Understanding and ultimately predicting the function of proteins is one of the frontiers in structural biology. This will only be possible if it becomes feasible to routinely observe proteins on the fast timescales on which they perform their tasks. Recently, laser flash melting and revitrification experiments have improved the time resolution of cryo-electron microscopy (cryo-EM) to microseconds, rendering it fast enough to observe the domain motions of proteins that are frequently linked to function. However, observations have been limited to a time window of just a few hundred microseconds. Here, we introduce time-resolved cryo-EM experiments based on jet vitrification that combine microsecond resolution with an observation window of up to seconds. We use a short laser pulse to initiate protein dynamics, and as they unfold, vitrify the sample with a jet of a liquid cryogen to arrest the dynamics at that point in time. We demonstrate that our approach affords near-atomic spatial resolution and a time resolution of 21 µs. This allows us to observe the photoinduced dynamics of the light-driven sodium pump *Er*NaR on the microsecond to millisecond timescale. Our experiments significantly expand the ability of cryo-EM to observe protein dynamics across multiple timescales.

Introduction

Understanding the dynamics of proteins is one of the frontiers in structural biology.[1,2] Advances in instrumentation and computational tools have ushered in a golden age for protein structure determination,[3,4] and the large number of structures that are now available have enabled machine learning approaches to even predict structures with good confidence.[3,5] However, while a structure allows one to infer how a protein functions, one can frequently only do so imperfectly. Fully understanding and ultimately predicting protein function will only succeed if it becomes possible to routinely observe proteins as they perform their tasks, a goal that has so far remained out of reach.[1] The development of new experimental methods is therefore urgently needed to advance our understanding of the dynamic nature of proteins.

X-ray crystallography has long been the workhorse of structural biology,[6] and the introduction of high-brightness, pulsed X-ray sources has made it possible to observe protein dynamics with time-resolved protein crystallography.[7–11] A number of experiments particularly stand out, in which the dynamics of light-activated proteins have been observed with ultrafast time resolution.[6,7,10] However, the need for the sample to be crystalline limits the scope of the method, with the crystal often hindering some of the large-amplitude domain motions that are typically associated with the function of a protein.[1]

Time-resolved cryo-EM enables the observation of protein dynamics without the need for the particles to be confined to a crystal, but has traditionally offered only a limited time resolution.[12–18] In these experiments, protein dynamics are typically initiated with a short pulse of light[19–21] or by rapid mixing,[18,22] after which the sample is vitrified to trap the particles in transient states. However, it has not been possible to plunge-freeze[20,21,23–26] or jet vitrify[27,28] samples with better than millisecond time-resolution, too slow to observe the microsecond domain motions that are frequently linked to function. We have recently introduced a new approach that makes the microsecond timescale accessible to cryo-EM.[29–31] It involves flash melting a cryo-EM sample with a microsecond laser pulse to provide a brief time window, during which protein dynamics are initiated, before revitrification arrests the proteins in their transient configurations.[32–34] However, observations with this technique have so far been limited to a time window of just a few hundred microseconds,[33] leaving a gap to the millisecond timescale, which can already be accessed with traditional approaches. Ideally, one would like to cover all timescales in

the same experiment. Here, we demonstrate time-resolved cryo-EM experiments based on jet vitrification that achieve this goal and combine microsecond time resolution with an observation window of up to seconds.

Results and discussion

Figure 1a illustrates our experimental approach. A protein solution is applied to a specimen support, and dynamics are initiated with a short laser pulse, for example, by releasing a photocaged compound such as caged ATP, caged ions, or caged peptides[35–37] Alternatively, conformational dynamics can be induced by creating a temperature jump[33] or by directly exciting a photoactive protein, as we show below. As the dynamics unfold, the sample is vitrified with a precisely timed jet of a liquid cryogen to arrest the proteins in their transient configurations, which are subsequently imaged.

Experimental concept and instrumentation

Figure 1 | Experimental concept and instrumentation. a Experimental concept. Protein dynamics are initiated with a short laser pulse. As they unfold, the sample is vitrified with a time-delayed jet of a liquid cryogen, trapping the proteins in their transient configurations. **b** Illustration of the experimental implementation. A sample grid is placed in the activation subunit (left) of the jetting assembly, and protein dynamics are initiated with a laser pulse. The sample is then vitrified with a liquid ethane jet that is generated in the jetting subunit (right), where a small volume of the cryogen is condensed and subsequently expelled with a short pulse of compressed nitrogen. As the liquid ethane jet travels towards the specimen grid, its passage is detected at two points in the activation subunit with laser beams. This allows us to predict the arrival time of the jet on the fly and fire the activation laser such that the sample is vitrified at a desired time delay after dynamics have been initiated. The precise instant of vitrification is determined with a third laser beam that is continuously reflected off the back side of the grid and that is deflected by the arrival of the jet. **c** Experimental setup with the jetting assembly integrated into a commercial plunge freezing device (Thermo Fisher Vitrobot Mark IV). The sample is prepared in the climate chamber, using a clipped grid held in a custom forceps. After single-sided blotting, it is lowered into the jetting assembly, where the time-resolved jet vitrification experiment is performed. Finally, the specimen grid is lowered into a liquid ethane/propane filled cup underneath the jetting assembly.

Figure 1b illustrates our design of the time-resolved jet vitrification device (Supplementary Information 1). The specimen grid is positioned in the activation subunit on the left (held at a temperature of about 290 K), where it is illuminated with the activation laser pulse. The cryogenic jet is generated in the jetting subunit on the right, which is cooled to 95 K. A small volume of the cryogen (about 0.3 mL of ethane or an ethane/propane mixture) is condensed into a reservoir and subsequently expelled with a short pulse of compressed nitrogen. As the liquid jet travels towards the sample, which takes about 10.7 ms, we detect its passage at two points in the activation subunit with laser beams. When the jet passes these laser gates, the laser beams are deflected, which we detect with photodiodes. This allows us to predict the arrival time of the jet on the fly and fire the activation laser accordingly, so that the sample is vitrified at a desired time delay after dynamics have been initiated. We determine the precise moment at which the jet impinges on the sample with a third laser beam that is reflected off the back of the grid at an angle of 45°. The arrival of the jet deflects this laser beam, which we similarly detect with a photodiode.

As shown in the photograph of Fig. 1c, the jet vitrification device is integrated into a commercial plunge freezing apparatus (Thermo Fisher Vitrobot Mark IV) that we have modified for time-resolved experiments. The sample is prepared in the climate chamber of the plunge freezing device by applying a small volume of the protein solution onto a clipped specimen grid held in custom forceps (inset), followed by single-sided blotting. The sample is then lowered into the jetting assembly, which is mounted beneath the climate chamber, and the time-resolved jet vitrification experiment is performed. The specimen grid is then quickly lowered further into a liquid ethane/propane filled brass cup underneath the jetting assembly, from where it is transferred to an electron microscope for imaging.

Figure 2a shows high-speed video frames of a typical ethane jet impinging onto a sample (Supplementary Information 2). The jet, traveling at a speed of 2.8 m/s, has a diameter of approximately 3 mm and features a slightly curved front with a radius of curvature of about 1.9 mm at its center. Upon contact with the jet, the sample cools rapidly. Figure 2b shows a typical temperature evolution (red), as measured with a resistance temperature detector placed at the sample location (Supplementary Information 3, 1:1 ethane-propane jet with a speed of 2.65 m/s). An exponential fit (solid black line) yields a 1/e cooling time of 15.7 µs, which provides an estimate of how rapidly we can induce vitrification

and trap proteins in their transient configurations. Figure 2c confirms that we can obtain near-atomic resolution reconstructions from jet vitrified samples, with a reconstruction of apoferritin yielding a resolution of 1.3 Å (Supplementary Information 5–6).

Jet vitrification, temporal and spatial resolution

a   **High-speed video frames of jet vitrification**

b Measurement of the cooling rate during jet vitrification

c   **High-resolution reconstruction of apoferritin (1.3 Å)**

Figure 2 | High-speed video frames of the jet vitrification process as well as characterization of the temporal and spatial resolution. a High-speed video frames of a liquid ethane jet, traveling at a speed of about 2.8 m/s, as it impinges on the sample. The time stamp of each frame is indicated with respect to the arrival time of the jet. Scale bar, 1 mm. **b** Typical temperature evolution (red) during the impact of the jet (1:1 ethane-propane, traveling at 2.65 m/s), as measured with a resistance temperature detector. An exponential fit (solid black line) yields a 1/e cooling time of 15.7 µs. The impact of the jet is detected with the arrival time laser, which is reflected off the back of temperature detector. As the jet impinges on the detector, the laser beam is deflected, which is detected with a photodiode (light blue, the dark blue curve represents the smoothed signal). We determine the timing of this event from the intersection of two linear fits to the signal, which are shown with dashed, black lines (the dashed, grey line provides a guide to the eye). The time is indicated with respect to the trigger sent to the pulsed valve. **c** A reconstruction of apoferritin from a jet vitrified sample yields a resolution of 1.3 Å. A model is placed into the density with rigid-body fitting (PDB: 8RQB).[38]

We precisely time the cryogenic jet with respect to the excitation laser pulse, which allows us to perform experiments with microsecond time resolution. If we synchronize the activation laser to the pulse of compressed nitrogen that expels that cryogenic jet, we can realize arbitrarily long time delays, but only with an accuracy of 0.78 ms (as measured by the standard deviation, Supplementary Information 4). This is due to the jitter in the opening of the pulsed valve as well as variations in the jet speed. We can improve the accuracy to 0.39 ms by detecting the passage of the jet with the first laser gate and triggering the activation laser accordingly. This allows us to realize time delays of up to ~3 ms, the time it takes for the jet to travel from the first laser gate to the sample. For even shorter time delays of up to ~300 μs, we detect the jet with both laser gates to predict its arrival time on the fly, which yields an accuracy of 38 μs. Note that this experimental design allows us to time the jet more precisely for shorter time delays. This reduces the number of experiments that have to be rejected because the relative timing error is too large, *i.e.* the relative difference between actual and desired time delay. We determine the actual arrival time of the jet with the laser beam reflected off the back of the specimen grid (Supplementary Information 4). As shown in Fig. 2b, the arrival of the jet deflects the laser beam, which we detect with a photodiode (light blue, with the smoothed signal shown in dark blue and linear fits indicated with dashed, black lines). This allows us to determine the arrival time with an accuracy of 9 μs, independently of the chosen time delay. If we also take the average 1/e cooling time of the sample of 19 μs into account, we can estimate that our jet vitrification experiment has a time resolution of 21 μs (Supplementary Information 3). Note that because of the curvature of the jet front (Fig. 2a), sample areas further away from the center of the grid likely vitrify later. In the time-resolved experiments presented below, we have therefore only collected micrographs from the center of the grid (Supplementary Information 6–7).

We demonstrate the capabilities of our method by studying the dynamics of the rhodopsin *Er*NaR (*Erythrobacter sp*. HL-111), which upon light activation, pumps sodium ions from the cytoplasm across the bacterial membrane to the ouside.[39] *Er*NaR belongs to a recently identified subgroup of the NDQ rhodopsins, which feature an additional glutamic acid residue close to the retinal Schiff base, allowing *Er*NaR to efficiently pump sodium ions even at acidic pH.[39] Uncovering the structural dynamics of *Er*NaR therefore promises to shed light on the sodium pumping mechanism of this subgroup. The dark state structure of the pentameric *Er*NaR is shown in Fig. 3a (Supplementary Information 5, 7, as derived

from a 2.1 Å resolution map), and the proposed ion transport pathway is illustrated.[39] The photocycle with its relevant timescales is shown in Fig. 3b.[39] Rhodopsins and other retinal-containing proteins have been popular targets for time-resolved X-ray crystallography studies.[40–44] Although we cannot match the ultrafast time resolution of these experiments and therefore miss some of the earliest events that follow the photoisomerization of the retinal Schiff base, our jet vitrification experiments can be performed with a benchtop instrument, using orders of magnitude less sample than required for time-resolved serial crystallography.[11] Moreover, we are able to study *Er*NaR in its naturally occurring pentameric form, which so far has resisted crystallization.[39]

Structural dynamics of the bacterial rhodopsin *Er*NaR

b *Er*NaR photocycle

c Photo-induced isomerisation of the retinal Schiff base (RSB)

Dark state   107 μs   13.3 ms

d Conformational changes in the active center

e Conformational changes at the periphery towards the end of the photocycle

Figure 3 | Structural dynamics of the bacterial rhodopsin *Er*NaR observed with microsecond time-resolved cryo-EM based on jet vitrification. a Dark state of the pentameric *Er*NaR, with a single monomer highlighted in blue, and proposed pathway along which the sodium ion is transported upon light activation (red, shown in a cutaway view of a monomer). **b** Illustration of the photocycle with the relevant timescales indicated.[39] Note that these timescales were determined for a 1000 mM sodium ion concentration, which is higher than the concentrations used in our experiment (Supplementary Information 5). However, this is not expected to significantly change the timescales of the states we probe. **c,d,e** Structural changes observed at 107 μs and 13.3 ms compared to the dark state. Light absorption leads to the isomerization of the retinal Schiff base (RSB), which returns to the all-*trans* on long timescales (**c**). In the active center close to the retinal Schiff base, changes in the hydrogen bonding pattern suggest the uptake and transport of sodium ions (**d**). At long times, a putative sodium

binding site forms near the exit of the ion transport channel, from which the ion is likely released to the extracellular space (**e**), in analogy to KR2.[40] Hydrogen bonds are indicated with dashed lines, with the bond lengths given in Å. Double headed arrows indicate disrupted interactions.

Samples of ErNaR are activated with a nanosecond laser pulse of 532 nm wavelength (6 ns FWHM pulse duration, 6.4 mJ/cm^2 fluence) and jet vitrified at 107 µs and 13.3 ms, to probe the K_2 and O_2 states, respectively (Supplementary Information 5, 7). We analyze the structural dynamics of ErNaR at the level of a monomer (C_5 symmetry expansion), neglecting potential cooperativity between the subunits because of the small amplitude of the motions involved. We remove monomers that are not undergoing the photocycle with 3D classification, which then allows us to obtain a 2.8 Å and 3.3 Å reconstruction for the K_2 and O_2 state, respectively, and build molecular models (Supplementary Information 7). Figure 3c–e illustrates key features of the structural dynamics occurring in the retinal Schiff base, in the active center close to it, as well as in a site near the exit of the ion transport channel (highlighted in Fig. 3b), where sodium has been proposed to transiently bind in the O_2 state of monomeric KR2,[40] a well-studied sodium pump.

At 107 µs after photoactivation, we observe the K_2 state. As shown in Fig. 3c, the chromophore has been switched from the all-*trans* configuration present in the dark state to the 13-*cis* configuration,[45,46] a movement that is accompanied by small rotations of the aromatic sidechains in the retinal binding pocket. Moreover, in the adjacent active center, a disruption of the tight hydrogen bond network occurs that characterizes the dark state (Fig. 3d). This network, which includes Lys246 to which the retinal cofactor is covalently bound, is believed to prevent transport through the channel. Photoisomerization of the chromophore is thought to partially disrupt this hydrogen bonding network allowing a sodium ion to be translocated through the cavity of the active center.[39,47] In particular, the densities for the side chains of Glu64 and Asp105 suggest increased flexibility. In the dark state, these sidechains are strongly connected through a short hydrogen bond, which has been suggested to provide the structural basis for allowing ErNaR to efficiently pump sodium even at acidic pH. Here, this hydrogen bond appears to have been disrupted, along with the hydrogen bond between the retinal Schiff base and Asp105. Moreover, the density for the water molecule that is coordinated by Glu64 and Asp242 in the dark state is absent. We propose that these conformational changes are related to priming of the active center for the translocation of sodium.

At 13.3 ms, we observe ErNaR in the O_2 state. The O states are associated with the sodium ion translocation, but differ in the configuration of the retinal Schiff base.[48,49] Transient absorption

spectroscopy suggests that the transition from the O_1 to the O_2 state is accompanied by an isomerization of the chromophore from the 13-*cis* back to the all-*trans* configuration.[39] Indeed, Fig. 3d shows that the retinal Schiff base adopts the all-*trans* conformation, with the aromatic sidechains surrounding the retinal returned to their dark state positions. In the active center, the hydrogen bonding network has partially reformed (Fig. 3e). The sidechains of Asp105 and Ser60 now show a stable interaction, and Glu64 and Asp242 coordinate a water molecule. These conformational changes potentially indicate transient sodium binding near the retinal Schiff base, as observed for the pentameric sodium pump KR2.[50] Finally, we also observe conformational dynamics at a site near the exit of the ion transport channel (Fig. 3e), which for monomeric KR2, has been proposed to be a transient sodium binding site in the O_2 state.[40] The sidechain of Asn95 rotates into the binding site, which could feasibly facilitate transient sodium ion binding. We observe a spherical density at this position, which we cannot unambiguously identify as a sodium ion due to the limited resolution of the map and which we have therefore chosen to model as a water molecule. It appears likely that our map contains multiple transient sodium binding configurations, which limits its resolution, allowing only speculative interpretation at this stage.

Conclusion

In conclusion, we have demonstrated microsecond time-resolved cryo-EM experiments based on jet vitrification. Our method significantly expands the ability of cryo-EM to observe protein dynamics and presents an alternative to flash melting and revitrification experiments for achieving microsecond time resolution.[31] With further technical improvements, it should be possible to time the cryogenic jet even more accurately and ultimately match the few-microsecond time resolution afforded by flash melting experiments. Jet vitrification offers the advantage that it does not suffer from a limited temporal observation window, allowing us to observe protein dynamics continuously from a timescale of microseconds to seconds. Moreover, the sample temperature can be controlled easily, whereas in flash melting experiment, the sample follows a complex temperature evolution.[33,51] For now, our experiments are limited to processes that can be initiated with a laser pulse, for example by releasing a photocaged compound[35–37], inducing a temperature jump, or activating a light-sensitive protein, as we have done here. To broaden the range of dynamics that can be studied, it will therefore be crucial to develop approaches that enable the mixing of two reactants on the grid with microsecond time resolution.

Finally, we expect that our experimental approach should find applications beyond studying single-particle dynamics. For example, we have recently shown that if we replace laser excitation with mechanical excitation of the sample by an ultrasonic transducer during jet vitrification, we are able to overcome preferred orientation, even for such a notoriously challenging protein as hemagglutinin.[42] Jet vitrification has also been shown to enable the vitrification of thicker objects, including cells,[28] which suggests opportunities for performing microsecond time-resolved cryo-electron tomography experiments with our experimental design. It should also be possible to employ our approach to prepare freeze-quenched samples with microsecond time resolution for other techniques than cryo-EM, such as EPR spectroscopy, X-ray absorption, optical spectroscopy, or FRET experiments.
