to forecast the difference in average opt-in and extra ticket behavior
between conditions where controllability was high and inelastic versus high and elastic.

Supplementary Information

S1 Table. Model validation. 10 full experimental datasets were simulated using each model.
Rows indicate the model used to simulate data and columns indicate the model recovered from
the data using the model comparison procedure.

	Controllability	Elastic controllability	Null
Controllability	10	0	0
Elastic controllability	0	10	0
Null	0	0	10

S2 Table. Parameter Recovery. We validated our model fitting procedure by simulating data
using the best fitting parameters for each subject and then recovering those parameters. Our
correlation between simulated and recovered parameters was at least .74 for all parameters of
interest that capture the effects of the experimental conditions, and at least .63 for all other
parameters.

Parameter	Correlation between Simulated and Recovered Parameters
β	.91
$\gamma_{controllability}$	.77
$\gamma_{elasticity}$	.74
α_1	.82
α_2	.81
α_3	.81
ρ	.89
κ	.63

S1 Figure. Shared variance between elastic controllability* model parameters. Heatmaps display squared Pearson correlations between parameter pairs for initial (left) and replication (right) studies. Color intensity indicates shared variance magnitude (0-1). Parameters: $\gamma_{controllability}$, $\gamma_{elasticity}$, β, a_{1-3}, ρ, κ. Diagonal elements=1; off-diagonal elements reveal parameter interdependencies.
