ABSTRACT

Staphylococcus aureus Panton Valentine Leukocidin (PVL) is a pore-forming toxin targeting the human C5a receptor (hC5aR), enabling this pathogen to battle the immune response by destroying phagocytes through targeted lysis. The mechanisms that contribute to rapid cell lysis are largely unexplored. Here we show that cell lysis may be enabled by a process of toxins targeting receptor clusters and receptor 'recycling' which allows multiple toxin pores to be formed close together. Using live cell single-molecule super-resolution imaging, Förster resonance energy transfer (FRET) and nanoscale total internal reflection fluorescence (TIRF) colocalization microscopy we visualized toxin pore formation in the presence of its natural docking ligand. We demonstrate disassociation of hC5aR from toxin complexes and simultaneous binding of new ligands. This effect may free mobile receptors to amplify hyper inflammatory reactions in early stages of microbial infections and have implications for several other similar bi-component toxins and the design of new antibiotics.

38 **INTRODUCTION**

39 *S. aureus* causes diseases ranging from superficial skin and soft tissue infections (SSTI) to severe

40 invasive diseases like osteomyelitis and necrotizing pneumonia (1). During the 1960s, methicillin-

41 resistant *Staphylococcus aureus* (MRSA) was identified as a nosocomial pathogen (2). In the 1990s,

42 infection of previously healthy community-dwelling individuals with MRSA was reported (3). Since

43 then, these community-associated (CA-) MRSA have rapidly emerged worldwide (4). Variants have

44 also recently been identified which have reduced susceptibility to the antibiotic vancomycin (5) as well

45 as complete resistance, so-called VRSA (6), and these forms of *S. aureus* pose a significant threat to

46 human health. S. *aureus* and resistant variants have also evolved adaptations to evade attack from cells

47 of the human immune system. However, the molecular processes which underlie these strategies are

48 underexplored in living cells. There are compelling scientific and societal motivations to understand the

49 mechanisms involved in immunogenic evasion strategies of *S. aureus*.

50 In the early 1930s, Panton and Valentine described a powerful leukocidal toxin produced by

51 multiple *S. aureus* isolates, now denoted Panton-Valentine Leukocidin (PVL), years later shown to be

52 cytotoxic to neutrophils, monocytes and macrophages but not to lymphocytes (7, 8). The majority of

53 CA-MRSA isolates carry the genes encoding PVL, partially due to the successful spread of the PVL

54 carrying clone USA300 in the USA (3, 4, 9, 10), rarely present in hospital-acquired antimicrobial

55 resistant MRSA and methicillin susceptible *S. aureus* isolates. Based on epidemiological studies, PVL

56 is associated with primary skin infections in humans, osteomyelitis and, in particular, severe

57 necrotizing pneumonia (11, 12). Necrotizing pneumonia is a severe complication caused by bacterial

58 lung infection. It is characterized by massive recruitment of neutrophils in the site of infection, diffuse

59 pulmonary inflammation, septic shock, and respiratory failure. Both host factors and microbial

60   virulence factors are thought to play an important role in the inflammation, however, it is unknown

61   how the interplay between these two factors affects the severity of the disease (13).

62   PVL is a pro-phage encoded bi-component, β-barrel pore-forming toxin (β-PFT) comprising protein

63   subunits LukS and LukF. LukS binding to the surface of target cells induces secondary LukF binding;

64   chemical and genetic analysis suggests that the resulting complex consists of a lytic pore-forming

65   hetero-octamer (14, 15). Stoichiometric analysis *in vitro* of this complex suggests it is an octamer of 4-

66   plus-4 subunits (16). In this complex only LukS is known to interact with the human C5a receptor

67   (hC5aR, CD88), a G-protein coupled seven-transmembrane receptor (GPCR). LukS targets at least the

68   extracellular N-terminus of hC5aR (17, 18), similar to the chemotaxis inhibitory protein of *S. aureus*

69   (CHIPS), but may also interact with the transmembrane receptor region (19). C5aR is the ligand for

70   C5a, a powerful anaphylatoxin released during complement activation. Complement is a powerful first

71   line defense mechanism against invading pathogens which can be initiated through three pathways: the

72   classical, lectin, or alternative pathway. Activation of any of the three pathways on the target leads to a

73   rapid opsonization with C3b (20). Further activation of complement leads to initiation of the terminal

74   pathway with release of C5a and formation of membrane attack complexes that are lytic for Gram-

75   negative but not Gram-positive bacteria (21, 22). Therefore, in defense against Gram-positive bacteria

76   C3b-opsonization together with attraction and activation of neutrophils via C5a-C5aR interaction are

77   essential (23, 24). In severe cases, formation of C5a can potentially lead to hyper activation of the

78   inflammatory response, an inability to regulate this potentially fatal reaction and eventually harm the

79   human host tissues. Because of this strong pro-inflammatory activity, therapeutic interventions have

80   recently focused on neutralizing antibodies against C5a and C5aR as potential candidates for the

81   treatment of severe inflammatory conditions such as bacterial induced sepsis (25, 26).

82   LukS binding to hC5aR inhibits C5a receptor binding which efficiently blocks neutrophil

83   activation (17). LukS receptor binding alone is not sufficient for cell lysis but requires simultaneous

84   interaction between the leukocidin subunits and hC5aR. However, multiple possible subunit and

85   receptor combinations are theoretically possible and the spatiotemporal dynamics in functional

86   complexes in live cells between LukS, LukF and hC5aR is not yet known. In addition to PVL *S. aureus*

87   can produce a number of other β-PFTs with varying receptor and cell type specificities. From these

88   LukED, LukAB (or LukGH) and γ-hemolysin (composed of two compound pairs, HlgA/HlgB or

89   HlgC/HlgB) are classified as bi-component toxins like PVL while α-hemolysin is the prototypical β-

90   PFT that assembles into a pore through the oligomerization of seven monomeric polypeptides (27).

91   Next to bacterial toxins, an entire group of other pore forming proteins have been identified

92   which are involved in human innate immunity, indicating that pore-forming proteins are employed in

93   survival strategies for several types of organisms (28). Development of methods to study dynamic

94   processes of pore formation by these toxins at a molecular level may improve our understanding of the

95   evolution of bacterial virulence and human immunity. There are several studies that have attempted to

96   explain the function of bacterial PFTs, including structural and subunit stoichiometry data from high

97   resolution X-ray crystallography and single-molecule fluorescence microscopy (16, 29, 30). However,

98   these studies focused on pathogen instead of host factors and were thereby limited in excluding the

99   specific interaction between host cell receptor and bacterial toxin component, the first step required for

100   toxin oligomerization on the host cell membrane and the presence of the most potent factor mediating

101   the inflammatory response via C5a recognition in the site of infection (17).

102   Here, we used single-molecule fluorescence detection with super-resolution localization

103   microscopy (31) to determine protein complex assembly on receptors in live and fixed cell membranes.

104   We studied human embryonic kidney (HEK) cells modified to express monomeric Green Fluorescent

5

105   Protein (mGFP) labeled hC5aR, exposed to Alexa dye-labeled *S. aureus* toxin components LukS and

106   LukF and imaged using total internal reflection fluorescence (TIRF) real time microscopy (Figure 2-

107   figure supplement 1a) allowing us to monitor the spatiotemporal dynamics of receptor and toxin

108   molecules in the cell membrane. Our findings indicate that LukS binds on clusters of membrane-

109   integrated hC5aRs. The receptor-bound LukS then binds LukF leading to the formation of a pore that is

110   consistent with previous stoichiometric studies. However, when LukF is bound to the complex, we

111   observe fewer colocalized hC5aRs with toxin in fixed cells, more immobilized toxin complexes in live

112   cells and a significantly reduced Förster resonance energy transfer (FRET) signal, indicating,

113   unexpectedly, that pore formation leads to simultaneous dissociation of the receptors from the complex.

114   In addition, our biochemical data suggests that the dissociated receptor can then be available for

115   additional LukS molecules or the C5a generated during complement activation as a response to LukSF

116   mediated cell lysis. This new finding suggests that a limited number of receptors can be 'recycled' as

117   docking for further toxin. This ensures that a sufficient number of pores will damage nearby

118   phagocytic cells, particularly important when high numbers of C5a anaphylatoxin are blocking LukS,

119   and potentially also enables simultaneous C5a mediated inflammatory response on adjacent cells.

120

121   **RESULTS**

122   **Maleimide-labeled LukSF mediates toxicity on human polymorphonuclear (PMN) and HEK**

123   **cells.** To study LukSF pore formation on live cells using single-molecule fluorescence microscopy,

124   single cysteine substitutions on the exposed surface of the cap domain of the toxin complex (Figure 2 –

125   figure supplement 1b), K281C on LukS and K288C on LukF, were engineered to facilitate maleimide

126   labeling of LukF and LukS. These were denoted as the modified protein mLukF or mLukS. A second

127   substitution Y113H on LukS was chosen on the stem domain to facilitate pore formation of the LukS

128   mutant (mLukS), based on previous studies (16). We compared the lytic activity of these mutants to

129   their unmodified wild type equivalents by measuring PMN membrane permeabilization after 30 min

130   toxin exposure using a DAPI fluorescent dye to measure the DNA of lysed cells by flow cytometry.

131   DAPI does not penetrate intact cell membranes, and is therefore a good measure for cell permeability

132   and cell death. In this assay each of the wild type toxins was replaced with the modified protein either

133   unlabeled (mLukF or mLukS) or with a single Alexa647 dye molecule label (mLukF* or mLukS*)

134   (Figure 1). All modified proteins displayed toxicity phenotypes towards PMN cells with 100% cell

135   lysis detected at concentrations of 1-10 nM (Figure 1a), compared to wild type equivalents at ~3 nM.

136   Similarly, both mLukF and mLukF* displayed toxicity towards PMN cells, with the labeled toxin

137   mLukF* requiring closer to 30 nM concentration for complete lysis of the cells within 30 mincompared

138   to the wild type LukF(wt). Since the LukS component mediates the toxin recognition on the target cells

139   we next studied the binding of mLukS or mLukS* on PMNs. In this assay, mLukS was able to inhibit

140   the interaction of FITC-labeled wild type LukS on PMN cells equally well as the maleimide-labeled

141   mLukS* (Figure 1b).

7

142

143   The LukS/LukF toxin is known to be specific towards human cells expressing human C5aR

144   (hC5aR) such as neutrophils, monocytes and macrophages but does not lyse cells that do not express

145   the receptor (17). To further investigate the specificity of the mutated and labeled toxins on human

146   cells we prepared HEK cells overexpressing hC5aR, which unlike neutrophils can be easily cultured for

147   genetic manipulation and optical imaging experiments. We used a monomeric variant of green

148   fluorescent protein (mGFP) cloned in the C-terminal end of the receptor to report on the spatiotemporal

149   localization of the receptor and for determining the subunit stoichiometry in observed receptor clusters.

150   As expected, the toxins lysed only cells expressing hC5aR while the CCR2 expressing cells remained

151   intact (Figure 1d). We did not observe any binding of mLukF* on the same cells (Figure 1c) which is

152   consistent with previous observations that LukF in the absence of LukS does not interact with PMN

153   cells (15). The toxin inhibited binding of mLukS* in a dose-dependent fashion (Figure 1e).

154   After analyzing the concentration required for efficient LukS binding and cell lysis we wanted

155   to quantify the dynamics of cell lysis in the presence of mLukF and mLukS. Since the maleimide-

156   labeled mLukF required up to 10-fold higher concentrations for complete lysis of HEK cells within 30

157   min compared to PMNs, and because of the loss of molecules during washing cycles, the assay was

158   optimized to have 20-fold excess of mLukF* (600 nM for mLukF*). Following pre-incubation of

159   hC5aR-mGFP expressing cells with LukS(wt) or mLukS the second toxin component was added and

160   the cellular uptake of DAPI was measured as before using flow cytometry. The wild type toxins

161   LukF(wt) and LukS(wt) caused significant cell lysis (defined as >80% of all sampled cells in the

162   population) within 10 min, while closer to 20 min was required for significant lysis by the mLukF* and

163   mLukS toxin combination (Figure 1f).

8

164 **LukS colocalizes to hC5aR then addition of LukF triggers cell lysis.** A similar analysis was

165 performed by monitoring the lysis of live cells, sampling every 2.5 s at 50 ms exposure time per frame

166 using total internal reflection fluorescence (TIRF) microscopy, at very low excitation intensity to

167 prevent photobleaching and facilitate data acquisition of dynamic events involved in the formation of

168 LukSF nanopores in cell membranes. Here, hC5aR-mGFP cells were first imaged in the absence of

169 toxin. In the green channel we observed mGFP localization consistent with the cell membrane,

170 manifest as relatively high apparent brightness towards the cell boundaries consistent with the cell

171 membrane curving away from the microscope coverslip perpendicular to the TIRF excitation field.

172 Controlled addition of mLukS* (labeled with Alexa647) to the sample petri dish followed by washing,

173 while imaging simultaneously throughout, resulted in colocalization of the hC5aR and mLukS (Figure

174 2, Movie 1). Further addition of mLukF resulted in complete lysis of the cell, as defined by the

175 observation of explosive release of membrane vesicles, after ~15 min (Figure 2, Movie 2).

176 Colocalization of hC5aR, mLukS* and mLukF* (labeled with Alexa594) was also confirmed by three

177 color experiments, imaging cells after addition of toxins and washes until the start of lysis (Figure 2).

178

179 **LukS forms tetramers and clusters hC5aR before binding LukF.** Using higher laser intensity TIRF

180 excitation enabled rapid millisecond single channel sampling of single fluorophores faster than their

181 molecular mobility (32), confirmed by imaging antibody-immobilized GFP and Alexa dyes (Figure 3 –

182 figure supplement 1). Imaging live hC5aR-GFP cells in these conditions saturated the camera CCD but

183 after 1-2 min of exposure, photobleaching was sufficient to reduce intensity and allow us to observe

184 several distinct, mobile, circular fluorescent foci at a mean surface density of ~1 per μm^2 in the planer

185 membrane regions which lie parallel to the TIRF field away from the cell boundaries (Figure 3a, Movie

186 3). We monitored the spatiotemporal dynamics of foci in the planar membrane regions using automated

187   tracking software (33) which allowed foci to be tracked for several seconds to a spatial precision of

188   ~40 nm (34). The measured foci width (half width at half maximum determined from their pixel

189   intensity profile) was in the range 200-300 nm, consistent with the point spread function (PSF) width of

190   our microscope. By using step-wise photobleaching analysis we estimated stoichiometry values for all

191   detected fluorescent foci by employing a method which quantifies the initial unbleached foci brightness

192   and divides this by the measured brightness for the relevant single dye reporter molecule (Figure 3 –

193   figure supplement 1) (35). These foci contained large numbers of receptors of up to ~2,500 hC5aR

194   molecules with a mean stoichiometry of ~180 (Figure 3b, Table 1 – source data 1). Addition of mLukS

195   and mLukF increased the mean stoichiometry by >50% consistent with the toxin causing receptor

196   clustering.

197   Imaging mLukS* incubated with hC5aR-GFP cells revealed distinct foci (Figure 3a, Movie 4).

198   The probability distribution of mLukS* stoichiometry values in live cells in the absence of mLukF is

199   shown in Figure 3c, rendered using a kernel density estimation which generates an objective

200   distribution that does not depend upon the size and location of subjective histogram bins (36). We

201   measured a broad range of stoichiometry values, spanning a range from only a few LukS molecules per

202   foci to several tens of molecules, with a mean of ~30 molecules per foci. Closer inspection of the

203   stoichiometry values indicated an underlying periodicity to their probability distribution, which we

204   investigated using Fourier spectral analysis (37). The resulting power spectrum (Figure 3d) indicated a

205   fundamental peak equivalent to a stoichiometry of 3.9 ± 0.2 molecules, suggesting that foci are

206   composed of multiples of tetrameric mLukS* complexes.

207   Fluorescent foci, if separated by less than the diffraction-limited PSF width of our microscope,

208   are detected as a single particle but with higher apparent stoichiometry. We therefore tested the

209   hypothesis that the observed mLukS* foci stoichiometry distribution could be explained by the random

10

210 overlap of isolated mLukS* tetramer foci. To do so we modeled the nearest-neighbor separations of

211 individual mLukS* tetramers in the cell membrane as a random Poisson distribution (38) and used

212 sensible ranges of tetramer surface density based on our single particle tracking results (Figure 3 –

213 Figure supplement 2). However, all random tetramer overlap models we explored showed poor

214 agreement to the observed experimental stoichiometry distribution, but we found that random overlap

215 of multimers of tetramers could account for the stoichiometry distribution well (Figure 3e). Optimized

216 fits indicated that the random overlap of mLukS* foci with a stoichiometry in the range ~4-20

217 molecules were able to best account for the experimental data.

218   We tested if there was a dependence of foci stoichiometry on incubation time with leukocidin.

219 Acquiring a time course for mLukF* accumulation following pre-incubation of cells with mLukS was

220 not feasible since unbound mLukF* had to be washed from the sample to prevent a prohibitively high

221 fluorescent background. However, we were able to acquire time courses in which mLukF was added to

222 cells that had been pre-incubated with mLukS*. For these, the mLukS* foci stoichiometry distribution

223 was measured as a function of time after mLukF addition for several different fields of view, each

224 containing typically ~5 cells. We found that the mean hC5aR foci stoichiometry indicated no obvious

225 correlation to mLukF incubation time (Figure 3f), however the mean mLukS* foci stoichiometry

226 increased with time (p<0.05).

227   By calculating the mean squared displacement (MSD) as a function of time interval (τ) for each

228 tracked foci we could determine its microscopic diffusion coefficient (D). The distribution of D for

229 hC5aR and mLukS/F* (Figure 3 – figure supplement 2) had similar low value peaks at ~0.05 μm^2/s,

230 consistent with immobile foci tracked with our localization precision spatial precision of 40 nm.

231 Several mobile foci were also seen, which diffused at rates up to ~5 μm^2/s. Based on the measured

232 width of the immobile peak width on these distributions we set a threshold of 0.12 μm^2/s to categorize

11

233   foci as either immobile, which indicated a mean $D=0.025 \pm 0.030$ $\mu m^2/s$ ($\pm$SD), or mobile, which

234   indicated a mean $D=0.47 \pm 0.40$ $\mu m^2/s$ (Table 1 - source data 1). Plots of the measured MSD *vs.* τ

235   relations for mobile foci indicated a linear dependence indicative of free Brownian (i.e. 'normal')

236   diffusion. However, similar plots for immobile foci indicated an asymptotic dependence consistent with

237   confined diffusion (39), whose plateau was equivalent to a confinement diameter of ~400 nm (Figure 3

238   – figure supplement 3). The relative proportion of mobile foci was ~35% of tracked foci for hC5aR,

239   regardless of toxin and similar for mLukS in the absence of mLukF. Addition of mLukF, caused a drop

240   in the mobile proportion by a factor of ~3 (Figure 3g) suggesting that LukF causes insertion of the

241   complex and possible disassociation from the hC5aR.

242   **LukSF pores disassociate, allowing further toxin to bind hC5aR.** To determine whether the toxin

243   remains bound to the receptor, and to quantify the relative stoichiometry of components, we imaged

244   fixed cells, halting cell lysis, using the same two spectrally distinct green/red dyes of mGFP and

245   Alexa647 to label receptor and toxin components, respectively, as for the live cell experiments. We

246   imaged cells incubated with mLukS*, followed by incubation with mLukF and mLukS+mLukF* and

247   observed foci (Figure 4a) with similar stoichiometries (Figure 4 – figure supplement 1, Table 1 - source

248   data 1) to live cells but colocalized with hC5aR. Only <10% of the toxin was detected colocalized with

249   hC5aR but ~32% of the hC5aR was found colocalized in the presence of mLukS* dropping to <10% in

250   the presence of mLukF (Figure 4b). This low percentage was within our estimate of the degree of

251   random colocalisation between the green and red fluorophores, entirely down to chance, of ~10%. This

252   suggests that in the presence of mLukF, the toxin is not colocalised with the receptor such that mLukF

253   causes at disassociation from hC5aR. The stoichiometry values for detected green hC5aR-mGFP foci

254   were calculated and plotted against the equivalent stoichiometry estimates for colocalized red foci of

255   mLukS* and mLukF* respectively (Figue 4c and Figure 4 – figure supplement 1). In the presence of

256   mLukS* but in the absence of mLukF, the hC5aR-mGFP foci stoichiometry showed an approximately

257   linear dependence on number of associated mLukS* molecules, suggesting that each colocalized

258   mLukS* molecule was associated on average with ~4-5 hC5aR molecules. In the presence of labeled or

259   unlabeled mLukF no dependence was observed (Figure 4 – figure supplement 1, $R^2<0$) consistent with

260   random association between toxin and receptor

261   We performed FRET experiments on FITC sortase-labeled hC5aR and Cy3-labeled mLukS or

262   mLukF, as donor and acceptor respectively, in live cells to further probe the association between toxin

263   and receptor. A FRET signal from whole cells of ~75% efficiency was observed, dropping to ~56%

264   when incubated with unlabeled mLukF (Figure 4d and e), as would be expected if the complex

265   formation leads to dissociation of the toxin from the receptor. In order to examine possible FRET

266   between hC5aR and Cy3-labeled mLukF we performed similar experiments on fixed cells. In these

267   experiments a FRET efficiency of ~60% was observed between hC5aR and labeled mLukS dropping

268   below 40% between hC5aR and labeled mLukF. These results are also consistent with disassociation of

269   hC5aR from the pore, although conformational or local environment changes cannot be ruled out with

270   FRET alone since the relatively high remaining signal might in principle also indicate remaining

271   association or other inter or intra hC5aR-Luk interaction. The greater drop in FRET when measured

272   with mLukF compared to mLukS might be caused by the 3-4 nm further distance of LukF from hC5aR.

273   The collated findings taken altogether, however, from the changes in mobility, colocalization and

274   FRET with addition of mLukF are strongly indicative of disassociation of the LukSF complex.

275

276

277

13

278

279   To further confirm that the LukSF complex dissociates from the target receptor we used a

280   monoclonal PE-labeled anti-CD88 antibody to detect the increase of free hC5aR receptors on the cell

281   membrane upon LukSF formation. When C5a or wild type LukS was incubated with the hC5aR

282   expressing HEK cells without LukSF both ligands showed clear inhibition of anti-CD88 binding at 100

283   nM concentrations (Figure 5a). However, when the hC5aR expressing cells were incubated with 100

284   nM of LukS followed by incubation with increasing concentrations of wild type LukF a statistically

285   significant increase in anti-CD88 binding was detected at a LukF concentration of 1 nM when

286   compared to a 0 nM LukF concentration. This indicates that this was a "sublytic" concentration at

287   which rebinding of anti-CD88 could be detected without significant cell lysis (% of lysed cells < 10%)

288   (Figure 5b). At a 3 nM LukF concentration the proportion of dead cells increased above 10% of all

289   measured cells.

290   Since C5a is the natural ligand for hC5aR and can outcompete binding of LukS on the receptor

291   we next analyzed whether LukSF formation and disengagement of hC5aR would allow rebinding of

292   C5a on the receptor. To detect C5a rebinding at higher LukF concentrations we used a G130D LukF

293   mutant that interacts with LukS but does not cause cell lysis. Non lytic activity of this mutant in this

294   assay was confirmed by DAPI staining that showed minimal cell lysis even at higher concentrations

295   (9% at a 300 nM LukFG130D concentration). At a 300 nM concentration a significant increase in C5a

296   binding was detected indicating that LukSF dissociates from hC5aR enabling simultaneous rebinding

297   of an hC5aR interacting ligand (Figure 5c). This assay showed that C5a can potentially interact with

298   these cells that are attacked by LukSF. Because C5a is a potent anaphylatoxin that is generated during

299   complement activation and potentially plays a crucial role in *S. aureus* infections (41) we next analyzed

300   whether LukSF could lead to complement activation and C5a formation in an *ex vivo* full blood assay.

301   We used soluble C5b-9 as a marker for terminal complement activation and C5a formation, not C5a,

302   because LukS is known to compete with C5a for binding to hC5aR on neutrophils (17). The presence

303   of 200 nM of LukSF clearly increased formation of soluble C5b-9 compared to full blood without any

304   toxin or only LukS (Figure 5d), indicating that LukSF mediated cell lysis increases C5a formation and

305   potentially also inflammation in the site of infection.

306

DISCUSSION

308   *S. aureus* toxin components LukF and LukS are encoded by two co-transcribed genes of a prophage

309   integrated in the *S. aureus* chromosome (42). Most of the *S. aureus* clinical isolates investigated have

310   the genes encoding α-hemolysin, γ-hemolysin, LukAB and LukED but only 5% of those have LukSF

311   (PVL). This ratio for PVL, however, is different among CA-MRSA isolates where 85% of the strains

312   carry the *pvl* gene linking the toxin epidemiologically to these strains (10). The specificity to cell

313   surface receptors makes it difficult to study PVL's role in *S. aureus* pathogenesis in a whole animal

314   model. It is possible that lysis of neutrophils by PVL is responsible for a reduced host defense

315   mechanisms allowing the pathogen to spread and cause eventual tissue damage. However, a previous

316   study using a rabbit animal model on necrotizing pneumonia suggests that PVL itself directly or

317   indirectly causes tissue injury and by this way induces local inflammation (43). Our finding that the

318   toxin complexes are found in receptor clusters indicates that lysis of cells depends on the local density

319   of close proximity hC5a receptors that will initiate the pore formation process by docking LukS close

320   to the cell membrane such that four hC5aR-LukS dimers (assuming that one LukS binds one hC5aR)

321   can interact with the free non-bound LukF that will eventually form an octamer (i.e. 4 by 4) and a

322   functional pore with LukS. These data also suggest that when proper assembly in an octamer is

15

323   ongoing/complete, hC5aR will dissociate from the complex and, at the same time, interact with the C5a

324   that is formed during complement activation amplified by LukSF-mediated cell lysis. This is logical

325   because, in addition to invading microbes, apoptotic and necrotic cells are known to activate

326   complement (44). The triggering of local complement activation by toxin damaged cells and the release

327   of locally generated C5a (Figure 5) and its interaction with adjacent cells such as endothelial or lung

328   epithelial cells (45) could explain the mechanism behind the exacerbated inflammation characteristics

329   exhibited in necrotizing pneumonia. This is an important finding, suggesting that the cause of infection

330   can dramatically affect the magnitude of the inflammatory response and is highly dependent on the

331   dynamics of microbial molecules interacting with human receptors. In addition, the disengaged hC5aR

332   is possibly available for new toxins to bind, as C5a has been shown to here, thus allowing the receptor

333   to be recycled and reused by additional LukS molecules. Our finding that C5a can rebind indicates that

334   the dissociated free hC5aR does not change in conformation due to previous contact with LukS and

335   therefore would also be available for binding with LukS. We find that roughly half of LukS complexes

336   are immobile prior to LukF binding, but that LukF binding then results in mostly immobile LukSF

337   complexes. Speculatively, this result may suggest that LukS binds hC5aR initially and then inserts

338   itself transiently in the membrane phospholipid bilayer via the exposed hydrophobic residues,

339   following binding of LukF molecules to LukS. This conformation would in principle then lead to pore

340   formation across the whole cell membrane, thus resulting in a more stable insertion of the LukSF

341   complex into the cell membrane.

342   Human C5aR expressing cells such as human PMNs are susceptible to LukSF-mediated lysis

343   and we show that the interaction between maleimide-labeled toxin component LukS and the cell

344   surface receptor is required for the target recognition and cell lysis similarly as shown before for wild

345   type LukS (17). By characterizing the mobility of hC5aR and LukS in live cells we find that roughly

346   half of hC5aR and LukS foci diffuse relatively freely in the cell membrane while the remainder, rising

347   to > 90% of LukS when LukF is present, are confined to zones in the membrane of ~400 nm effective

348   diameter. We cannot directly determine the cause of this confinement in our present study. However, if

349   LukS were to undergo a conformational change following LukF binding then this may potentially

350   expose hydrophobic residues that could then insert the toxin into the hydrophobic interior of the

351   phospholipid bilayer; in other words, hydrophobobicity-mediated anchoring. This hypothesis is

352   strongly supported by the β-barrel prepore-pore formation putative mechanism of γ-hemolysin. Here

353   the residues responsible for binding with the phospholipid head group are located at the bottom of the

354   rim domain whereas the stem domain forms an antiparallel β-barrel of which the bottom half comprises

355   the transmembrane portion of the pore (30). This change from receptor associated LukS to cell

356   membrane associated LukSF complex can be seen as a change in the proportion of mobile (receptor

357   associated LukS) and immobile (toxin complexes inserted into cell membrane) foci detected in live

358   cells. GPCRs similarly are known to have heterogeneous mobility and lateral distribution properties in

359   living cells at different states for example before and after activation (46).

360   Crystallographic evidence from the monomeric LukF and LukS components and the intact γ-

361   hemolysin pore suggests that the pore is octameric formed from 4-plus-4 LukF/LukS subunits (29, 47,

362   48). Our findings support this octamer model but unlike previous studies also indicate that higher

363   stoichiometry clusters are formed on live cell membranes which have a measured periodicity of

364   stoichiometry equivalent to 4 LukS molecules, which cannot be accounted for by random overlap of the

365   diffraction-limited fluorescence images of individual tetrameric LukS or LukF complexes, but are

366   explained by a model which assumes the presence of octamer clusters. Each octamer component

367   consists of cap, rim and stem domains. Here, the cap domain contains the site for LukS/LukF

368   interaction while the stem domain unfolds and forms the transmembrane β-barrel upon pore formation.

17

369   Within crystallization the 2-methyl-2,4-pentanediol (MPD) molecules are bound at the base of the rim

370   domain, and recognized by Trp177 and Arg198 residues, that may participate in recognition of the

371   phospholipid bilayer as suggested in a crystal structure of the LukF monomer (49). In contrast, the

372   structure of the γ-hemolysin suggests a membrane interaction site within residues Tyr117, Phe119 and

373   Phe139 on the same toxin component (29). The crystal structure of LukED determined recently reveals

374   important details of the residues on LukE required for receptor identification (50). This component

375   corresponds to the receptor binding component LukS on the LukSF complex, scanning mutagenesis

376   indicting that LukS residues Arg73, Tyr184, Thr244, His245 and Tyr250, and to a lesser extent Tyr181,

377   Arg242 and Tyr246, are involved in binding to the neutrophil surface (51).

378   To determine the stoichiometry of the toxin components without immobilizing the protein on a

379   surface or within a crystal we implemented our fluorescence imaging method which allows us to

380   monitor the actual pore formation mechanism within a living cell, including the target receptor crucial

381   for the complex formation. This kind of study on protein complex formation has not been done before

382   due primarily to the difficulty of labeling the components and the high native fluorescence background

383   in mammalian cells. Our covalent labeling strategy and high excitation intensity TIRF microscopy,

384   combined with advanced image analysis tools, opens the way for further studies into many other pore

385   forming toxins and processes involving membrane bound protein complex formation.

386   Fourier spectral analysis combined with foci overlap modeling suggests that LukS complexes

387   comprise a multimer of ~4-5 hC5aR subunits each of which contain 4 LukS molecules. Our findings

388   are consistent with the hetero-octamer model of 4-plus-4 LukS/LukF subunits (16, 29, 30), but with the

389   refinement that 4-5 hetero-octamers associate as higher order multimers in the functional cell

390   membrane. However, our colocalization analysis also indicates the presence of stable complexes of

391   LukS with hC5aR independent of LukF. Similarly, we observe clusters of pre-established hC5aR in

18

392   the absence of LukS or LukF, but the addition of LukS or LukF significantly increased the mean cluster

393   stoichiometry. These results suggest that further binding sites for hC5aR on LukS could be possible in

394   addition to those identified in the LukS rim domain (51). However, since the binding of LukS to

395   neutrophils is inhibited by the C5a it is likely that LukS has only one binding site on the receptor (19).

396   This is also supported by the similar inhibition profiles of LukS and C5a towards anti-CD88 binding on

397   hC5aR shown in this study. Therefore, the association of LukS with approximately 4-5 hC5aR

398   molecules could be explained by the previous suggestion that C5aR forms homo-oligomers in living

399   cells (52). Our findings imply that LukSF assembly is dependent on hC5aR cell membrane area density

400   as opposed to the effective hC5aR concentration when calculated over in the whole of a target cell

401   volume, such that even when hC5aR cellular expression levels are low a cell lysis response may still be

402   achieved through the efficient targeting of receptor clusters and recycling of the receptor molecules in

403   the cell membrane to be re-used by free non-bound LukS to get engaged in octamer pore formation.

404   Previous *in vitro* studies on LukSF pores formed on human leukocytes and rabbit erythrocytes

405   have found evidence for both octamers and hexamers, but importantly both suggest a LukF/LukS ratio

406   of 1:1 (16, 53, 54). Interestingly we did not observe any correlation to the number of hC5aR present

407   with LukF incubation time once LukF was already bound to LukS. Moreover, when LukS was

408   incubated with LukF using sortase-labeled hC5aR cells a significant reduction was observed in the

409   FRET efficiency signal. It is unlikely that the reduction that was observed in FRET efficiency would be

410   due to a conformational change because the cysteine mutation used for maleimide labeling was

411   designed to be exposed on the cap domain of LukS and LukF (Figure 2 – figure supplement 1) that in

412   light of the structural data undergoes minimal or no conformational changes during complex assembly

413   (30). Since our biochemical assays indicate that LukF does not bind directly to hC5aR expressing cells

414   and, that binding of LukF to LukS results in an increased distance between the receptor and the

415   complex, this suggests that LukF binding to LukS results in LukS dissociating from the receptor,

416   released as a newly formed LukSF complex.

417   We cannot directly determine the cause of this behavior in our present study, however one

418   explanation may lie in the conformational change during the prepore-to-pore transition that has been

419   shown to occur on γ-hemolysin complexes subsequently after binding of LukF to LukS (29, 30).

420   Interestingly, this same study shows that during the pre-pore state the space for the transmembrane

421   region is occupied by the rim domain of the adjacent octamer in a LukSF crystal. One explanation for

422   these observations, that remains to be explored, is that in addition to the stem domain the residues

423   within the rim domain that interact with the receptor might also have different orientations in the pre-

424   pore state when compared to the pore state. The putative dissociation of the hC5aR from the LukSF

425   complex was further verified by incubating LukS-coated hC5aR cells with increasing concentrations of

426   LukF. Here, increase in anti-CD88 binding also clearly indicates LukSF dissociation. This kind of

427   receptor disengagement has been shown before by at least the cytotoxin intermedilysin which interacts

428   with a GPI-anchored complement regulatory molecule on the cell membrane (55). Moreover,

429   dissociation of LukSF complex is also supported by electron microscopy of LukSF on human leukocyte

430   membrane fragments. Here, the ring-shaped oligomers with outer and inner diameters of 9 nm and

431   3 nm were shown without a receptor (54).

432   In this study we also show, for the first time to our knowledge, that the dissociated receptor can

433   be reused by free unbound C5a. This indicates that LukS binding on the receptor does not change

434   receptor conformation and thereby can putatively also be reused by additional LukS. In our full blood

435   model we observed that LukSF mediated cell lysis clearly increased complement activation and C5a

436   formation. The increase in C5a concentration in the site of infection could potentially limit the

437   availability of hC5aR for LukS molecules on neutrophils and thereby reduce lytic activity of the toxin

20

438   as C5a has previously been shown to reduce LukSF mediated lysis *in vitro* (17). Rebinding of C5a on

439   the receptor may therefore indicate that in natural settings where all components (i.e. LukS, LukF and

440   C5a) are present C5a can outcompete binding of LukSF on the target cells. Therefore, recycling of the

441   receptor could be one strategy for the toxin to ensure that a sufficient number of pores will damage the

442   cells especially when limited number of receptors are available.

443   There are several steps on the leukocidin complex assembly that may be critical for the function

444   of the toxin. Based on our observations we provide new information on leukocidin-receptor interactions

445   and propose two additional stages to the processes of pore formation and the mechanism by which

446   LukSF potentially induces inflammation (Figure 6). Stage 1 is the binding of LukS to hC5aR clusters.

447   The first step in this process is the target recognition of LukS binding to the membrane receptor. The

448   LukS-hC5aR complexes were detected on clusters of receptors indicating that pore formation takes

449   place in these clusters. Stage 2 is the dissociation of the LukSF complex from the receptors and

450   rebinding of free unbound ligand back to the receptor. We measured a correlation between the number

451   of LukS and hC5aR molecules present in LukS-hC5aR complexes, but with no obvious correlation

452   between the number of LukF and hC5aR molecules when LukF was added to the LukS-hC5aR

453   complex. In addition to previous studies (43) we suggest that LukSF-mediated cell lysis and

454   dissociation from hC5aR can potentially amplify *S. aureus* mediated inflammation in the site of

455   infection (Figure 6). The direct lysis of neutrophils is enhanced by newly formed LukSF complexes

456   that are formed on the cell membrane hC5aR via reattachment of new LukS. Neutrophil lysis activates

457   the complement system and the newly generated C5a induces cytokine/chemokine production and

458   neutrophil chemotaxis via the C5a/C5aR signaling pathway on adjacent cells. Furthermore, the

459   increased vasodilation and vascular permeability leads to massive neutrophil accumulation and tissue

460   injury at the site of bacterial infection (56).

461   In summary, our findings that the receptors of targeted host cells dissociate rapidly from the

462 leukocidin complex upon formation of a harmful toxin pore, freeing up mobile receptor 'seeds' that can

463 diffuse to other parts of the cell membrane, suggest a hitherto undiscovered strategy used by microbes

464 to kill human immune cells that enables a limited number of receptors to be recycled as docking for the

465 leukocidin or potentially the anaphylatoxin C5a to ensure that enough pores will form to damage the

466 host cell and simultaneously maintain or possibly amplify the inflammation in the site of infection. This

467 discovery may generalize to other bi-component toxins which employ a similar docking receptor like

468 the C5aR receptor, including the family of *Staphylococcal* bi-component leukocidins of HlgC/HlgB,

469 HlgA/HlgB, LukE/LukD (CXCR1, CXCR2, CCR5), and LukM/LukF' for bovine CCR2. These results

470 highlight the importance of leukocidin-receptor interactions in pore formation and may facilitate further

471 understanding in the role of pore-forming toxins in *S. aureus* infections. This new mechanistic insight

472 may prove valuable to the development of future antibacterial and anti-inflammatory therapies,

473 especially important in light of the growing menace of global antimicrobial resistance.

474

475 **MATERIALS AND METHODS**

476 **Experimental model and subject details**

477 *PMN isolation, Cell Lines, and Transfections*. Human blood was obtained from healthy volunteers

478 and the polymorphonuclear (PMN) cells were isolated by Ficoll/Histopaque centrifugation (57).

479 Informed consent was obtained from all subjects, in accordance with the Declaration of Helsinki and

480 the Medical Ethics Committee of the University Medical Center Utrecht (METC-protocol 07-125/C

481 approved 1 March 2010). A fusion construct of hC5aR with the monomeric GFP variant mGFP with

482 A206K mutation (also denoted GFPmut3) (58) was made at the C-terminus (primers used listed in

483 Table 2 - source data 2) or a sortase A LPXTGG sequence was made in the N-terminus and cloned into

484 pIRESpuro vectors (Table 2 - source data 2) by PCR. The amplification reaction was performed in

485 three separate amplification steps using overlap extension PCR on hC5aR and mGFP templates. hC5aR

486 (Accession number of human C5aR = NM_00173) was used as the template using enzymes and

487 purification kits as described above. The clones were ligated into the vectors and transferred into

488 TOP10 *E. coli* competent cells, then amplified and sequenced similarly to the toxin clones described

489 previously. The pIRESpuro/hC5aR-mGFP vector was transfected into Human Embryonic Kidney

490 (HEK) 293T cells (a HEK cell line, Invitrogen), stably expressing G protein Gα16, using

491 Lipofectamine-2000 Reagent according to manufacturer's instructions (Thermo Fisher Scientific).

492 After 24–48 hr, transfected cells were harvested with 0.05% trypsin. To obtain a uniform, stable

493 culture, cells were sub-cloned in a concentration of 0.5 cells/well in a 96-well plate in Dulbecco's

494 modified Eagle's medium (DMEM, Lonza) supplemented with 10% fetal calf serum (Invitrogen) 100

495 U/ml penicillin/ 100 µg/ml streptomycin (PS; Invitrogen), 1 µg/ml Hygromycin and 250 µg/ml

496 Puromycin. For N-terminal labelling of the sortase A recognition sequence containing HEK cells with

497 FITC were successfully performed in two steps as described previously (59). The expression of hC5aR

23

498   was analyzed by incubating the cells in 50 µl RPMI (Invitrogen) supplemented with 0.05% human

499   serum albumin (Sanquin), RPMI-HSA, at 5×10^6 cell/ml concentration for 45 min with PE-conjugated

500   anti-CD88 and detected by flow cytometry. The presence of mGFP or FITC-LPXTG was detected

501   directly by flow cytometry.

502   ***Recombinant Protein Production and Purification.*** Polyhistidine-tagged LukS and LukF were cloned

503   and expressed using an *E. coli* expression system. For maleimide-based labeling a single-cysteine

504   mutation was designed to the LukS and LukF components based on previous data and the crystal

505   structure of the octameric pore (29). An additional mutation Y113H was included in LukS to facilitate

506   oligomerization of the maleimide-labeled protein (16). The target genes were amplified by PCR (Table

507   2 - source data 2) from the wild type sequences using Phusion High-Fidelity DNA polymerase (Thermo

508   Scientific) (17). The PCR product was cloned into a slightly modified pRSET expression vector

509   (Invitrogen), resulting in expression of proteins with an N-terminal 6xHIS-tag. For LukF mutant

510   G130D we useda gBlock (custom dsDNA sequence via Integrated DNA Technologies) to incorporate

511   the LukF in the pRSET vector. Clones were sequenced to verify the correct sequence. The recombinant

512   proteins were expressed in Rosetta Gami (DE3) pLysS *E. coli* using 1mM IPTG induction and isolated

513   by a native isolation method. The expressed proteins were purified according to the manufacturer's

514   instructions (Invitrogen) using 1 ml Nickel HisTrap and Superdex 75 HiLoad columns (GE Health Care

515   Life Sciences). Toxin components were labeled with either Cy3 (GE Healthcare), Alexa Fluor® 594 or

516   Alexa Fluor® 647 C_2 Maleimide reagent according to the manufacturer's instructions (Thermo

517   Scientific) resulting in negligible unlabeled content. The labeling efficiency was 100% as determined

518   by protein concentrations using absorption at A280 and dye concentrations using absorption at A650 by

519   a Nanodrop ND-1000 Spectrophotometer.

520

521   **Method details**

522   ***Binding Assays***. Binding of the maleimide-labeled proteins to PMN and HEK cells was confirmed by

523   flow cytometry. LukS-K281C-Y113H (mLukS) or wild type, LukS (wt) was labeled with FITC or

524   Alexa Fluor maleimide 647 or 594. For competition assays 3 µg/ml of the labeled protein and

525   increasing concentration of non-labeled mLukS or LukS(wt) was incubated with isolated PMNs or

526   HEK hC5aR-mGFP cells (5×10^6 cell/ml) in a total volume of 50 µl RPMI-HSA on ice. For binding

527   assays without competition the cells were incubated with increasing concentration of mLukF*. After

528   30 min incubation on ice, cells were washed, fixed with 1% paraformaldehyde and analyzed by flow

529   cytometry. HEK cells transfected with CCR2 receptor were used as negative control for mLukS

530   binding. To see inhibition of PE anti-CD88 (BD biosciences) binding by LukS(wt) or C5a hC5aR

531   expressing HEK cells were first incubated with increasing concentrations of LukS or C5a for 45 min at

532   4°C. Then 2 µl of anti-CD88/200,000 cells was added and incubated as previously. Cells were washed

533   once with RPMI-HSA, fixed with 1% paraformaldehyde and analyzed by flow cytometry. To detect

534   hC5aR dissociation using sublytic concentrations of LukSF hC5aR expressing HEK cells were

535   incubated with 100 nM of wild type LukS for 45 min at 4°C. After washing the unbound LukS sublytic

536   concentrations of wild type LukF was added to the cells and incubated for 20 min at 37°C and 5% CO_2

537   atmosphere. Percentages of lysed vs. non lysed cells were measured by using 1µg/ml of DAPI in the

538   reaction. For C5a rebinding assay 1 µM of C5a (Sigma) was labeled with NT-647 according to

539   manufacturer's instructions (Monolith NT™). Free label from the sample was removed by three times

540   centrifugation trough Amicon Ultra 0.5 mL centrifugal filters (Sigma). The hC5aR expressing HEK

541   cells were incubated with 1 µM of wild type LukS for 45 min at 4°C. After washing 20 nM of NT647-

542   C5a and increasing concentrations of wild type LukF was added to the cells and incubated for 20 min at

543   37°C and 5% CO_2 atmosphere. Cells were washed once with RPMI-HSA, fixed with 1%

25

544 paraformaldehyde and analyzed by flow cytometry. Percentages of lysed vs. non lysed cells were

545 measured by using 1µg/ml of DAPI in the reaction. *S. aureus* Ecb (extracellular complement binding

546 protein) was used as negative control as it interacts with another cell surface receptor, CR1 (60). Flow

547 cytometry data were analyzed using FlowJo v10 software package.

548 *Cell Permeability Assays*. Isolated PMNs or HEK hC5aR-mGFP cells (5×10^6 cell/ml) were exposed to

549 labeled and unlabeled mixtures as appropriate of mLukF/mLukS recombinant proteins at equimolar

550 concentrations in a volume of 50 µl RPMI-HSA with 1 µg/ml of DAPI. Cells were incubated for

551 30 min at 37°C with 5% CO_2 and subsequently analyzed by flow cytometry. To calculate the lysis time

552 cells were first incubated with 150 nM of mLukS for 15 min. Then 600 nM of mLukF was added and

553 immediately subjected to flow cytometry analysis where the permeability was measured at several time

554 points. Cell lysis was defined as intracellular staining by DAPI. HEK cells transfected with human

555 CCR2 receptor was used as negative control for toxin-mediated lysis. Statistical differences between

556 means of repeated experiments were calculated using two-tailed Student *t*-tests.

557 *Ex vivo complement activation assay.* To maintain complement activity the blood samples were

558 anticoagulated with lepirudin (Refludan, Schering, Berlin, Germany). Increasing concentrations of

559 LukSF or LukS (0 to 2000 nM) was incubated in full blood for 30 min at 37°C under continuous

560 rotation (300 rpm). Complement activity was stopped by adding 10 mM EDTA in the suspension and

561 the plasma was separated from the blood cells by centrifugation at $5000 \times g$. A 1:30 dilution of each

562 plasma sample was analyzed by SC5b 9 Enzyme Immunoassay according to manufacturer's

563 instructions (MicroVue SC5b 9 Plus Enzyme Immunoassay, Quidel). One *S. aureus* colony (1 x 10^8

564 cells) was used as a positive control for SC5b-9 formation. The bacteria were grown over night on

565 blood agar plate at 37°C 5% CO_2 atmosphere.

566 ***Fluorescence microscopy***. Cells were imaged using a Nikon A1R/STORM microscope utilizing a x100

567 NA oil immersion Nikon TIRF objective lens. We used a total internal reflection fluorescence (TIRF)

568 microscopy module. We used laser excitation at wavelengths 488 nm (for mGFP), 561 nm (for

569 Alexa594) and 647 nm (for Alexa647) from a commercial multi laser unit fiber-coupled into the

570 microscope, capable of delivering maximum power outputs up to ~200 mW, with a depth of

571 penetration in the range ~100-130 nm for the TIRF excitation evanescent field. Fluorescent images

572 acquired on an iXon+ 512 EMCCD camera detector (Andor) at a magnification of 150nm/pixel. Green

573 and red channel images were obtained by imaging through separate GFP or Alexa647 filter sets. For

574 high laser excitation intensity single-molecule millisecond imaging, green channel images to determine

575 mGFP localization were acquired continuously using 488 nm wavelength laser excitation over a period

576 of ~5 min through a GFP filter set, then the filter set was manually switched to Alexa647 as for red

577 channel images acquisition continuously using 647 nm wavelength laser excitation until complete

578 photobleaching of the sample after 1-2 min. For photobleaching laser powers ranged between 15 mW

579 (Alexa 647) to 100 mW (mGFP). For fixed cell analysis cells were either incubated first with mLukS or

580 mLukS*, washed and incubated with mLukF or mLukF*, or incubated first just with mLukS* with

581 mLukF* absent, then washed and fixed with 1% paraformaldehyde.

582   For fluorescence imaging the HEK cells were grown on 0.1% poly-L-lysine which coated

583 8-well chambered cover glass slides (Ibidi) in standard growth conditions described above. To analyze

584 the deposition of mLukS* on live cells the cells were first imaged in PBS buffer in the absence of

585 toxin. Here, a 256×256 pixel area covered approximately one cell per field of view. Then the cells

586 were incubated for 2 min with 5 µg/ml of Alexa594 maleimide-labeled LukS in RPMI-HSA and the

587 cells were carefully washed with PBS keeping the imaging area and focus constant. Because of the fast

588 bleaching of the Alexa647 label a more stable Alexa594 label was used for the LukS deposition

589   imaging. The deposition of mLukS was detected for 10 min and the lysis of the cell was recorded for

590   15 min after addition of 600 nM of unlabeled mLukF. Cells were imaged in TIRF at 50 ms per frame

591   with the laser automatically switched between 488 nm/0.22 mW, 647 nm/3 mW and 561 nm/3 mW or

592   488 nm/0.22 mW and 561 nm/3 mW (Figure 2).

593   *FRET experiments*. The Cy3-labeled LukS or non-labeled LukS and Cy3-labeled LukF or non-labeled

594   LukF and controls (only FITC-labeled cells or unlabeled cells with only Cy3-labeled LukS) were

595   incubated at 4°C for 30 min and then 10 min at 37°C, washed 2 x with RPMI-HSA and fixed as before.

596   The cells were in PBS during imaging. FITC experiments were performed using Leica TCS SP5

597   microscope, using a 62× oil immersion objective lens, and FRET Sensitized Emission Wizard in Leica

598   Application Suite Advanced Fluorescence (LAS AF). Images were acquired using 488 nm and 543 nm

599   wavelength lasers and a laser power of 27% 12.0 (A.U.) and a scan size of 512×512, 800 ms, 50 ms

600   per frame, beam splitter TD 488/543/633.

601   FRET efficiency ε was calculated using the donor, directly excited acceptor and donor excited

602   acceptor intensity from n=5-10 manual regions of interest inside cells for each experiment, using the

603   following formula (61):

$$\varepsilon = \frac{\beta(B - D) - \gamma A}{A}$$

604   B = Intensity signal, donor excited acceptor
605   D = Intensity signal, donor
606   A = Intensity Signal, directly excited acceptor
607   β = calibration for ratio of measured intensities of $B_{donor\ channel}/A_{donor\ channel}$
608   γ = calibration for ratio of measured intensities of $B_{acceptor\ channel}/A_{acceptor\ channel}$
609

610   *Single-molecule imaging of live and fixed cells*. GFP and Alexa647 fluorescence micrograph time

611   series of fixed and live cells were sampled taken at. 20 ms per frame. Green channel images were

612   acquired continuously using 488 nm wavelength laser excitation over a period of *ca.* 5 min via the GFP

613   filter set. Then the filter set was manually switched to that for Alexa647 and red channel images were

614   acquired continuously using 647 nm wavelength laser excitation was until complete photobleaching of

615   the sample after 1-2 min. The step-wise single-molecule fluorescence photobleaching was analyzed

616   both for live and fixed cells. For live cell photobleaching analysis the cells were incubated with 150 nM

617   of labeled or unlabeled mLukS as required for *ca.* 15 min. After washing with PBS, 600 nM of labeled

618   or unlabeled mLukF was added and the imaging was done immediately within 10-15 min. If labeled

619   LukF was added the wells were washed with PBS before analysis. Also samples with only LukS and

620   without toxins were analyzed. For fixed cell analysis the cells were incubated first with mLukS or

621   mLukS* for 30 min at +4°C in RPMI-HSA, washed with same buffer and incubated for 10 min at 37°C

622   with mLukF or mLukF*, or the same protocol was followed but using mLukS* alone with mLukF*

623   absent. Then the cells were washed and fixed with 1% paraformaldehyde. 1M mercaptoethylamine

624   (MEA) buffer was used for fixed cell analysis. Photobleaching of recombinant mGFP and mLukS-

625   Alexa647 were also separately analyzed in a tunnel slide comprising two pieces of double-sided tape

626   forming a channel sandwiched between a standard glass microscope slide and a plasma cleaned

627   coverslip. Proteins solutions (1μg/ml) were immobilized onto the coverslip coated by anti-GFP or anti-

628   His antibodies respectively with phosphate buffered saline washes in between.

629

630 **Quantification and statistical analysis**

631

632 ***Binding and permeability assays.*** Statistical significance between repeated (n>1) experiments was

633 analyzed using two-tailed Student's *t*-tests where using a standard p-value threshold of <0.05 as

634 indicating statistical significance. Means and standard deviations of repeated experiments are shown in

635 error bars, unless indicated otherwise.

636 ***Image analysis***. Basic image extraction, cropping and quantification was done using NIS-Elements

637 microscope imaging software and Image J. More advanced foci tracking was done using bespoke

638 software written in MATLAB (Mathworks) (33) which enabled automatic detection and localization of

639 individual fluorescent foci to within 40 nm lateral precision (Figure 3 – figure supplement 1a). The

640 software identifies candidate foci by a combination of pixel intensity thresholding and image

641 transformation. The intensity centroid and characteristic intensity, defined as the sum of the pixel

642 intensities inside a 5-pixel radius circular region of interest around the foci intensity centroid minus the

643 local background and corrected for non-uniformity in the excitation field are determined by repeated

644 Gaussian masking. If the signal-to-noise ratio of a foci (the intensity per pixel/background standard

645 deviation per pixel) is greater than a pre-set threshold, nominally here set at 0.4 based on prior

646 simulations, it is accepted and fitted with a 2D radial Gaussian function to determine its width. Foci in

647 consecutive frames within a single PSF width, and not different in intensity or width by greater than a

648 factor of two, are linked into the same track.

649 Foci intensity was used to quantify stoichiometry information. As foci photobleach over time

650 during continuous laser excitation their intensity falls in a stepwise manner due to photobleaching of an

651 integer number of fluorophore tags in each sampling time window. By quantifying the size of a single

652 step, the characteristic intensity of a single fluorophore can be obtained and thus the stoichiometry of

30

653   the foci from its initial intensity. The step size is found from the periodicity in the distribution of foci

654   intensities corroborated by the pairwise distance (PwD) distribution of these intensities and the Fourier

655   spectrum of the PwD which contains peaks at the characteristic intensity and harmonics at multiples of

656   this value (Figure 3- figure supplement 1d-e).

657   Here, the copy number of hC5aR-mGFP was comparatively high such that the TIRF images

658   were initially saturated in regards to pixel intensity output. After ~20 s of photobleaching the non-

659   saturated foci intensity values were fitted by an exponential function which characterized the rate of

660   intensity decay, equivalent to an exponential photobleach time of ~20 s, and extrapolated back to zero

661   time to determine the initial foci intensity (Figure 3 – figure supplement 1f). The Alexa647 dye also

662   bleached during 647 nm wavelength laser excitation but images were not initially saturated, but also in

663   some images which were exposed to the 488nm laser and then the 647nm laser, also bleached by the

664   488 nm wavelength laser. In these images a fixed correction factor of 6x, determined by comparing to

665   images exposed to the 647 nm laser first, was used. The stoichiometry of each foci was then

666   determined as the initial intensity divided by the intensity of the appropriate single fluorescent dye tag

667   (i.e. either mGFP or Alexa647 in this case).

668   We characterized the mobility of tracked foci by calculating their MSD as a function of time

669   interval (τ). For each detected foci the MSD was calculated from the measured intensity centroid

670   ($x(t)$,$y(t)$) at time t assuming a foci track of N consecutive image frames at a time interval $\tau=n\Delta t$ where

671   n is a positive integer and Δt is the frame integration time (here 20 ms):

$$MSD(\tau) = MSD(n\Delta t) = \frac{1}{N-1-n} \sum_{i=1}^{N-1-n} \left(\left(x(i\Delta t + n\Delta t) - x(i\Delta t)\right)^2 + \left(y(i\Delta t + n\Delta t) - y(i\Delta t)\right)^2 \right)$$

$$= 4D\tau + 4\sigma^2$$

672

673   The lateral (xy) localization precision is given by σ which we determine to be 40 nm. We fitted a

674   straight line to each separate MSD relation. Assuming a line fit has an optimized gradient g to the first

675   4 points (defined as the first we 3 measured MSD data points for $n=1$, 2 and 3, in addition to a 4$^{\text{th}}$ data

676   corresponding to $n=0$ obtained from constraining the intercept be $4\sigma^2$ to within measurement error of

677   the localization precision) then estimated the microscopic diffusion coefficient D as $g/4.\Delta t$. For

678   immobile foci, tracks were collated and compiled to generate a mean MSD vs. τ relation which was

679   fitted to an asymptotic rising exponential function as an analytical model for confined diffusion of

680   MSD plateau equal to $L^2/6$ where L is the effective confinement diameter (39), enabling us to estimate

681   the confinement diameter.

682   *Colocalization analysis*. The extent of colocalization between red and green detected foci was

683   determined using a method which calculated the overlap integral between each green and red foci pair,

684   whose centroids were within ~1 PSF width (~3 pixels). Assuming two normalized, two-dimensional

685   Gaussian intensity distributions g_1 and g_2, for green and red foci respectively, centred around (x_1, y_1)

686   with sigma width σ_1, and around (x_2, y_2) with width σ_2, the overlap integral ν is analytically determined

687   as:

$$\nu = e^{\left(-\Delta r^2/2\left(\sigma_1^2+\sigma_2^2\right)\right)}$$

688

689   Where:

$$\Delta r^2 = (x_1 - x_2)^2 + (y_1 - y_2)^2$$

690

691

692   We use a criterion of an overlap integral of 0.75 or above to indicate putative colocalization

693   (38) since this corresponds to a foci centroid separation equivalent to the localization precision in this

694   case. By quantifying the standard deviation on the number of detected foci in each channel we estimate

695   that the standard error of colocalisation proportion under our typical imaging conditions is

696   approximately 9%.

697   ***Random foci overlap models***. We calculated the probability of foci overlap in a single color channel by

698   first estimating a sensible range of foci surface density n. For the lower limit we used the number of

699   foci tracks detected in a 20 image frame time window, for the upper limit we used the average

700   measured value of the background-corrected pixel intensity value divided by the intensity of a single

701   fluorophore (equivalent to ~1 mLukS* molecule per pixel). We implemented these probability

702   estimates into a surface density model which assumed a random Poisson distribution for nearest-

703   neighbor separation (37, 38, 40, 62-64). This model indicates that the probability that a nearest-

704   neighbor separation is greater than w is given by $\exp(-\pi w^2 n)$. The probability of overlap for each

705   density estimate (Figure 3 – figure supplement 3) was convolved with a real molecular stoichiometry

706   distribution and a Gaussian function $p(x)$ of stoichiometry (x):

$$p(x) = 2\pi\sigma^2 \exp\left(-\frac{(x-n)^2}{2\sigma^2\sqrt{n}}\right)$$

707   where σ is the width of single fluorophore intensity distribution (~0.7 molecules), and n is the real

708   molecular stoichiometry. The tetramer model assumes $n=4$, then all higher order stoichiometries are

709   due to overlapping PSFs. The tetramer oligomer molecule assumed an equal number of multimerized

710   tetramers up to 5, which gave the best fit to the data.

711   The same strategy was used to model the random overlap probability for green and red color

712   channel fluorescent foci in dual color imaging experiments to assess the extent of apparent

713   colocalization due to random overlap between hC5aR and mLukS*/F*. The probability that a nearest-

714   neighbor separation is greater than w for foci of two different types is the same as a single type

715   multiplied by 2/3. (38)

716

717   **Statistical tests and replicates**

718   All statistical tests used are two-tailed unless stated otherwise. For single-molecule TIRF imaging each

719   cell can be defined as a biological replicate sampled from the cell population. We chose sample sizes of

720   5-7 cells yielding thousands of foci, generating reasonable estimates for stoichiometry and diffusion

721   coefficient distributions. Technical replicates are not possible with the irreversible photobleaching

722   assay.

723

724   **Ethics statement**

725   Human polymorphonuclear (PMN) cells, obtained from healthy volunteers were isolated by

726   Ficoll/Histopaque centrifugation (57). Informed written consent was obtained from all subjects, in

727   accordance with the Declaration of Helsinki and the Medical Ethics Committee of the University

728   Medical Center Utrecht (METC-protocol 07-125/C approved 1 March 2010).

908   **Legends**

909   **Figure 1. Toxin functionality on PMN and HEK cells.** (A) PMN cell permeability in the presence of

910   unlabeled LukSK281CY113H and LukFK288C (mS+mF, number of biological replicates n=2), Alexa-

911   labeled mS* or mF* and wild type LukF (F(wt)) or LukS, (S(wt)) (n=1), compared to PMN cell

912   permeability of S(wt) and F(wt), (n=3); (B) Inhibition of 3 µg/ml of FITC-labeled S(wt) (n=3) and mS*

913   (n=1) binding to PMN cell by mS; Permeability dose dependencies for (A) and (B) are shown with a

914   polynomial spline fit, statistical significance indicated between low (0.3 and 0.001 nM) and high (300

915   nM) toxin concentrations using Student's *t*-test. Error bars indicate SD. (C) Column indicating binding

916   responses for mF* on hC5aR cells (n=2). *** Indicates a statistically significant difference (p<0.001)

917   between mS* binding on HEK-hC5aR cells compared to HEK-CCR2 and mF* binding on these cells.

918   (D) Permeability of hC5aR transfected HEK cells using unlabelled mS and mF, and Alexa-labeled mS*

919   and mF* compared to wild type S(wt) and F(wt) (n=2). (E) Inhibition of 3 µg/ml of mS* binding by

920   mS on HEK-hC5aR cells, (n=3). CCR2-transfected HEK cells used as negative controls for toxin

921   binding and lysis in (C, D) n=2 or (C) one representative experiment. Dose dependency shown with

922   polynomial spline fit. Statistical significance calculated between low (0.3 and 0.001 nM) and high

923   (300 nM) toxin concentrations using Student's *t*-test. (F) Permeability response of hC5aR-transfected

924   HEK cells following incubation with unlabeled mS and Alexa maleimide-labeled mF* or wild type

925   toxins F(wt) and S(wt) (n=3). Statistical significance calculated between 15 min and 0 min time points

926   using Student's *t*-test. Error bars indicate SD. Percentages of mean fluorescence intensities is shown as

927   relative to the maximum intensity in each individual experiment (B, C and E).

928

929   **Figure 2. Colocalization of LukS with hC5aR on HEK cells.** (A) (left panel) TIRF image of hC5aR-

930   mGFP on the surface of a HEK cell before addition of toxin; (right panels) zoom-in of yellow dashed

931   square of left panel immediately following 2 min incubation with Alexa647-labeled

43

932 LukSK281CY113H (mS*-Alexa647). (B) Equivalent images of same cell of (B) after > 15 min

933 incubation with LukFK288C (mF). (C) (upper panel) TIRF image of colocalization of Alexa594- and

934 Alexa647-labeled mF and mS (mF*Alexa594 and mS*Alexa647) with hC5aR-mGFP on HEK cells;

935 (lower panel) zoom-in of yellow-dashed square of upper panel with colocalized foci indicated (white

936 arrow).

937

938 **Figure 2- figure supplement 1. Construction of recombinant leukocidin proteins.** (A) Schematic of

939 TIRF imaging assay. (B) (left panel) Crystal structure of octameric pore complex of γ-hemolysin (PDB

940 ID:3B07). K273/Y111 and K289 on S and F components of γ-hemolysin corresponds to our engineered

941 mutations, K281C/Y113H and K288C, on LukSF marked in their equivalent places on γ-hemolysin;

942 (right panel) SDS-PAGE of the unlabeled LukSK281CY113H and LukFK288C (mLukS and mLukF)

943 and Alexa-labeled mLukS* and mLukF* toxin components, bands visible at locations consistent with

944 molecular weight of 33 kDa and 34 kDa for LukS and LukF respectively.

945

946 **Figure 3. Spatiotemporal dynamics of hC5aR, LukS and LukF in live cells.** (A) Images of HEK

947 cells treated with LukSK281CY113H (mS) and Alexa-labeled LukFK288C (mF*) showing brightfield

948 (left), hC5aR-GFP (middle) and mF* (right). (B) Probability distribution for stoichiometry of hC5aR in

949 absence and presence of Alexa-labeled mS (mS*) and mF*, and (C) of mS* foci, indicating (D)

950 tetramer periodicity from Fourier spectral analysis. (E) A random tetramer overlap model cannot

951 account for mS* experimental stoichiometry data (R^2<0), but a tetramer-multimer model results in

952 excellent agreement (R^2=0.85). (F) hC5aR and mS* stoichiometry as a function of incubation time.

953 Proportion of immobile and mobile colocalized foci in the (G) presence and absence of mS and mF.

954 Error bars show standard error of the mean from n=5-15 image subregions.

968 **Figure 3 – figure supplement 2. Density of LukS spots.** A. micrograph of mLukS* (white) with

969 found foci (orange circles) B. Probability distribution of overlap frequency using spots in A to calculate

970 density. C. Zoom in of mLukS micrograph. D. Probability distribution of overlap frequency using

971 intensity in C to calculate maximum density estimate.

972

973

974 **Figure 3 – figure supplement 3. Mobility analysis.** A**.** The probability distribution of microscopic

975 diffusion coefficient showing the threshold for immobility as black dotted line and B. the mean squared

976 displacement against time interval for mobile (upper) and immobile (lower) of hC5aR. C. and D.

977 similar for mLukS/F*.

978

979 **Figure 4. Relative stoichiometry of hC5aR, LukS and LukF in fixed cells.** (A) Micrographs of fixed

980 hC5aR-GFP HEK cells treated with LukSK281CY113H (mS) and LukFK288C (mF) showing hC5aR-

981 GFP (left) and Alexa647 (middle) and merge (right) on Alexa-labeled mS (mS*) above and mF (mF*)

982 below (B) Proportion of foci colocalized and not colocalized, treated with mS, mS*+mF and mS+mF*

983 for hC5aR (green) and mLuk* (orange). Error bars show standard error of the mean from n=4 image

984 subregions. (C) Heatmap of correlation between hC5aR and mS stoichiometry (red dash line indicates

985 4 mS per hC5aR molecule), R^2 ~0.15 (D) and (E) FRET images and efficiencies. The FRET

986 experiment was performed in live and fixed sortase-tagged FITC-hC5aR expressing cells. Live cells

987 (number of biological replicates n=2) were incubated in the presence of Cy3-labeled mS* for 1 h at

988 +4°C and washed, after which unlabeled mF was added. FRET was analyzed before (mS*) or after

989 addition of mF (mS*+mF). FRET from fixed cells (n=3) was analyzed in the presence of mS* or

990 unlabeled mS and Cy3-labeled mF* respectively (n=2). Statistical significance between cells with only

991 mS and both of the toxin components, mS and mF, was analyzed using Student's *t*-test. Error bars

992 indicate SD.

993

994 **Figure 4 – figure supplement 1. Colocalization analysis.** The probability distribution of linked (A)

995 and unlinked (B) hC5aR and similar for mLukS* (C. and D.). E. and F. False-color heatmap scatter

996 plots indicating that h5CaR stoichiometry is uncorrelated to mLukS or mLukF stoichiometry in the

997 presence of mLukF.

998

999

1000 **Figure 5. LukSF dissociation and rebinding of C5a on hC5aR expressing cells.** (A) Inhibition of

1001 anti-CD88 binding on hC5aR expressing HEK cells using increasing concentrations (horizontal axis) of

1002   wild type LukS, S(wt) and C5a. Wild type LukF, F(wt), is used as a negative control for inhibition of

1003   anti-CD88 binding (number of biological repeats n=2). (B) Disengagement of hC5aR from LukSF was

1004   observed as increase in PE conjugated anti-CD88 binding (right vertical axis) on S(wt) pre-coated cells

1005   using increasing but sublytic concentrations (horizontal axis) of F(wt). Minimal cell lysis (% of lysed

1006   cells, left vertical axis) detected in F(wt) concentrations below 3 nM (n=3). (C) Rebinding of constant

1007   amount of NT647 labeled C5a (647-C5a) on hC5aR upon LukSF formation analyzed by incubating

1008   S(wt) pre-coated cells with increasing concentrations (horizontal axis) of LukF mutant G130D that

1009   associates with LukS but does not lead to cell lysis (n=2). (D) Effect of LukSF mediated cell lysis on

1010   complement activation and C5a formation on full blood measured by using C5b-9 as a marker for

1011   complement activation in plasma (n=3). Maximal C5a formation is observed by incubating full blood

1012   with live *S. aureus* bacteria. Ecb (B and C), F(wt) (A) or S(wt) (D) are used as negative controls in the

1013   assays. Percentages of mean fluorescence intensities is shown as relative to the maximal intensity in

1014   each individual experiment (A-C). Statistical significances are calculated using Student's *t*-test. Error

1015   bars indicate SD.

Figure 6. Model for LukSF-receptor binding and the mechanism of LukSF-induced

inflammation. (A). LukS (PDB ID: 1T5R) binds on hC5aR (structure based on angiotensin receptor

data PDB ID: 4YAY) as a soluble monomer on the cell membrane. Each LukS monomer binds one

hC5aR molecule via the receptor interacting residues R73, Y184, Y250, T244 (marked with blue dots)

within a cluster of approximately 4-5 hC5aR homo-oligomers Upon binding to hC5aR LukS exposes

residues for LukF (PDB ID: 1LKF) binding. In these tight clusters each LukF can bind to two LukS

monomers via two interfaces. (B). Binding of LukF on LukS and formation of the octameric pore (PDB

47

ID: 3B07) causes dissociation of the receptors from the complex because of leakage of the cell

membrane and possibly also since the receptor binding region (marked with a circle) is buried between

the monomers in the complex. (C) The detached hC5aR molecule can be reused by its ligands LukS or

C5a anaphylatoxin (PDB ID: 1KJS). (D) Schematic illustrating the putative mechanism of LukSF

induced inflammation.

1016

1017

1018   **Movie 1.** Deposition of mLukS on hC5aR-mGFP HEK cells. The movie is shown in two clips before

1019   (no toxin) and after addition of Alexa 595 labeled mLukS (add mLukS*). This movie was recorded for

1020   *ca.* 13 min and displayed here at 100x speed.

1021

1022   **Movie 2.** Lysis of hC5aR-mGFP HEK cells incubated with Alexa594 labeled mLukS* and mLukF.

1023   The cells were preincubated with mLukS* and the lysis of the cells were monitored for *ca.* 13 min after

1024   addition of mLukF (add mLukF). The red arrow points to the vesicles released during cell lysis. This

1025   movie was recorded for *ca.* 13 min and displayed here at 100x speed.

1026

1027   **Movie 3.** Imaging live hC5aR-mGFP cells. After 1-2 min of exposure, several distinct, mobile,

1028   circular fluorescent foci in the planer membrane regions were observed. Movie is displayed in real

1029   time.

1030

1031   **Movie 4.** Imaging mLukS* incubated with hC5aR-mGFP cells. Several distinct, mobile, circular

1032   fluorescent foci were observed. Movie is displayed in real time.
