Abstract

Chirality is a property of asymmetry between an object and its mirror image. Most biomolecules and cells are intrinsically chiral. Whether cellular chirality can be transferred to asymmetry at the tissue scale remains an unresolved issue. This question is particularly relevant in the left-right organizer (LRO), where cilia motility and chiral flow are thought to be the main drivers of left-right axis symmetry breaking. Here, we built a quantitative approach based on live imaging to set apart the contributions of various pathways to the spatial orientation of cilia in the Kupffer's vesicle (KV, zebrafish LRO). We found that cilia populating the zebrafish LRO display an asymmetric orientation between the right and left side of the LRO. Cilia orientations, therefore, give the KV cells a sense of chirality which is different from the chirality of cilia rotation. Surprisingly, we found this asymmetry does not depend on the left-right signalling pathway or flow. Furthermore, we show the establishment of the chirality is dynamic and depends on planar cell polarity. Together, this work identifies a different type of asymmetry in the LRO and sheds light on the complexity of chirality genesis in developing tissues.

36   A chiral object cannot be superimposed on its mirror image. Most biological molecules are chiral. Yet,
37   how macroscopic chiral asymmetries arise in physics and biology is still debated (Morrow et al., 2017;
38   Wagnière, 2007). In living systems, a number of independent mechanisms of chirality establishment have
39   been identified, from the subcellular to the tissue scale (Blum et al., 2014; Coutelis et al., 2014; Dasgupta
40   and Amack, 2016; Gomez-Lopez et al., 2014; Hamada and Tam, 2014; Levin, 2005; Naganathan et al.,
41   2014; Noel et al., 2013; Tee et al., 2015). The most studied system is certainly the mechanism that sets
42   asymmetric gene expression around the left-right organizers (LRO) of vertebrates (Ferreira and Vermot,
43   2016). Generally, asymmetrical signals are generated in LROs as a response to a directional flow driven
44   by motile cilia (Shinohara and Hamada, 2017). In the LRO, the orientation of cilia rotation follows a
45   clockwise motion and is invariable amongst vertebrates (Okada et al., 2005). These properties are key for
46   controlling the chiral direction of the flow (Hilfinger and Julicher, 2008; Shinohara and Hamada, 2017).
47   Nevertheless, other cellular chiral features at the scale of the whole LRO have never been investigated.
48
49   In zebrafish, the LRO is called the Kupffer's vesicle (KV) (Figure 1A). Before any sign of asymmetric cell
50   response, the KV consists of a sphere containing monociliated cells where a directional flow progressively
51   emerges as a result of stereotyped cilia spatial orientation (Ferreira et al., 2017). Over the course of
52   hours, the cilia-generated flow triggers an asymmetric calcium response on the left side of the cavity
53   (Francescatto et al., 2010; Sarmah et al., 2005; Yuan et al., 2015), and, consequently, a left-biased
54   asymmetric pattern of gene expression (Essner et al., 2005; Kramer-Zucker et al., 2005). Coordinating
55   appropriate cilia spatial orientation with directional flow generation is thus critical for the subsequent
56   asymmetric response and proper LR patterning (Hashimoto and Hamada, 2010). Current studies have
57   posited that flow patterns arise first in the LRO and then dictate the symmetry-breaking event (Blum et al.,
58   2014; Shinohara and Hamada, 2017). This has led to the inference that symmetry breaking initiation
59   depends on the establishment of symmetrical LRO where cilia orientation is tightly controlled by the
60   Planar Cell Polarity (PCP) pathway (Hashimoto and Hamada, 2010; Marshall and Kintner, 2008; Song et
61   al., 2010). In this model, the direction of cilia rotation leading to the directional flow is the only known
62   chiral element in the LRO. However, a number of studies have suggested that subcellular chirality
63   associated with cytoskeletal asymmetric order could also participate in setting the LR axis, in particular in
64   asymmetric animals where no LRO have been identified (Davison et al., 2016; Hozumi et al., 2006;
65   Kuroda et al., 2009; Sato et al., 2015; Shibazaki et al., 2004; Speder et al., 2006). This raises the
66   intriguing possibility that the LRO could use subcellular chiral information for symmetry breaking. In the
67   absence of tools for visualizing potential chirality in the LRO, however, it is difficult to establish if cell
68   chirality could participate in the process of symmetry breaking. To meet this challenge, we developed a
69   quantitative analysis based on live imaging allowing the investigation of the LRO chirality and the
70   identification of the factors controlling it.
71

72   Tissue chirality can result from asymmetric cell shape and asymmetric organelle distribution at the cell

73   scale (Wan et al., 2011; Xu et al., 2007). We reasoned that as an asymmetry generator, the LRO itself

74   constitutes a candidate for being a chiral organ. We made use of the ellipsoidicity of the KV to assess the

75   symmetry of cilia orientation by focusing on the two angles defining cilia orientation in 3D (Figure 1B): θ

76   (tilt) is the angle of the cilium with respect to the KV surface normal (0° for a cilium orthogonal to the KV

77   surface and 90° for parallel); φ is the orientation of the cilium projected on the KV surface (0° for a cilium

78   pointing in a meridional direction towards the dorsal pole). Thus, the meridional tilt of cilia reported in wild-

79   type (WT) KV corresponds to $\theta > 0°$ and φ close to 0°, meaning that cilia point dorsally following the

80   meridians of a sphere (Ferreira et al., 2017). We performed live-imaging using the zebrafish

81   *act2b:Mmu.Arl13bGFP* transgenic line where cilia are fluorescently labelled (Borovina et al., 2010). Next,

82   we extracted the angles θ_{avg} and φ_{avg} of the average cilia orientation vector in both hemispheres of the KV

83   between the 9 and 14 somite stage (SS), when the chiral flow is fully established. To quantify differences

84   in cilia orientation between the left and right sides, we calculated separately for each side the average

85   cilium direction in local coordinates (Figure 1B). In analogy to an individual cilium, the angles φ_{avg} and θ_{avg}

86   describe the direction of the average orientation vector on each side. In case of a mirror-symmetric KV,

87   θ_{avg} of the average cilium is equal on the left and on the right sides and the φ_{avg} angles are mirror-imaged:

88    $\theta_{avg\_left} = \theta_{avg\_right}$, and $\varphi_{avg\_left} = - \varphi_{avg\_right} = \varphi_{avg\_right\_mirror}$. To quantitatively assess the significance of

89   asymmetries in the KV, we designed a permutation test based on the definition of chirality (see Methods)

90   and calculated p-values estimating the likelihood that an *a priori* symmetric KV will show an equal or

91   larger difference Iφ_{avg_left} - $\varphi_{avg\_right\ mirror}$I due to variability.

92

93   We extracted and averaged the results obtained from 14 WT vesicles with a total of 730 cilia, and

94   estimated the θ_{avg} and φ_{avg} angles of the average cilium in 3D. There was a difference between the

95   measured φ angle on the left and the right sides of the KV (Figure 1C). While right-sided cilia are almost

96   perfectly oriented along the meridional direction ($\varphi_{avg\_right} = +1°$, Figure 1D-E), cilia in the left hemisphere

97   exhibit a strong tilt following the direction of the flow ($\varphi_{avg\_left} = +28°$, Figure 1D-E). On average, it defines

98   a dextral orientation over the whole vesicle (Sup. Figure 2A). The permutation test confirmed the

99   significance (p<0.001) of the observed asymmetry in cilia orientations between the left and right side of

100   the KV ($\varphi_{avg\_left} \neq - \varphi_{avg\_right}$) (Methods and Table 1). No difference in tilt angles was observed between the

101   left and right hemispheres ($\theta_{avg\_left} = \theta_{avg\_right}$; Sup. Figure 1A). Together, these results show that cilia

102   orientation is asymmetric in the KV and follows a dextral chirality.
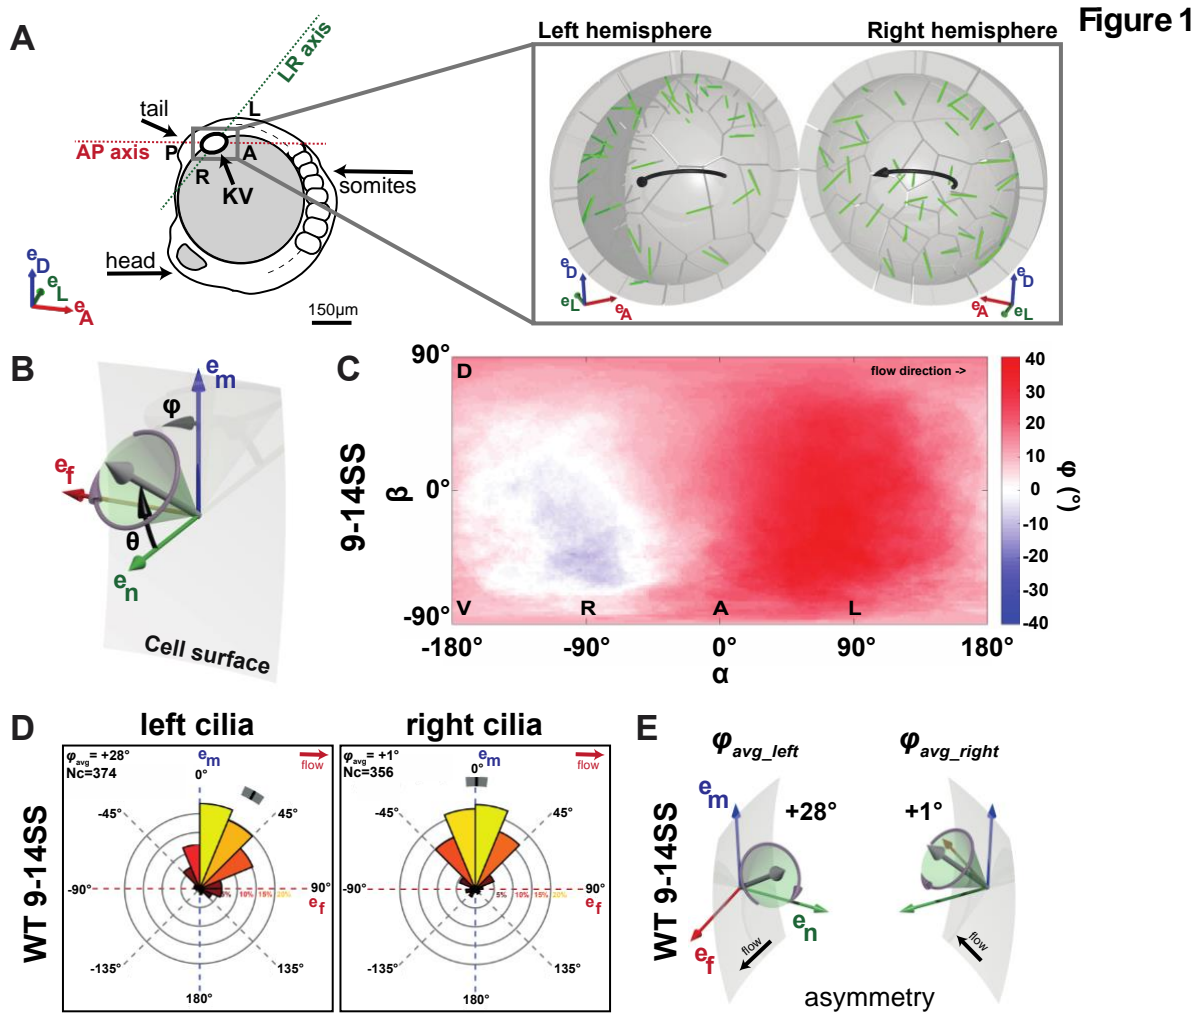

Figure 1: The zebrafish left-right organizer is asymmetric. (A) Schematics of the zebrafish embryo (left panel) highlighting the KV localization (grey box). The zoom-up box (right panel) shows the transverse section of the KV, depicting the cilia (in green) and the directional flow (black arrows). The embryonic body plan axes are marked as AP (anterior-posterior) and LR (left-right). The body plan reference frame is defined by basis vectors e_D (dorsal), e_L (left), e_A (anterior). **(B)** Cilia orientations are represented by two angles: θ (tilt angle from the surface normal e_n) and φ (angle between the surface projection of the ciliary vector and the meridional direction e_m). Cell surface is represented in grey, e_m in blue, e_f in red and the normal e_n in green. **(C-D)** Distributions of φ at 9-14SS in a 2D flat map (C) or rosette plots (D) obtained from 14 wild-type vesicles with a total of 730 cilia. **(C)** Average φ values displayed in a 2D flat map showing φ on the left (0° ≤ α ≥ 90° and -90° ≤ β ≥ 90°) is higher (red) than φ on the right (-90° ≤ α ≥ 0° and -90° ≤ β ≥ 90°). **(D)** Rosette plots showing the φ angle distribution for the left and right-sided motile cilia, and the 95% confidence interval (grey stripe) for the population mean (black tick). In each rosette, 0° indicates the meridional direction (e_m) and 90° the flow direction (e_f). Most cilia exhibit φ angles between [-45°; +45°], corresponding to a meridional tilt (Ferreira et al., 2017). **(E)** Schematics showing the φ_avg of the 3D resultant vector on the left and right sides of the KV at 9-14SS. Nc = number of cilia.

To gain a better sense of when the chirality of cilia orientation begins, we analyzed cilia orientation in KV in embryos at different developmental stages. We quantified the φ angle distributions of cilia from both hemispheres of WT embryos at 3SS (early-stage), when the first signs of LR asymmetry have been reported (Yuan et al., 2015), at 6SS and at 8SS (mid-stages). At 3SS, two populations of cilia exist in the

121   KV, motile and immotile. Neither the motile (φ_{avg_left} = +15° and φ_{avg_right} = -20°; Figure 2A-B), nor the

122   immotile cilia population (φ_{avg_left} = +32° and φ_{avg_right} = -8°; Sup. Figure 2B) exhibit a significant difference

123   between the left and right sides of the KV (φ_{avg_left} ≈ - φ_{avg_right}, Table 1), resulting in a φ_{avg} close to 0° at

124   3SS (Figure 3A). WT embryos at 6SS show some asymmetry (Figure 3A), but it is not yet statistically

125   significant (p=0.086, Table 1). Interestingly, at 8SS the side-biased orientation (φ_{avg_left} = +19° and φ_{avg_right}

126   = +4°; Figure 2A-C) becomes significant enough to reveal an overall asymmetry of the KV (Figure 3A and

127   Table 1). These results show that the orientation differences are not changing linearly between left and

128   right, where the left angle does not change much between 3SS and 8SS and the right side changes more

129   significantly. We also assessed the variability of cilia orientation by plotting the mean orientation on the

130   left vs. right side for each embryo (Sup. Figure 3A). The variability between embryos is always

131   substantial, but it reduces with time and all 14 embryos at 9-14SS show asymmetry in the same direction.

132   When considering θ angle distributions at 3, 6 and 8SS, we did not find any asymmetry between the left

133   and right-side of the KV, demonstrating that the cilia tilt remains symmetrical over time (Sup. Figure 1A).

134   Together, these results demonstrate that cilia orientation in the LRO does not exhibit any asymmetry until

135   6SS and becomes progressively asymmetric during the course of KV development and LR patterning.

Figure 2

136
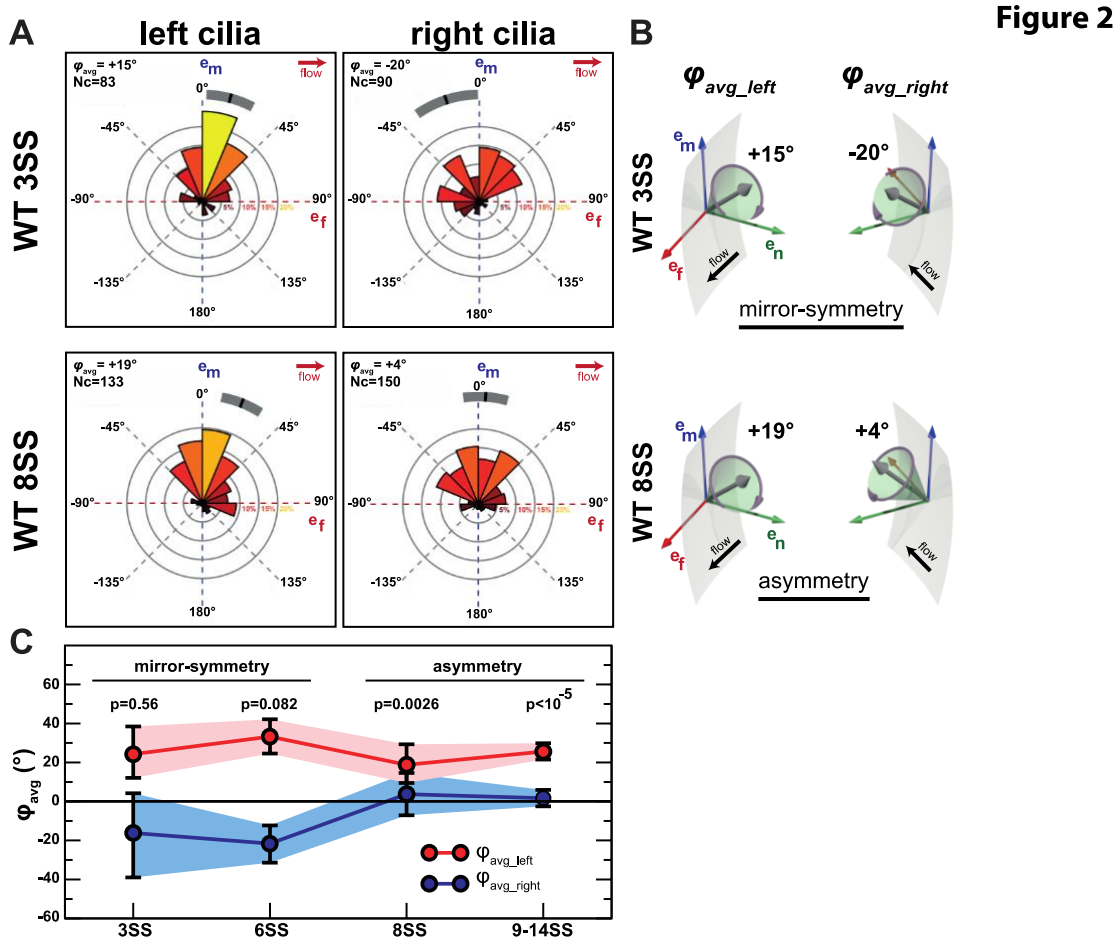

137 **Figure 2: Asymmetric cilia orientation arises over time. (A)** Rosette plots showing the φ angle distributions for the left- (left

138 panel) and right-sided (right panel) cilia, with their mean (black tick) and associated 95% confidence interval (grey stripe), for WT

139 3SS (upper panel) and WT 8SS (lower panel). In each rosette, 0° indicates the meridional direction (e_m) and 90° the flow direction

140 (e_f). **(B)** Schematics showing the φ_{avg} of the 3D resultant vector on the left and right sides of the KV at 3SS (upper panel) and 8SS

141 (lower panel). **(C)** Mean orientation φ_{avg} of motile cilia in the left (red) and right (blue) half of the KV as a function of time. The error

142 bars and shaded regions display 95% confidence intervals. Nc = number of cilia.

143

144 Considering the function of the KV is to generate an asymmetrical signal, we investigated whether the

145 observed asymmetry of the KV itself is modulated by the LR signalling pathway. According to current

146 models of symmetry breaking, the asymmetric expression of genes around the LRO is under the control

147 of *pkd2* that acts as a flow sensor and leads to the left-sided expression of *spaw*, a nodal-related gene

148 involved in the establishment of the left-right asymmetry (Schottenfeld et al., 2007; Yuan et al., 2015). To

149 test the impact of flow sensing and asymmetric gene expression downstream of flow on asymmetric cilia

150 orientation, we used cup^{tc241} (Schottenfeld et al., 2007) and $spaw^{s457}$ (Kalogirou et al., 2014) mutants

151 where *pkd2* and *spaw* are not functional, respectively. As expected, both $cup^{-/-}$ and $spaw^{-/-}$ embryos have

152 laterality defects (Sup. Figure 4B-C and Table 2). By analyzing the KV cilia orientation, we found a normal

153 meridional orientation of cilia (Sup. Figure 2C, $\varphi_{avg} \neq 0°$ in Figure 3A) and permutation tests show that

154 there is an overall asymmetry in the KV ($\varphi_{avg\_left} \neq - \varphi_{avg\_right}$) in both $cup^{-/-}$ and $spaw^{-/-}$ KV cilia at 8SS.

155 Together these results indicate that asymmetric cilia orientation is not dependent upon the LR signalling

156 cascade in the LRO.

157

158 Actomyosin contractility is a well-known modulator of tissue chirality *in vitro* (Wan et al., 2011) and *in vivo*

159 during early development of asymmetry in Xenopus embryos (Qiu et al., 2005), and cardiac looping in

160 vertebrate embryos (Noel et al., 2013; Taber, 2006). In addition, it has been shown that the migration of

161 the basal body to the apical surface of cells is essential for cilia formation (Hong et al., 2015; Pitaval et al.,

162 2010) as well as important for cell-cell tension regulation during KV morphogenesis (Wang et al., 2012)

163 and LR determination (Gros et al., 2009; Tabin and Vogan, 2003; Wang et al., 2012). Furthermore,

164 actomyosin contractility has been shown to be important for KV morphogenesis and flow (Wang et al.,

165 2011; Wang et al., 2012). We thus assessed its impact on asymmetric cilia orientation. To do so, we used

166 blebbistatin and the *rock2b*-morpholino (*rock2b*-MO) to block myosin-II activation (Wang et al., 2011).

167 Both blebbistatin-treated and *rock2b*-MO embryos exhibit laterality defects (Sup. Figure 4B-C and Table

168 2) and abnormal cell clustering in the anterior side of the KV (Sup. Figure 1D) as previously described

169 (Wang et al., 2011; Wang et al., 2012). Cilia orientation analysis showed that the *rock2b*-Myosin-II

170 pathway does not interfere with the meridional tilt of KV cilia (Sup. Figure 2C). Permutation tests show

171 that the KV at 8SS is overall asymmetric ($\varphi_{avg\_left} \neq - \varphi_{avg\_right}$) for both blebbistatin and *rock2b*-MO treated

172 embryos ($\varphi_{avg} \neq 0°$ in Figure 3A with corresponding p values; Table 1). Overall these results indicate that

173 asymmetric cilia orientation is not under the control of the *rock2b*-Myosin-II pathway (Ferreira et al.,

174 2017), and, more generally, the main components of the LR signaling acting upstream and downstream

175 of the flow operating in the LRO.

176
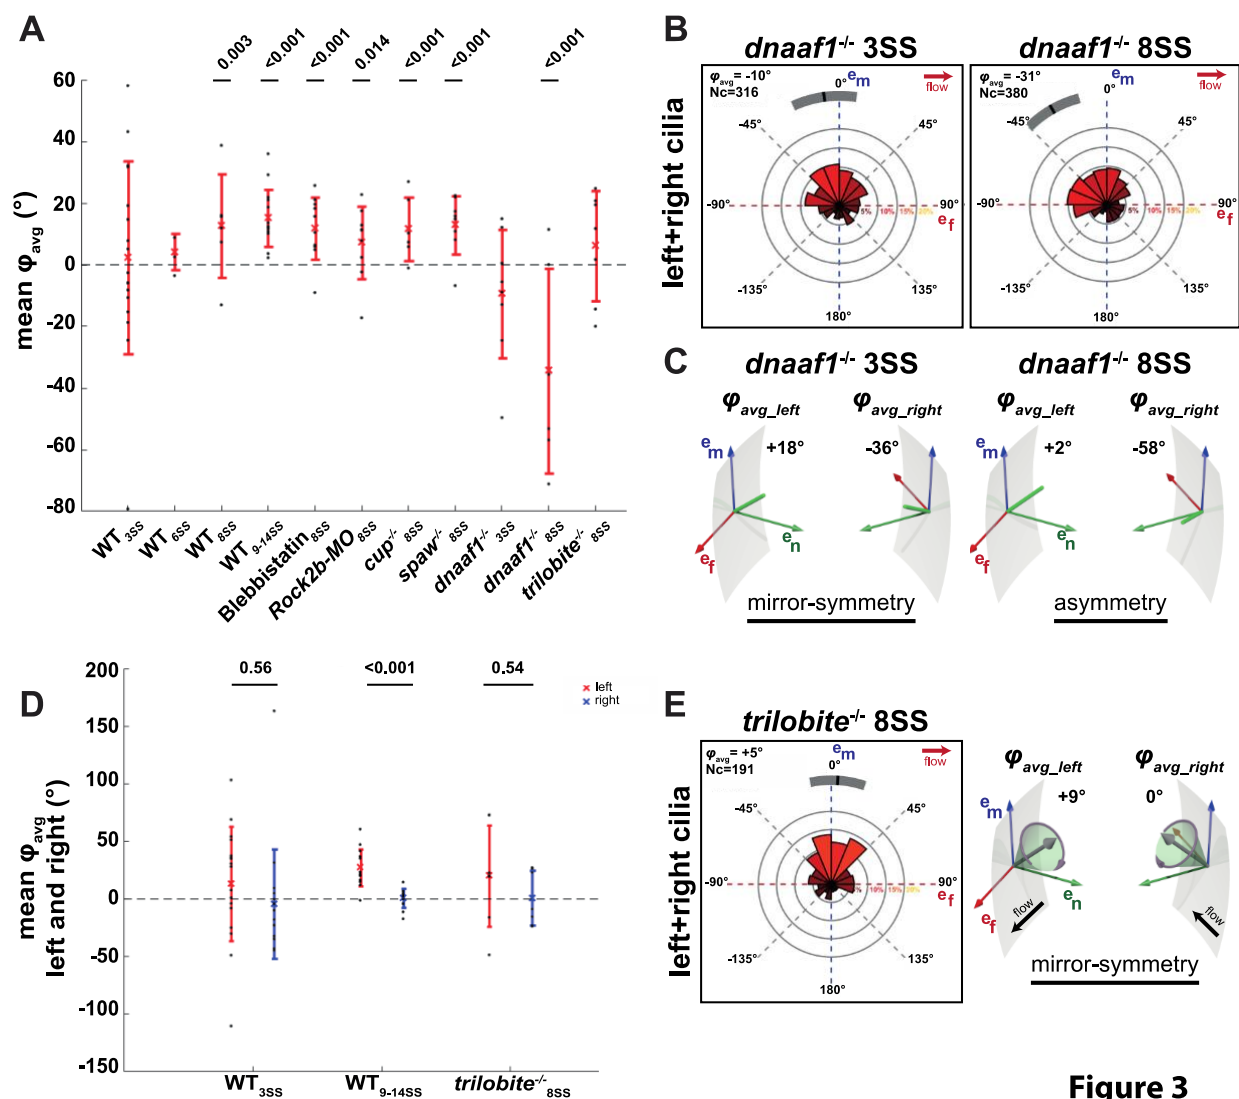

Figure 3: DNAAF1 and PCP are important for asymmetric cilia orientation. (A) Dot plot displaying the mean values of φ_{avg} for each condition. Each black dot represents the mean values for one individual KV, the cross displays the average value for all KVs of the respective condition and the line the standard deviation. The mean values of φ_{avg} are always greater than zero, except for *dnaaf1*[-/-], which are below zero, revealing that its orientation with respect to the meridional direction is reversed. Also, WT$_{3SS}$, WT$_{6SS}$, *dnaaf1*[-/-]$_{3SS}$, and *trilobite*[-/-]$_{8SS}$ have φ_{avg} mean values close to zero, demonstrating a LR symmetry in the KV. The p-values result from a permutation test under the null hypothesis of a mirror-symmetric KV $\varphi_{avg\_left} = - \varphi_{avg\_right}$, which is equivalent to $\varphi_{avg} = 0$ (see Methods). **(B)** Rosette plots showing the φ angle distribution of cilia in both KV hemispheres (left+right cilia), for *dnaaf1*[-/-] 3SS (upper panel) and *dnaaf1*[-/-] 8SS (lower panel). Both *dnaaf1*[-/-] 3SS and *dnaaf1*[-/-] 8SS cilia are inclined in the opposite direction to the flow (e_f). **(C)** Schematics showing the φ_{avg} of the 3D resultant vector on the left and right sides of the KV for *dnaaf1*[-/-] 3SS (upper panel) and *dnaaf1*[-/-] 8SS (lower panel). **(D)** Dot plot displaying the mean values of φ_{avg} on the left (in red) and on the right (in blue) sides of the KV for WT$_{3SS}$, WT$_{9-14SS}$, and *trilobite*[-/-]$_{8SS}$. *trilobite*[-/-]$_{8SS}$ display no difference between the mean φ_{avg} on the left and right sides of the KV. The p-values result from a permutation test under the null hypothesis of $\varphi_{avg\_left} = - \varphi_{avg\_right}$. **(E)** Rosette plot showing the φ angle distribution of cilia in both KV hemispheres (left+right cilia) for *trilobite*[-/-] 8SS. In contrast to other conditions studied so far, φ_{avg} of *trilobite*[-/-] KV cilia is close to zero, reinforcing the observation that the KV is symmetrical at 8SS. **(F)** Schematics showing the φ_{avg} on the left and right sides of the KV for *trilobite*[-/-]$_{8SS}$. Nc = number of cilia.

193

194   Ciliary components involved in cilia motility have also been shown to modulate cilia orientation (Jaffe et

195   al., 2016). We thus assessed if cilia motility could be a factor controlling asymmetric cilia orientation. We

196   first analyzed cilia orientation in the WT at 3SS and found that WT immotile cilia have a distinct

197   orientation compared to the motile cilia at the same stage ($\theta_{avg\_WT3SS\ immotile}$ = +15° and $\theta_{avg\_WT3SS\ motile}$ =

198   +30°; $p<10^{-4}$), suggesting that motility could be involved in modulating cilia orientation. To confirm cilia

199   motility involvement, we analyzed the effects *dnah9* (*lrdr1*) knock-down and found that asymmetric cilia

200   orientation was perturbed (FigureS2A). We next studied the *dnaaf1$^{-/-}$ (dynein axonemal assembly factor*

201   *1;* old nomenclature: *lrrc50 - leucine-rich repeat-containing protein 50)* mutants. *dnaaf1* encodes for a

202   cilium-specific protein required for the stability of the ciliary architecture and when mutated abrogates its

203   ability to interact with specific targets important for cilia motility (Sullivan-Brown et al., 2008). Importantly,

204   *dnaaf1$^{-/-}$* cilia have ultrastructural defects and display abnormal dynein arms orientation in beating cilia

205   (Loges et al., 2009). We found that all cilia are immotile in the *dnaaf1$^{-/-}$* KVs (Movie 1) and that LR axis

206   establishment is randomized (Sup. Figure 4B-C and Table 2). We next assessed the symmetry in the

207   *dnaaf1$^{-/-}$* cilia and found that their orientation does not show any sign of asymmetry at 3SS (φ_{avg_left} ≈ -

208   φ_{avg_right}) (φ_{avg} ≈ 0° in Figure 3A; Figure 3B-C and Table 1), similar to the controls at the same stage

209   (Figure 2 and Sup. Figure 2B). At 8SS, we found that *dnaaf1$^{-/-}$* cilia orientation is asymmetric (φ_{avg_left} ≠ -

210   φ_{avg_right} in Figure 3B-C and Table 1; φ_{avg} ≠ 0° in Figure 3A) showing that asymmetric cilia orientation is

211   flow independent. Surprisingly though, we found that *dnaaf1$^{-/-}$* cilia have a meridional tilt (Figure 3B) but

212   are inclined in a sinistral direction, which is the opposite direction than WT at 8SS ($\varphi_{avg\_dnaaf1^{-/-}8SS}$ = -31°

213   (Figure 3B) and $\varphi_{avg\_WT8SS\ motile}$ = +11° (Sup. Figure 2A); $p<10^{-5}$. See also Figure 3A with φ_{avg} < 0°). Thus

214   *dnaaf1* is involved in the control of chiral cilia orientation and it may do so independently of the flow.

215

216   Finally, since cilia motility and planar cell polarity are interdependent (Jaffe et al., 2016), we directly tested

217   the role of the PCP in KV chirality. It has been shown that the PCP pathway modulates cilia tilt in the

218   mouse LRO (Hashimoto and Hamada, 2010; Marshall and Kintner, 2008; Song et al., 2010). Generically,

219   PCP proteins are required to establish cell polarity within tissues across a large variety of animal species

220   (Wallingford, 2012). We used the zebrafish *trilobite* mutant line, where Van Gogh/Strabismus homologue

221   - *Van gogh-like 2* (*Vangl2*) -, a gene encoding a protein essential for PCP signalling, is mutated (Jessen

222   and Solnica-Krezel, 2004). *Vangl2* function is required for the posterior tilt observed in KV cilia, and

223   anomalies in cilia orientation disrupt the cilia-driven flow and LR determination (Borovina et al., 2010).

224   After confirming the *trilobite^{tc240a}* have left-right defects (Sup. Figure 4B-C and Table 2), we studied cilia

225   orientation at 8SS using *trilobite^{tc240a}; actb2:Mmu.Arl13b-GFP* (Heisenberg and Nusslein-Volhard, 1997)

226   mutant embryos, and found cilia orientation still follows a meridional tilt (Figure 3E and Sup. Figure 1A).

227   Our flow simulations (see Methods and Sup. Figure 4D) predict that flow is significantly weaker in

228   *trilobite^{tc240a}* than in the WT (p=0.024), as expected for a PCP mutant (Borovina et al., 2010). In contrast

229   with other conditions studied so far, permutation tests could not detect any asymmetry in the *trilobite$^{-/-}$* KV

230   cilia at 8SS, meaning φ_{avg_left} = - φ_{avg_right} (p=0.54, Figure 3D,E, Sup. Figure 2C and Table 2) with a φ_{avg} ≈

231   0° (Figure 3A). Altogether, these results indicate that the PCP pathway is involved in chiral cilia

232   orientation in the KV.

233

234   Since PCP is known to alter the basal body position at the cell surface of the vertebrate LRO (Borovina et

235   al., 2010; Hashimoto and Hamada, 2010; Juan et al., 2018; Song et al., 2010), we developed a

236   quantitative analysis of basal cilia orientations in the KV to test if both are interdependent (Sup. Figure

237   3B-C). As expected, we found that the basal body is localized posteriorly along the anterior-posterior (AP)

238   axis of the WT embryo and is symmetrical along the left-right axis of the cell (Figure 4A, C, D). We next

239   assessed the AP position of the cilia in the *dnaaf1* mutants and found that it is altered along the AP axis,

240   with basal body located more centrally to the cell (Figure 4 A-D), in line with the finding that

241   Dnaaf1/Lrrc50 interacts physically with C21orf59, which is involved in polarizing motile cilia (Jaffe et al.,

242   2016). By contrast, we did not detect any chirality in the basal body AP or right-left (RL) positions when

243   testing the positions of right cilia against the mirror image of left cilia in controls and mutants (p>0.15).

244   Thus, the chirality of cilia orientation seems not dependent on basal body positioning along the LR axis of

245   the cells, which more generally suggests cilia orientation is not solely controlled by basal body position. In

246   addition, these results show that *dnaaf1* is involved in setting AP basal position and that cells might need

247   to be properly planar polarized for the establishment of chiral cilia orientation. Overall, we conclude that

248   proper cilia positioning along the AP axis of the cell and asymmetric cilia orientation might be

249   interdependent.

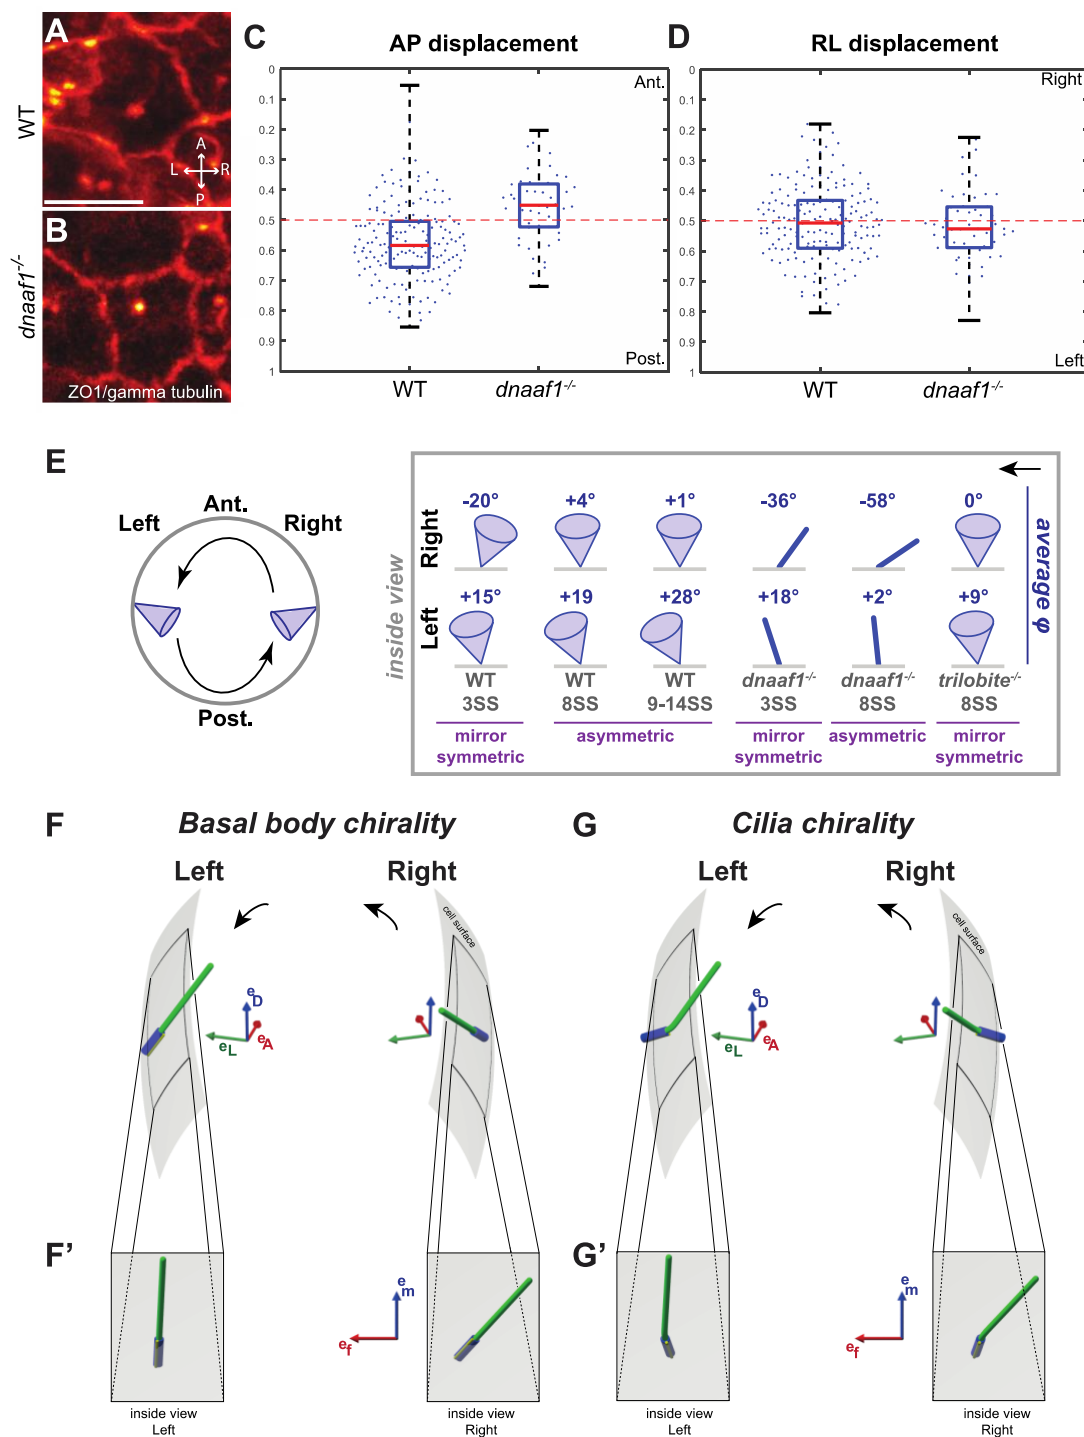

Figure 4

Figure 4: Basal body position in KV cells, schematic summary of the contributions of different pathways and the potential origins of chirality leading to asymmetric cilia orientation in the KV. (A-D) Basal body position analysis. The positions of the cilia basal body relative to the AP (Anterior-to-posterior) or LR (Left-to-right) extension of each cell were extracted from WT **(A)** or *dnaaf1⁻/⁻* embryos **(B)** using an orthogonal projection of the fluorescence intensity on the plane tangential to the KV surface after

256 ZO1 and gamma tubulin staining of KV cells. The distributions of AP displacement (dots from 0 for anterior to 1 for posterior in **(C)**)

257 and LR displacement (dots from 0 for right to 1 for left in **(D)**) are centered at the middle of the cell (displacement at 0.5) for all

258 cases, except a significant posterior displacement of basal bodies in the WT. **(E)** Left: Dorsal view of a mirror-symmetric KV showing

259 a representative cilium on the left and on the right side. Right: schematic view of the average φ orientation over time in WT, *dnaaf1*[-/-]

260 and *trilobite*[-/-] KV for cilia in the right (upper row) and in the left (lower row) KV hemispheres. KV is mirror-symmetric at 3SS both in

261 WT and *dnaaf1*[-/-] embryos evolving to an asymmetric orientation at 8SS. In contrast, *trilobite*[-/-] 8SS KVs do not show any evidence of

262 asymmetry. **(F-G)** Schematics of the two hypotheses for the observed chirality (dorsal-posterior views of the KV in F and G, inside

263 views of both sides in F' and G'): **(F)** the orientation of cilia can be asymmetric between left and right because the orientation of the

264 basal bodies is chiral; **(G)** alternatively, the basal bodies can be arranged symmetrically, but the intrinsic chiral structure of each

265 cilium leads to an overall asymmetric distribution of cilia orientations. The black arrows in E, F and G indicate the direction of the

266 flow.

267

Discussion

269 Previous work has focused on identifying signals that trigger the specification of the left embryonic side in

270 response to flow, but the chirality of the LRO remained untested. We took advantage of the zebrafish

271 LRO (KV) as an established model system in which cilia orientation and LR symmetry can be accurately

272 quantified and show that cilia orientation is not symmetrical between the left and right side of the LRO.

273 Our study revealed that cilia orientation progressively changes from mirror-symmetric to asymmetric

274 (Figure 4E) and that this new type of asymmetry emerges independently of the LR symmetry cascade.

275 Interestingly, even if we found that there is a strong variability in cilia orientation, we found that they will

276 invariably become chiral in every KV, suggesting a very robust process for chirality determination.

277

278 Considering that several key modulators of symmetry breaking such as Pkd2, Rock2b (and the

279 associated actomyosin pathway) or Spaw do not affect cilia orientation, we conclude that the LRO

280 promotes left-right symmetry breaking and asymmetric cilia orientation through distinct mechanisms. If

281 the asymmetry of cilia orientation is independent of the LR machinery, how can we explain its

282 emergence? One possibility would be that cilia reorient themselves in response to the flow so that the

283 flow forces themselves would be the source of chiral information. During blood vessel morphogenesis,

284 endothelial cells polarize themselves against the flow in a similar way (Franco et al., 2015; Kwon et al.,

285 2016). There are, however, three strong arguments opposing this hypothesis. First, we still observe an

286 asymmetric orientation of cilia in *dnaaf1* mutants where flow is absent and in *rock2b* knockdown where

287 flow is weak. Second, our previous work (Ferreira et al., 2017) along with our simulations (Sup. Figure

288 4E) show that the torque resulting from the global flow is much smaller than the drag on a motile cilium. A

289 similar conclusion has been drawn when comparing the forces exerted on cells by beating ependymal

290 cilia with those mediated by the fluid (Mahuzier et al., 2018). Finally, we found that the left cilia reorient

291 less than the right cilia even though the flow has the same magnitude on both sides (Ferreira et al.,

292 2017). It seems thus that the relationship between flow direction and cilia orientations cannot be causal. It

293 is more likely that both could reflect disorders in cilia orientation in the respective mutants.

294

295   Rather than being induced by the flow, we propose that the asymmetry could arise from chiral influences
296   generated by the cytoskeletal components that operate at the cellular and subcellular scales (Satir, 2016).
297   In line with this idea is the fact that cells can display chiral behaviours *in vitro* and *in vivo* independently of
298   a LRO (Naganathan et al., 2014; Noel et al., 2013; Speder et al., 2006; Tee et al., 2015). For example,
299   basal body and cilia ultra-structure display obvious signs of chirality (Afzelius, 1976; Marshall, 2012;
300   Pearson, 2014). This suggests two possibilities: either the orientation of the cilia basal bodies is chiral
301   (asymmetric between left and right, Figure 4F-4F'), or they are oriented symmetrically and the intrinsic
302   chiral structure of each cilium leads to an overall asymmetric distribution of cilia orientations (Figure 4G-
303   4G'). The fact that *dnaaf1*, a cilia specific protein, can reverse cilia orientation from dextral to sinistral
304   seems to argue for the latter. However, we found that *dnaaf1* is also involved in modulating planar cell
305   polarity, so its function within the cilium remains difficult to assess. Interestingly, we did not detect chirality
306   in the distribution of basal body positions. This suggests that the chirality is related to the basal body
307   orientation but not its position. An attractive hypothesis is that cells need to be planar cell polarized to
308   express chirality and that the PCP (through Vangl2 and Dnaaf1) participates in the process that sets
309   basal body orientation. Among the many PCP components that affect LR determination (see for example
310   ciliary components (Jaffe et al., 2016) or unconventional myosin 1d (Juan et al., 2018; Tingler et al.,
311   2018)), it will be interesting to assess if some are more important than others in controlling cilia chirality
312   and the robustness of cilia orientation. More work will be needed to establish the molecular basis of cell
313   and cilia chirality in the KV and whether it is conserved in other ciliated LRO.

314

315   The demonstration that the asymmetry is actively modulated by the PCP, cilia motility and, potentially, by
316   the internal organization of cilia has important implications for the understanding of chiral information
317   distribution and its control in developing organs. First, it shows that chiral information is dynamic and
318   temporally controlled during the course of LR specification. In that respect, it is interesting that cells
319   establish chiral organization as a result of cell migration *in vitro* (Wan et al., 2011) and that asymmetric
320   cell migration is well described in the chicken LRO (Gros et al., 2009). It is thus possible that the
321   progressive establishment of asymmetric cilia orientation in the LRO reflects an active acquisition of
322   cellular chirality during the time of LRO function. If confirmed, chirality would represent a unique
323   conserved feature between fish and chicken LRO. This raises the intriguing possibility of a more general
324   role of chirality in morphogenetic pattern formation and LR symmetry breaking. Could the chiral cilia
325   orientation participate in symmetry breaking in the LRO? We have previously tested different hypothetical
326   mechanisms of flow detection and shown that a quantitative analysis of physical limits favours chemical
327   sensing (Ferreira et al., 2017). While the basic mechanism of flow generation, as well as flow detection,
328   do not require any prior asymmetry in the KV, we cannot exclude that the ciliary asymmetry participates in
329   the process of symmetry breaking by playing hand-in-hand with the chiral flow to optimize the flow
330   direction or the detection of signalling particles.

331

332 More generally, proper cilia orientation is essential for directed flow generation in ciliated tissues or for

333 swimming in ciliated microorganisms (Goldstein, 2015). An important open question is whether cilia can

334 reorient themselves in the direction of flow (Guirao et al., 2010; Mitchell, 2003) and if so, whether this

335 reorientation is a consequence of hydrodynamic forces. Another possibility is that cell polarity is affected

336 by the flow. Since some ciliary proteins involved in cilia motility also participate in planar cell polarity (Jaffe

337 et al., 2016), it is possible that the spatial orientation of motile cilia is an intrinsic mechanism, which is

338 independent of the flow they generate. In the case of brain cavities, the orientation of cilia beating

339 dynamically follows the circadian rhythm and may be driven by transient changes in cell-cell interactions

340 and in PCP (Faubel et al., 2016). Similarly, ciliated microorganisms can reorient the direction of ciliary

341 beating in the course of an avoidance reaction (Tamm et al., 1975). Mechanical strain has also been

342 shown to be involved in dictating cilia orientation, length and motility features (Chien et al., 2018). Our

343 study sheds a different light on these systems as it shows that cilia orientation is related to cell polarity in

344 a complex way that includes an intrinsic sense of chirality. Furthermore, as there is increasing evidence

345 that congenital diseases like idiopathic scoliosis (Grimes et al., 2016), *Kartagener* syndrome, neonatal

346 respiratory distress, hydrocephaly, and male infertility involve cilia motility (Mitchison and Valente, 2017),

347 precise cilia orientation analysis becomes critical to understand the biological principles that govern cilia

348 function and their potential involvement in pathology. In this context, our conclusions and method could

349 be relevant in the studies of a variety of developing organs.

350

351

352

Materials and Methods

Zebrafish strains

355 The zebrafish (*Danio rerio*) lines used in this study were the following: *Tg*(*actb2*:Mmu.*Arl13b-GFP*)
356 (Borovina et al., 2010), *Tg*(*dnaaf1^tm317b^; actb2*:Mmu.*Arl13b-GFP*) (Sullivan-Brown et al., 2008),
357 *Tg*(*trilobite^tc240a^; actb2*:Mmu.*Arl13b-GFP*) (Heisenberg and Nusslein-Volhard, 1997), *Tg*(*spaw^s457^;*
358 *actb2*:Mmu.*Arl13b-GFP*) (Kalogirou et al., 2014), *Tg*(*cup^tc241^; actb2:Arl13b-GFP*) (Schottenfeld et al.,
359 2007). None of the mutant lines display cilia length or KV shape defects (Sup. Figure 1B-C). All zebrafish
360 strains were maintained at the IGBMC fish facility under standard husbandry conditions (14h light/10h
361 dark cycle). Adult fish were anaesthetized with 80µg/mL Tricaine/MS-222 (Sigma, Cat. # A-5040) for
362 genotyping experiments. The Animal Experimentation Committee of the Institutional Review Board of
363 IGBMC approved all animal experiments performed in this project.

364

Morpholino (MO) knockdown

366 MO designed to block the *rock2b* RNA splicing site (Wang et al., 2011) was obtained from *Gene Tools,*
367 *LLC*. One-cell stage embryos were injected with 0.66ng of *rock2b*-MO (5'-
368 GCACACACTCACTCACCAGCTGCAC-3').

369

Blebbistatin treatment

371 Embryos were dechorionated and treated with 35µM of Blebbistatin (SIGMA B0560/DMSO) from bud-
372 stage until 3SS when they were washed in 0.3% Danieau medium and kept at 32ºC until the desired
373 stage for live imaging (8SS). 1%-DMSO treated embryos were used to monitor potential drug-control
374 effects.

375

2-photon excited fluorescence (2PEF) microscopy

377 Live imaging experiments were performed as described in (Ferreira et al., 2017), in order to maximize the
378 scanning artefact that allows to properly reconstruct cilia orientation in 3D as described in (Supatto and
379 Vermot, 2011).

380

3D-Cilia Map: quantitative 3D cilia feature mapping

382 We used *3D-Cilia Map*, a quantitative imaging strategy to visualize and quantify the 3D biophysical
383 features of all endogenous cilia in the Kupffer's vesicle (KV) in live zebrafish embryos, such as KV size
384 and shape and cilia density, orientation or motility. This image analysis workflow using Imaris (Bitplane
385 Inc.) and custom-made scripts in Matlab (The MathWorks Inc.) was first described in (Ferreira et al.,
386 2017). We improved its automation to facilitate the analysis of a large number of cilia. In addition, we
387 added new feature quantification, such as the length of both motile and immotile cilia, which is estimated
388 based on the radial fluorescence intensity profile originating from the position of each cilium basal body.

389 All coordinate system definitions are described by (Ferreira et al., 2017). In particular, the cilium

390 orientation is represented as a unit vector from its base to its tip, with angle θ and φ defined in a local

391 basis (Fig 1B). This vector represents the orientation of the rotation axis of motile cilia or of the cilium

392 body orientation in the case of immotile cilia, which are both obtained from experimental images. The

393 average angles $φ_{avg}$ and $θ_{avg}$ used throughout this work describe the direction of the 3D resultant vector,

394 which is the sum of all considered cilia unit vectors.

395

396 **Whole-mount *in situ* hybridization (WISH)**

397 Whole-mount *in situ* hybridization was performed as described previously (Thisse and Thisse, 2008).

398 Digoxigenin RNA probes were synthesized from DNA templates of *spaw* (Long, 2003) and *foxA3*

399 (Monteiro et al., 2008). Embryos for *spaw* and *foxA3* WISH were fixed at 17SS and 53 hours post

400 fertilization (hpf) respectively. The zebrafish heart looping was assessed at 48hpf when the heart is

401 already beating. Due to its transparency, the heart loop can be visible using brightfield illumination. We

402 performed WISH for *foxA3* at 53hpf in order to visualize the gut *situs* (Monteiro et al., 2008) in the same

403 embryos in which we previously assessed the heart looping at 48hpf. Embryos were evaluated after

404 WISH and scored according to the curvature between the liver and the pancreas. For the sake of

405 simplicity, we merged the laterality information of both heart and gut and described it according to the

406 clinical terminology: *situs solitus* (heart and gut with normal orientation), *situs inversus* (complete reversal

407 of both organ laterality) and *heterotaxy* (any combination of abnormal LR asymmetries that cannot be

408 strictly classified as *situs inversus*) (Fliegauf et al., 2007; Ramsdell, 2005; Shapiro et al., 2014; Sutherland

409 and Ware, 2009). *Spaw* expression patterns in the lateral plate mesoderm (LPM) can be classified into

410 four main categories: left, bilateral, right or absent (Sup. Figure 4A)(Long, 2003). After scoring, embryos

411 were individually genotyped.

412

413 **Immunohistochemistry**

414 Embryos at 8SS were fixed by MEMFA (3.7% formaldehyde, 0.1M MOPS, 2mM EGTA, 1mM $MgSO_4$) for

415 2h at room temperature (RT). Embryos were changed to 100% Methanol and stored at -20ºC overnight

416 (OV). After rehydration, embryos were washed in PBBT (PBS with 2mg/mL BSA and 0.1% TritonX-100)

417 and blocked in PBBT with 10% goat serum at RT. Subsequently, embryos were incubated OV at 4ºC with

418 primary antibodies - 1:50 mouse anti-ZO1 antibody (33-9100, *Thermo Fisher Scientific*) and 1:200 mouse

419 anti-gamma tubulin antibody (T6557, *Millipore Sigma*). After, embryos were washed with PBBT, followed

420 by blocking solution, and incubated overnight at 4ºC with secondary antibody - 1:300 anti-mouse Alexa

421 Fluor 546 IgG (A-11030, *Thermo Fisher Scientific*). Embryos were finally washed with PBBT and stored in

422 PBS at 4ºC. For imaging, single embryos were flat mounted onto the dish and imaged in a TCS SP8

423 confocal microscope (*Leica Microsystems*).

424

425 **Quantifications and statistical analysis**

426 To statistically test the mirror-symmetry in the KV, we used a permutation test (also called randomization

427 test) (Hesterberg T, 2005). We compute the statistic $|\varphi_{avg\_left} - \varphi_{avg\_right\ mirror}|$, where φ_{avg_left} is the φ angle of

428 the average resultant vector of left cilia and $\varphi_{avg\_right\ mirror}$ is the φ angle of the resultant vector of right cilia

429 after LR mirror symmetry. This statistic is based on the definition of chirality as we test if the left cilia

430 orientation superimposes with the mirror image of right cilia. Left and right labels of cilia are then

431 randomly permutated 300,000 times to construct the sampling distribution of possible $|\varphi_{avg\_left} - \varphi_{avg\_right}$

432 $_{mirror}|$ values. The p-value is finally estimated as the proportion of permutations resulting in values greater

433 than or equal to the experimental one. We define the structure of the KV as chiral (or asymmetric) when

434 the p-value is lower than 0.05 and the null hypothesis ($\varphi_{avg\_left} = \varphi_{avg\_right\ mirror}$) can be rejected. The same

435 test is used to investigate θ mirror-symmetry. The p-values of the effective angular velocity vector ($\vec{\overline{\Omega}}$) of

436 all conditions against the WT were calculated using Welch's test on the dorsal component Ω_D.

437

438 **Fluid dynamic simulations**

439 We characterized the circulatory flow in the KV by calculating the effective angular velocity vector ($\vec{\overline{\Omega}}$) as

440 described in (Ferreira et al., 2017). We described each cilium in a KV as a chain of beads moving along a

441 tilted cone with the orientation obtained from 3D-CiliaMap and calculated the flow using Green's function

442 for the Stokes equation in the presence of a spherical no-slip boundary. The effective $\vec{\overline{\Omega}}$ is defined as the

443 angular velocity of a rotating rigid sphere with the same angular momentum as the time-averaged flow in

444 the KV.

445

446 **Analysis of cilia basal body positions**

447 Embryos at 8SS were fixed by MEMFA and labeled with anti-ZO1 and anti-gamma tubulin antibodies,

448 followed by Alexa Fluor 546 IgG labeling (detailed protocol in "Immunohistochemistry" method section).

449 Samples were imaged in a TCS SP8 confocal microscope (*Leica Microsystems*). Cilia basal bodies were

450 segmented in 3D from fluorescence images using Imaris (Bitplane Inc.). A local reference frame at the

451 origin of each basal body was defined to identify the local tangent plane to the vesicle in 3D. Using

452 custom-made scripts in Matlab (The MathWorks Inc.), the fluorescence intensity of pixels up to 2μm away

453 from it was orthogonally projected on this plane (Sup. Figure 3B) to manually draw the cell contour and

454 extract the antero-posterior and left-right extension of the cell. The relative position of the basal body

455 relatively to them has then been calculated for every cilium as shown in Sup. Figure 3B-C.

456

457

458 ## Supplementary figures
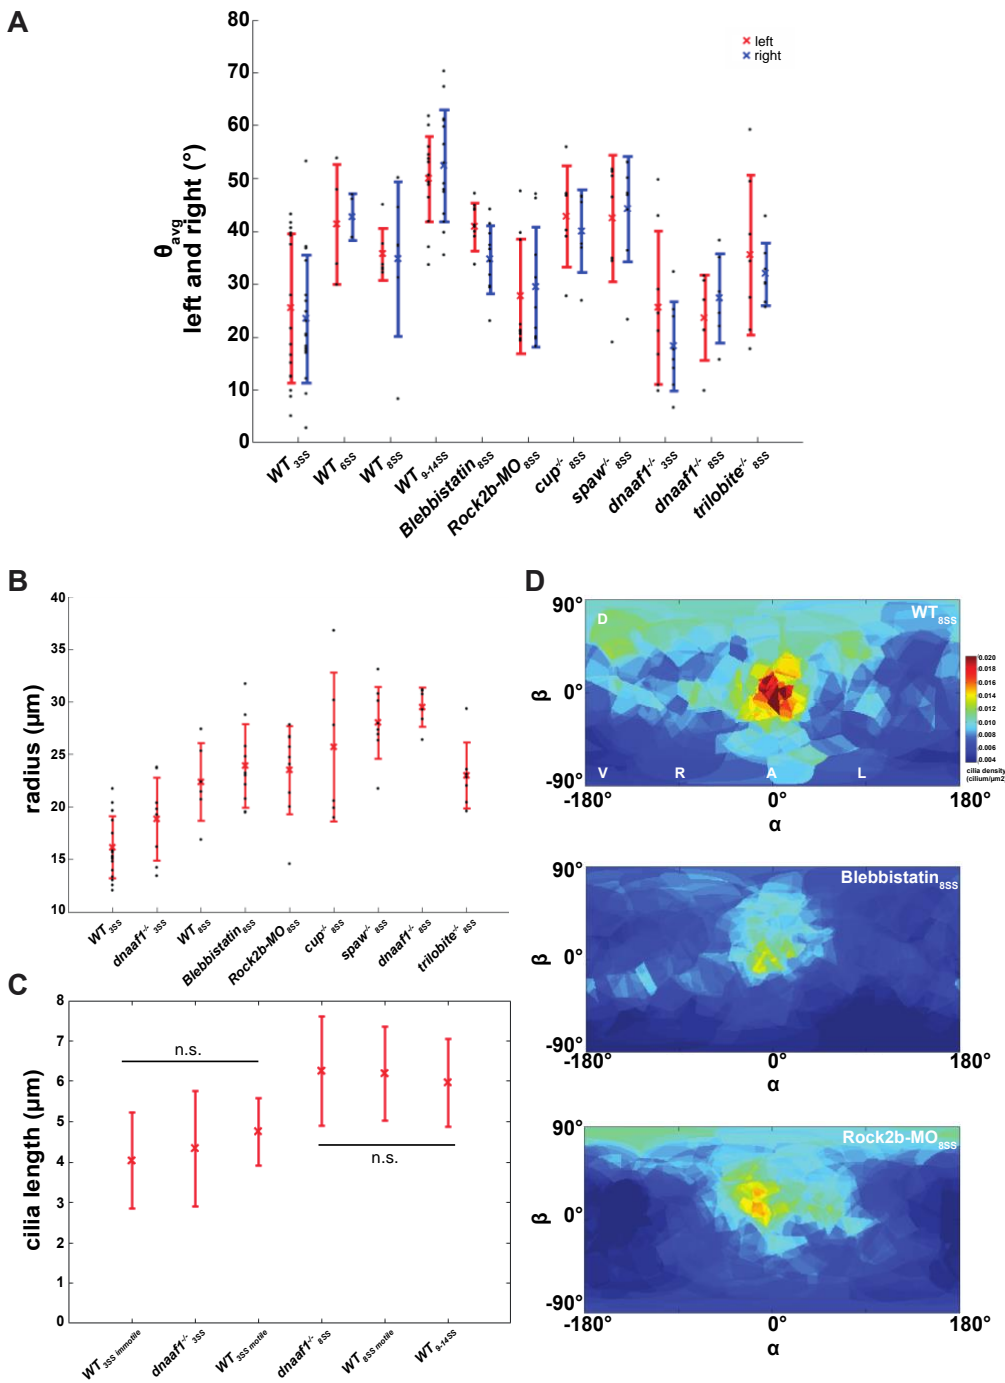

Supplemental Figure 1

459

460 **Sup. Figure 1: Distribution of θ angles on the right and on the left sides of the KV and additional information about the KV**

461 **size, cilia length and cell density in different experimental conditions. (A)** Dot plot displaying the mean values of θ_{avg} on the left

462 (in red) and on the right (in blue) sides of the KV for all conditions. Permutation tests show there are no signs of asymmetry relating

463 to θ_{avg} in all conditions studied (p > 0.05). **(B)** Average KV radius for WT and other conditions analyzed, at 3 and 8SS. The average

464   KV radius shows no significant difference between conditions from the same developmental stage. **(C)** Average cilia length of WT

465   immotile and motile cilia and *dnaaf1*$^{-/-}$ immotile cilia, at 3- and 8SS. There is no significant difference between the average cilia

466   length of WT and *dnaaf1*$^{-/-}$ KV cilia. **(D)** Averaged cilia density obtained from KVs of WT, blebbistatin, and rock2b-MO represented

467   on a 2D flat map revealing a disruption of the steep density gradient along the anteroposterior (AP) axis observed in WT

468   (enrichment at the anterior pole - in red).

Supplemental Figure 2

Sup. Figure 2: Additional information about φ angle distributions displayed in rosette plots. Rosette plots showing the φ angle distribution and φ_{avg} values of cilia in both KV hemispheres (left+right cilia) for WT cilia at different stages **(A)**, and left and right separately for the immotile cilia population in both WT, $dnaaf1^{-/-}$ and $lrdr1$-MO **(B)** and for the $cup^{-/-}$, $spaw^{-/-}$, blebbistatin, $rock2b$-MO

473 and *trilobite*[-/-] conditions **(C)**. All conditions presented asymmetric KVs at 8SS, with the exception of *trilobite*[-/-], which is mirror-
474 symmetric like KVs analyzed at 3SS and 6SS. Statistics provided in Table 1. Nc = number of cilia
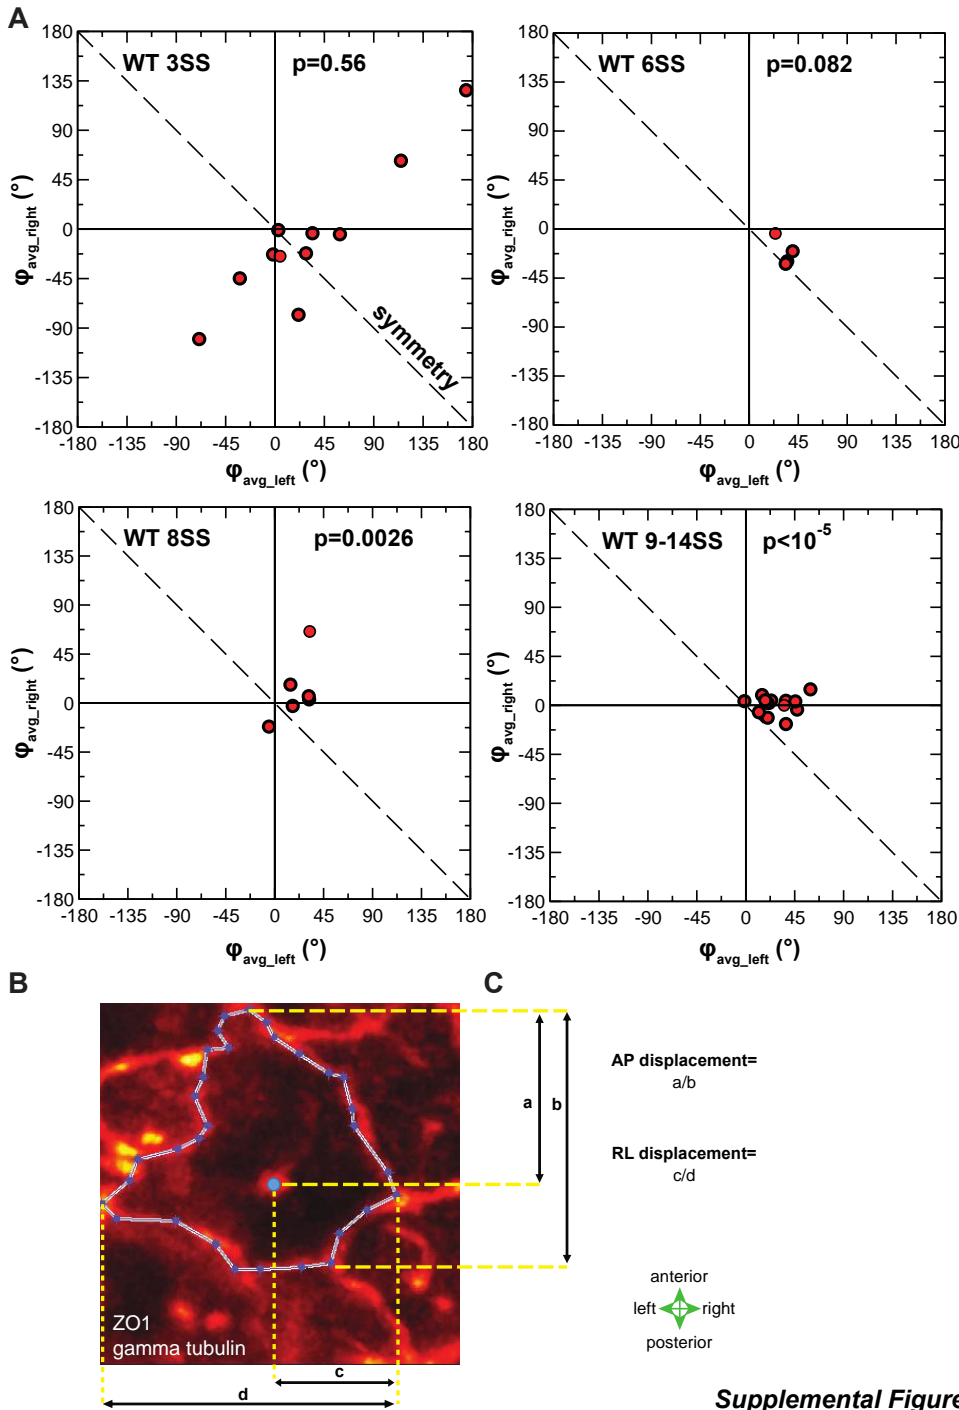

Supplemental Figure 3

475
476 **Supplemental Figure 3: Asymmetry of cilia orientations in individual WT embryos at different stages and basal body**
477 **localization quantification. (A)** Plot showing the average orientation (φ_{avg}) in the right- vs. the left half of the KV at a given stage. In
478 a symmetric KV, the points would lie on the dashed line, indicating $\varphi_{avg\_right}=-\varphi_{avg\_left}$. Although the variability among embryos remains
479 large, all 14 KVs at the later stage display an asymmetry with the same sign. The p-values (obtained from a permutation test)
480 indicate the likelihood that an intrinsically symmetric KV (null hypothesis) would randomly show the same or larger degree of
481 asymmetry. **(B-C)** Quantification of basal body position relative to the KV cell extent. **(B)** Orthogonal projection of the fluorescence

482   intensity on the plane tangential to the KV surface. Basal body position (large blue dot) and cell contour (small blue dots connected

483   with white lines) are used to measure the anterior-to-posterior and right-to left cell extents (b and d values, respectively) and the

484   anterior-to-basal body and right-to-basal body distances (a and c values, respectively). **(C)** The anterior-to-posterior (AP) and right-

485   to-left (RL) basal body relative positions are then estimated as a/b and c/d, respectively.
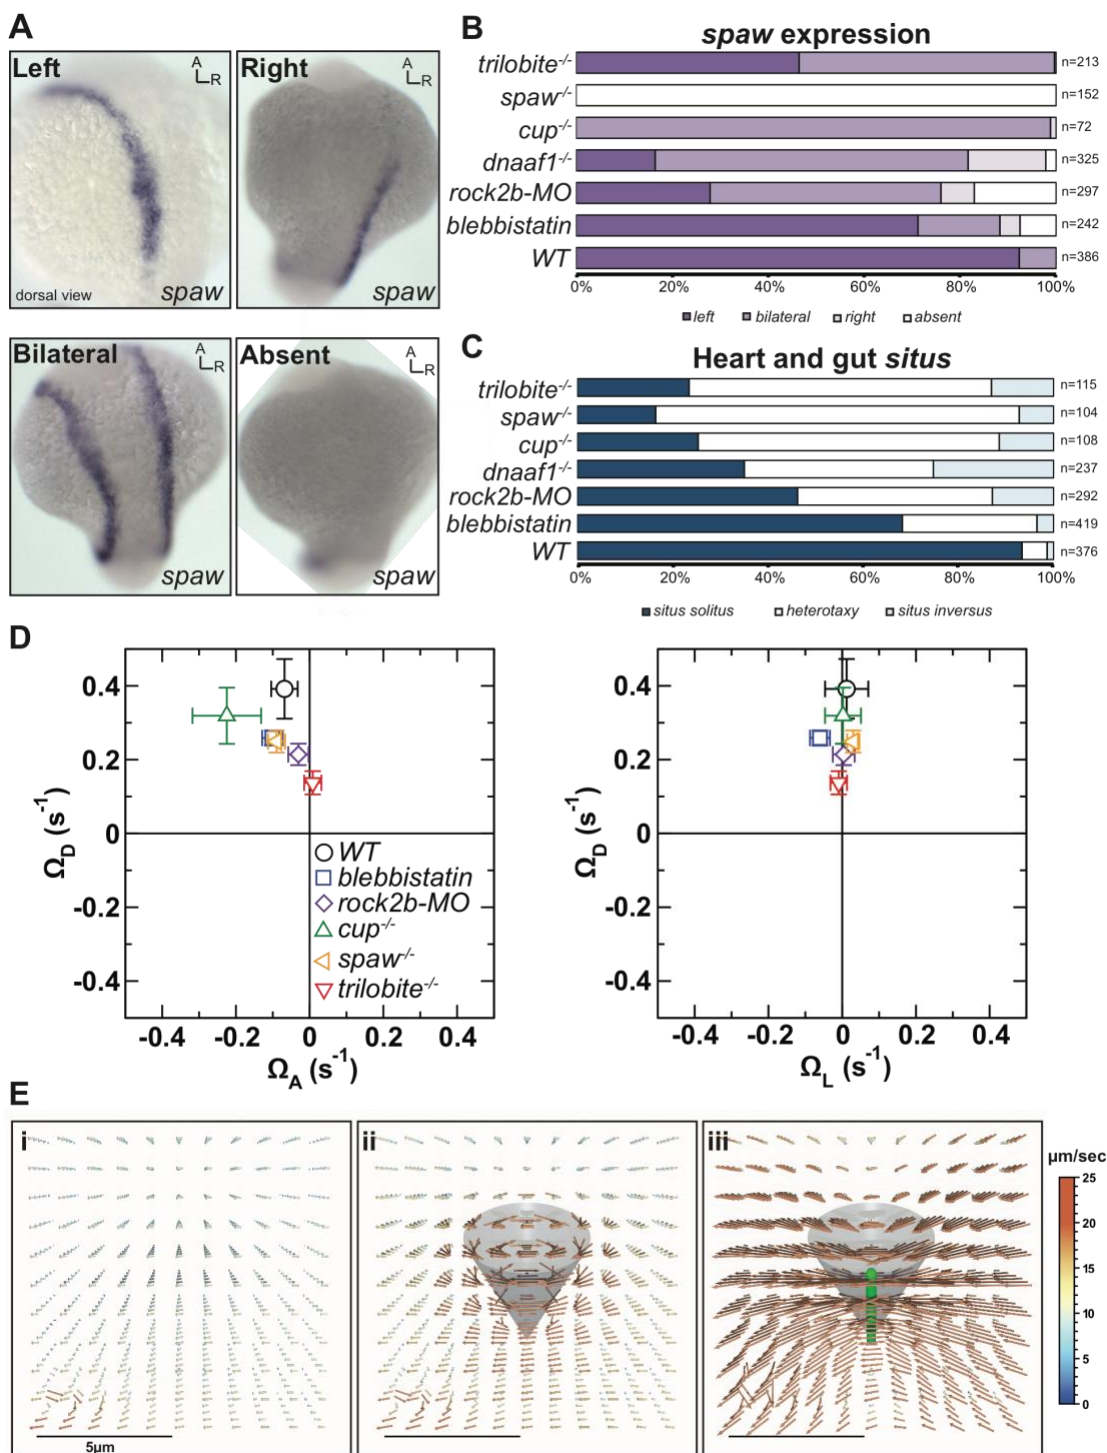

Supplemental Figure 4

486

487 **Supplemental Figure 4: Quantification of the *spaw* expression patterns in the LPM and heart and gut *situs* in all conditions**

488 **studied and flow profiles around simulated beating cilia. (A)** *spaw* expression patterns in the LPM can be divided in left,

489 bilateral, right or absent. **(B-C)** Percentages of *spaw* expression patterns in the LPM **(B)** and the *situs* phenotypes **(C)** respectively.

490 The number of embryos analyzed is displayed next to each bar. *Situs* phenotypes are classified according to the clinical terminology

491 in *situs solitus*, *heterotaxy* and *situs inversus*. **(D)** Effective angular velocity $(\overline{\vec{\Omega}})$ of the flow in the KV, determined computationally

492 from cilia orientations and motility. The main graph shows the right view of the $\overline{\vec{\Omega}}$ (dorsal vs. left anterior component), the insets

493 show the anterior view (dorsal vs. left component). In contrast with the other conditions, *trilobite*[-/-] embryos have a significantly

494 weaker flow (p=0.024) when compared to WT at 8SS. **(E)** Flow around a cilium located at the right pole of the vesicle, determined in

495 a simulation with a randomly generated ("synthetic") cilia distribution, see (Ferreira et al., 2017) viewed from the center of the KV: i)

496 time-averaged flow if the central cilium is removed and all others preserved, such that only the global flow remains, ii) time-averaged

497 flow, iii) instantaneous flow. The results show that the global circulatory flow is much weaker than the local flows around a moving

498 cilium.

503 **Table 2:** Relative frequencies of LR scoring outcomes and their standard errors (Supplemental Figure 4).

504

505 **Table 3:** Supplemental information concerning the genotyping strategies of the mutant lines used, including the designed primers

506 and mutation details. All primers were designed with the program ApE (http://biologylabs.utah.edu/ jorgensen/wayned/ape/) and

507 using the genomic sequences available on Ensemble (*Ensembl genome browser 84*) for *dnaaf1, spaw* and *cup* genes. Embryos

508 from the *trilobite*[tc240a] (Heisenberg and Nusslein-Volhard, 1997) mutant line were identifiable by phenotype at all the stages

509 analyzed. *dnaaf1*[tm317b] (Sullivan-Brown et al., 2008) *and cup*[tc241] (Schottenfeld et al., 2007) mutant embryos were identifiable for

510 heart and gut scoring analysis (48-53 hpf) and were genotyped only at earlier stages. *spaw*[s457] (Kalogirou et al., 2014) mutant

511 embryos were always genotyped by sequencing.

512

513 **Movie 1: Cilia motility is impaired in the *dnaaf1^{-/-}* embryos.** The movie shows the 3D live imaging of two KVs from the

514 *Tg*(*dnaaf1^{tm317b}; actb2*:Mmu.*Arl13b-GFP*) (Sullivan-Brown et al., 2008). Each embryo was soaked for 60 minutes in Bodipy TR

515 (Molecular Probe) and imaged using 2PEF microscopy at 930 nm wavelengths, as described in (Ferreira et al., 2017). A full z-stack

516 of both KVs can be seen. On the left, a KV from a sibling *dnaaf1^{+/+}* with motile cilia (fan cones) is shown. On the right, a KV from a

517 *dnaaf1^{-/-}* embryo, with 100% of immotile cilia (bright straight lines) is shown.
