Abstract

34

35   The adenosine A_{2A} receptor ($A_{2A}R$) is a prototypical G protein-coupled receptor (GPCR) that

36   couples to the heterotrimeric G protein G_S. Here we determine the structure by electron cryo-

37   microscopy (cryo-EM) of $A_{2A}R$ at pH 7.5 bound to the small molecule agonist NECA and

38   coupled to an engineered heterotrimeric G protein, which contains mini-G_S, the βγ subunits

39   and nanobody Nb35. Most regions of the complex have a resolution of ~3.8 Å or better.

40   Comparison with the 3.4 Å resolution crystal structure shows that the receptor and mini-G_S

41   are virtually identical and that the density of the side chains and ligand are of comparable

42   quality. However, the cryo-EM density map also indicates regions that are flexible in

43   comparison to the crystal structures, which unexpectedly includes regions in the ligand

44   binding pocket. In addition, an interaction between intracellular loop 1 of the receptor and the

45   β subunit of the G protein was observed.

46

47

Introduction

The adenosine A_{2A} receptor ($A_{2A}R$) is an archetypical Class A G protein-coupled receptor (GPCR)[1]. $A_{2A}R$ is activated by the endogenous agonist adenosine and plays a prominent role in cardiac function, the immune system and central nervous system, including the release of the major excitatory neurotransmitter glutamate[2,3]. Given the widespread tissue distribution and physiological relevance of $A_{2A}R$, it is a validated drug target for many disorders[4], including Parkinson's disease[5] and cancer[6]. $A_{2A}R$ is one of the most stable GPCRs and structures have been determined of $A_{2A}R$ in an inactive state bound to inverse agonists[7-13], an active intermediate state bound to agonists[14-16] and the fully active state bound to an agonist and coupled to an engineered G protein, mini-G_S[17]. In addition, structure-based drug design has been applied to inactive state structures of $A_{2A}R$ to develop potent and subtype specific inverse agonists with novel scaffolds[9] and these are currently in clinical trials. Comparison of the structures has led to an understanding of the molecular determinants for an inverse agonist compared to an agonist[15], the conformational changes induced by agonist binding to convert the inactive state to the active intermediate state[18], and the role of the G protein in stabilising the fully active state[17]. The active state was determined by crystallizing the receptor coupled solely to mini-G_S, an engineered G protein with eight point mutations and three deletions, including the whole of the α-helical domain[19]. Although pharmacologically mini-G_S recapitulates the ability of a heterotrimeric G protein to increase the affinity of agonist binding to the receptor[17], the roles for the βγ subunits could not be described. In terms of the interactions between a heterotrimeric G protein and a Class A GPCR, the vast majority of interactions are made by the α subunit, in particular the C-terminal α5 helix[20]. However, there was an interaction between the β subunit and the β2-adrenoceptor[20] and also between the β subunit and the class B receptors for calcitonin[21] and glucagon-like peptide[22]. In addition, there is mutagenesis data suggesting that the α2-adrenergic receptor directly interacts with the β subunit. We therefore determined the structure of $A_{2A}R$ coupled to an engineered heterotrimeric G protein.

There are now two choices in how to determine the structure of a GPCR coupled to a heterotrimeric G protein, which are X-ray crystallography and electron cryo-microscopy (cryo-EM). The disadvantage of X-ray crystallography lies in the difficulty of producing good quality crystals of a GPCR coupled to a heterotrimeric G protein. The only successful strategy so far has been to use lipidic cubic phase composed of the lipid MAG7:7 and to

81   crystallise a GPCR fusion protein with T4 lysozyme at the N-terminus, but there is only a

82   single structure published to date[20]. The other option is to use cryo-EM and single particle

83   reconstruction techniques. This is now possible given the recent developments in the field

84   over the last few years[23] together with the improved contrast provided by the recently

85   developed Volta phase plate (VPP)[24], which enhances the probability of getting structural

86   data of small proteins[25]. The structure determination of two Class B receptors coupled to G_S

87   at ~4 Å resolution shows the potential of this methodology[21,22]. We thus decided to use cryo-

88   EM to determine the structure of $A_{2A}R$ coupled to an engineered heterotrimeric G protein.

89   This would provide insights about the role of the β subunit in coupling to $A_{2A}R$, but would

90   also provide an opportunity to directly compare the structure of the receptor determined in

91   the active state by X-ray crystallography and cryo-EM.

92

93

Results

95

Preparation of an $A_{2A}R$-G_S complex

97

98   In this work we used a construct of $A_{2A}R$ that contained thioredoxin at the N-terminus of the

99   receptor[26]. This was originally designed with a rigid linker between the thioredoxin and the

100   receptor to generate a large hydrophilic surface to $A_{2A}R$ to improve crystallisation, although

101   this proved unsuccessful. The presence of thioredoxin did not significantly affect the

102   pharmacology of $A_{2A}R$, as assessed by determination of its apparent K_D for the inverse

103   agonist ZM241385 or in agonist shift assays (Figure 1). It could also be purified to

104   homogeneity and coupled effectively to both mini-G_S[26] and to the heterotrimer containing

105   mini-G_S, $β_1$, $γ_2$ and Nb35 (Figure 1). Detergent-solubilised $A_{2A}R$ coupled to the heterotrimer

106   had a molecular weight (excluding the detergent micelle of LMNG) of approximately 130

107   kDa[26].

108

The impact of the Volta Phase Plate on the cryo-EM $A_{2A}R$-G-protein complex map

110

111   Initial micrographs for the $A_{2A}R$ complex were collected on a FEI Titan Krios

112   microscope using a K2 Summit detector in the absence of a Volta-potential phase plate (VPP)

113   (Figure 2a). Data processing showed the characteristic 2D class averages of a GPCR coupled

114   to a heterotrimeric G protein (Figure 2a). After 3D classification and refinement, the best

115   model (containing 72,486 particles) reached 6.7 Å resolution and showed clearly defined α-

116   helices in both the receptor and G protein (Figure 2a). We then collected data using the VPP

117   on a FEI Titan Krios microscope using either a K2 Summit detector or a Falcon III detector

118   in electron counting mode (Figures 2b and 2c). The K2 dataset consisted of micrographs

119   pooled from different days and collected somehow heterogeneously regarding total dose and

120   doses rates (see Methods for details), while the Falcon III dataset was collected in a single

121   session over 48h. Both datasets were processed in an equivalent manner to the non-VPP data,

122   with only few minor exceptions (see Methods). Since images collected with a VPP possess

123   higher contrast (Figures 2b and 2c) the auto-picking feature in RELION that uses a Gaussian

124   blob as a reference resulted in optimal particle picking without the need for specific 'auto-

125   picking' references[27]. After 2D and 3D classification (see Methods for details), refinement

126   yielded models with overall resolution of 4.88 Å and 4.45 Å for the K2 Summit and Falcon

127   III detector respectively (Figure 2b and 2c). The Falcon III model was later improved to 4.11

128   Å with further processing (see below) showing details for most amino acid side chains after B

129   factor sharpening. The effect of the VPP for this particular dataset was therefore essential

130   making 'side-chain' resolution accessible. A B factor plot (assessing the number of particles

131   *vs* resolution) was used to assess the impact of the VPP (Figure 2e). It is observed that, in the

132   presence of the VPP, the $A_{2A}R$ map not only has a better resolution for the same number of

133   particles, but the B-factor improves significantly from 213 to 85 (when comparing K2

134   Summit with and without VPP). This becomes essential when trying to reach high resolution

135   information in a reasonable time scale (especially important for high throughput structure

136   determination in drug discovery). As an example, to obtain the same resolution of 4.88 Å

137   using the K2 Summit detector without the VPP, one would have needed about 5 million

138   particles, that would require ~65 days of data collection at a Titan Krios electron microscope

139   (in comparison to 145,169 particles collected in 48 hours with a VPP).

140   All cryo-EM grids were plunge-frozen from a single batch of $A_{2A}R$–G protein complex

141   and most of the duplicate grids were made in a single freezing session. Data collection was

142   performed at higher magnification for the non-VPP data (magnification 200,000x and 0.66

143   Å/pixel) than for the VPP dataset (1.14 Å/pixel and 1.07 Å/pixel for the K2 Summit and

144   Falcon III detectors respectively), positioning the high-resolution information of the non-VPP

145   data at a better location in the detector DQE range (Nyquist being 1.32 Å *vs* 2.14 Å/2.28 Å

146   for the non-VPP *vs* the VPP K2/Falcon III respectively). The VPP resolution enhancement

147   therefore could potentially be higher if equivalent magnifications were used. Data processing

148   was carried out as equivalent as possible for all datasets in order to make them comparable.

149   We therefore believe that the comparison between the VPP and non-VPP datasets is as fair as

150   possible, although if anything we are favouring the non-VPP data.

151   Comparisons of data with and without VPP had only been previously been published

152   for samples that readily reached high resolution without VPP. Although in our experience the

153   improvement is sample dependent, these data show the potential to which the VPP can be

154   useful in certain cases and more comparisons will be needed in order to understand the

155   variability in enhancement between samples. Although we see a significant difference

156   between the K2 and Falcon III performance, data for the K2 with VPP was a result of

157   merging data with different dose rates and total doses. We therefore do not have an

158   absolutely identical comparison of the two detectors.

159

160   **Structure determination of the $A_{2A}R$–G_S complex**

161

162   The highest resolution data set corresponded to micrographs collected on a Falcon III

163   detector in electron counting mode using a VPP, therefore this map was used for model

164   building and subsequent analysis. Data collection parameters and processing are described in

165   the Methods section. In summary, 837 movies were collected and corrected for stage drift,

166   beam induced movement and dose weighting with MotionCor2. CTF fitting, defocus and

167   phase estimation were performed with Gctf-v0.1.06[28]. Particle picking was performed using a

168   Gaussian blob, as implemented by RELION[29] 2.0. 3D classification was performed with an

169   *ab initio* model and refinement of the best classes with clear GPCR-like features (128,002

170   particles) attained an overall resolution of 4.45 Å (using gold standard FSC of 0.143)[30].

171   Attempts to improve the model included further 3D classification, which revealed that around

172   50% of the particles contained a heterogeneous γ subunit. However, the resolution and

173   quality of the overall model suffered when removing these particles, so we therefore

174   compromised on having poor quality density for the γ subunit, but having higher resolution

175   for the rest of the complex.

176   In further attempts to improve the model, during refinement, the low-pass filter effect

177   of the Wiener filter in the regularised likelihood optimisation algorithm was relaxed through

178   the use of a regularisation parameter (T=5). This allowed the refinement algorithm to

179   consider higher spatial frequencies in the alignment of the individual particles yielding a map

180   of higher quality. Nevertheless, both half-reconstructions were kept completely separately,

181   and the final resolution estimate (at the post-processing stage in RELION) was based on the

182   standard FSC between the two unfiltered half-reconstructions. Although resolution did not

183   improve, the quality of the map improved noticeably.

184   Calculation of the local resolution in RELION showed that although the overall

185   resolution was estimated to be 4.5 Å the core of the complex was ~3.8 Å with most of the

186   map at 4.0 Å resolution or higher, with clearly visible density for the majority of amino acid

187   side chains. As shown in Figure 3, the regions that showed poorer resolution were the

188   thioredoxin and the detergent micelle (a significant fraction of the small complex), which

189   hinders a realistic overall resolution estimation.

190   In order to accurately estimate the resolution of the $A_{2A}R$ complex map and to

191   eliminate noise from refinement, the detergent micelle and thioredoxin moiety needed to be

192   excluded. Excluding the micelle by simply tightening the mask did not yield optimal results

193   with artefacts produced at the interface between the model and the mask. Such a strong signal

194   might be specific to LMNG since, in our experience, the signal from other detergents can be

195   masked out in this manner. We then decided to perform a double signal subtraction protocol

196   where initial coordinates were used to create a tight mask around the protein component

197   excluding thioredoxin ($A_{2A}R$, mini-G_S, β, γ, Nb35), which was then subtracted from the

198   original particles. The resulting particles were used to produce an accurate map of the micelle

199   and thioredoxin, which was then used to perform signal subtraction of the original particles,

200   leaving them devoid of micelle or thioredoxin. Refinement of these particles yielded an

201   improved map at 4.11 Å resolution. However, it appeared that the refinement process focused

202   primarily on the intracellular G protein heterotrimer complex leaving a lower quality map at

203   the receptor region. In order to circumvent this problem, we performed refinement with the

204   original particles and then exchanging them for their signal subtracted equivalent (without

205   micelle and thioredoxin) only in the last iteration of refinement. This resulted in the best

206   overall map at 4.11 Å resolution with quality density throughout (Table 1).

207   Attempts to remove particles with low phase shift and poor contrast (~22,000 particles

208   with <0.25π) decreased resolution and map quality. We therefore kept low phase shift data in

209   the final model.

Overall structure of the NECA-bound A$_{2A}$R mini heterotrimeric G protein complex

The A$_{2A}$R cryo-EM complex structure provides insights into its structure in solution, in the absence of crystal contacts and at more physiological conditions (pH 7.5) than the X-ray structure (pH 5.7 or below for inactive structures). The density map of the A$_{2A}$R–G protein heterotrimer displayed a local resolution varying from 3.3 Å to 6.4 Å (Figure 3). Side chain densities were observed for most amino acid residues, which were of similar quality to those in the X-ray crystallographic map of the A$_{2A}$R–mini-G$_S$ structure (Figure 4). The lowest resolution was found at the C-terminus of the β subunit and most of the γ subunit, which had very poor density. Signal subtraction and 3D classification protocols have been used to isolate different protein conformations of small regions[31]. Upon implementation of these strategies, we did not find any other discrete conformations of the heterotrimeric G protein, suggesting that the C-terminus of the β subunit and most of the γ subunit region are flexible. Within the cryo-EM structure of A$_{2A}$R there are two regions that lack density and are therefore also probably disordered and flexible, namely the N-terminal section of ECL2 (G147 to Q163) and the whole of ICL3 (E212 to S223). These regions are ordered in some crystal structures, but this usually correlates with these regions forming lattice contacts. Sections of the cryo-EM density map for which there is poor quality density and high B-factors of the refined coordinates (Figure 3 and Figure 3 – Figure Supplement 1) include TM1, helix 8, the second section of ECL2 that contributes relevant residues for ligand binding (see below), ECL1 and ECL3.

The overall architecture of the A$_{2A}$R–heterotrimeric G protein complex is similar to the heterotrimeric G$_S$-coupled complexes for the β$_2$-adrenergic receptor[20], GLP1[22] and the calcitonin receptor[21]. The receptor and mini-Gs portions of the A$_{2A}$R–G protein complex are very similar to the crystal structure of the A$_{2A}$R–mini-G$_S$ complex, with the RMSD of C$_\alpha$ atoms for the receptor and mini-G$_S$ components being 0.5 Å and 0.6 Å, respectively. The largest differences are found at the interface between mini-G$_S$ and the β subunit, which have a different conformation when βγ is bound. This may contribute to a minor difference in curvature of the α5 helix in mini-G$_S$ when it is in the heterotrimer complex compared to when it is bound to the receptor alone (Figure 5). However, this does not have any major impact on the interface between the receptor and mini-G$_S$, thus further validating the use of mini G proteins as a surrogate for G protein heterotrimers[17,19,26].

248   **Cryo-EM map at the ligand binding pocket**

249

250   The structure of $A_{2A}R$ orthosteric binding pocket is described by two crystal

251   structures of $A_{2A}R$ bound to NECA, with one structure of $A_{2A}R$ in an active intermediate

252   conformation (PDB code 2ydv)[15] and the other structure in the active state coupled to mini-

253 G_S (PDB code 5g53)[17]. The extracellular half of $A_{2A}R$ does not undergo any major structural

254   changes in the transition from the active intermediate to the mini-G_S coupled active state,

255   with the volume of the binding pocket remaining constant and the interactions to NECA

256   being identical[17]. The orthosteric binding site in the cryo-EM map has well defined density

257   although the map has slightly lower resolution towards the extracellular surface. The density

258   for NECA is of sufficient quality to allow an unambiguous orientation of NECA and the

259   same interactions to the receptor are observed as present in the crystal structures (Figure 4

260   and Figure 5).

261   Despite the similarities between the orthosteric binding site observed in the cryo-EM

262   and X-ray structures, small differences were found in ECL2 that forms part of the binding

263   pocket. The C-terminal half of ECL2 in the X-ray structures forms a helical turn that caps the

264   pocket and contributes side chains that interact with NECA (Phe168 and Glu169). In the

265   cryo-EM structure this region is more disordered. As a consequence, there is no significant

266   side chain density for Phe168 and Glu169 in the cryo-EM map. The fact that there is clear

267   density for NECA and His264 excludes the possibility that the whole of this region has poor

268   resolution *i.e.* the extracellular portion of the receptor is not moving as a rigid body. This is

269   consistent with ECL2 being dynamic.

270   A second difference between the NECA-bound X-ray structures and the cryo-EM

271   structure is the absence of an interaction between Glu169 and His264. This ionic bridge

272   affects small molecule binding kinetics and in most of the crystal structures caps the binding

273   pocket. In the cryo-EM structure, the imidazole group of His264 is pointing away from the

274   orthosteric binding pocket, and it is too far away from Glu169 to form a salt bridge (Figure

275   5). This might be a consequence of the pH in which the respective structures were

276   determined. The pK_a of the histidine side chain is ~6 and most crystal structures have been

277   obtained at lower pH (~pH 5), favouring protonation of His264 and the formation of the ionic

278   bridge. At a more physiological pH of 7.5 that was used for the cryo-EM structure, His264

279   would be predominantly deprotonated and unable to form the ionic bridge. Indeed, crystal

280   structures obtained at higher pH, such as the complexes with caffeine, XAC and ZM241385

281   (~pH 8), all show a broken ionic bridge. Therefore, it is likely that in the physiological state

282   (represented by the cryo-EM map) this ionic bridge is absent, unless the surrounding pH is

283   momentarily lowered for specific functions (e.g. the release of high concentrations of

284   glutamate in glutamatergic synapses).

285

286   **Comparison of the G protein–receptor interface between the crystal and cryo-EM**

287   **structures**

288

289   The interface between mini-G$_S$ in the heterotrimeric G protein and A$_{2A}$R in the cryo-

290   EM structure is very similar to the interface between mini-G$_S$ and A$_{2A}$R in the X-ray structure

291   (PDB code 5g53). The interface in the cryo-EM structure has a buried surface of 1135 Å^2

292   compared to 1048 Å^2 for the X-ray structure 5g53; the slight increase is due to interactions

293   between ICL1 of A$_{2A}$R (residues Leu110 and Asn113) and the N-terminal helix of mini-G$_S$

294   (residues His 41 and Arg38). The near full length N-terminal helix was present in the mini-

295   G$_S$ construct in the cryo-EM structure, because this is required for the stable interaction

296   between the α subunit and the βγ subunits, whereas it was truncated and disordered in the X-

297   ray structure. The main interactions between A$_{2A}$R and mini-G$_S$ in both the cryo-EM and X-

298   ray structures are made predominantly by the C-terminal α5 helix in mini-G$_S$ and amino acid

299   residues in H3, H5, H6, H7, H8 and ICL2 of A$_{2A}$R[17]. The amino acid residues that make

300   these interactions are identical, but the rotamers sometimes differ between the cryo-EM and

301   X-ray structures. This may be a reflection of the different chemical environments in which

302   the structures were determined or the slight difference in curvature of the α5 helix in mini-

303   G$_S$. In addition, some interactions may be transient and are captured in one structure and not

304   another. For example, Arg291 at the intracellular end of H7 of A$_{2A}$R adopts a different

305   conformation in the cryo-EM structure compared to the crystal structure. This results in the

306   absence of interactions between the Arg291 side chain and mini-G$_S$, although the backbone

307   carbonyl can still makes potential interactions with Glu392 and the adjacent residues in H8

308   are still sufficiently close to mini-G$_S$ to make interactions.

309   The major difference between the structure determined by cryo-EM of the A$_{2A}$R-

310   heterotrimeric G protein complex and the X-ray structure of the A$_{2A}$R-mini-G$_S$ complex was

311   the presence of the βγ subunit in the cryo-EM structure. No interactions were observed

312   between A$_{2A}$R and the γ subunit, but potential interactions were observed between ICL1

313   (residues Ser35, Asn36 and Gln38) of A$_{2A}$R and the β subunit (Arg52, Asp312, Asp333 and

314   Phe335). This interface between A$_{2A}$R and the β subunit is considerably more extensive than

315   that observed in the β_2AR complex (Figure 6). However ICL1 shows higher B-factors than

316   the rest of the A_{2A}R cryo-EM structure, which may suggest that the interaction is fairly weak.

317

318   **Discussion**

319

320   The structure determination of A_{2A}R in complex with mini-G_S, β, γ and Nb35 at a

321   physiologically relevant pH has highlighted a number of differences to the structure

322   determined by X-ray crystallography of A_{2A}R coupled to mini-G_S[17]. Firstly, contacts between

323   A_{2A}R and the heterotrimeric G protein were identified between ICL1 and the β subunit, and

324   between ICL2 and part of the N-terminal α-helix of the α subunit; these regions of the G

325   protein were either absent or disordered, respectively, in the crystal structure. Secondly, the

326   difference in pH under which the cryo-EM structure was determined (pH 7.5) compared to

327   many X-ray structures (pH <6) led to ECL2 being more dynamic, as the potential salt bridge

328   between His264 and Glu169 was absent, and consequently Phe168 was disordered. The

329   implications of these observations are discussed more below.

330   There are now two Class A receptors whose structures have been determined coupled

331   to heterotrimeric G_S, β_2AR[20] and A_{2A}R, and after this work was completed, two Class B

332   structures coupled to G_S were also published[21,22]. As expected the overall architecture of the

333   receptors coupled to G_S are conserved, but the details differ. The biggest difference between

334   coupling of Class A receptors to Class B receptors is that the position of H8 in the Class B

335   receptors is angled towards the G protein by ~30° compared to the Class A receptors. This

336   results in extensive contacts between H8 and the G protein β subunit that are absent in Class

337   A receptors. All the receptor structures coupled to G_S show the majority of the contacts

338   between the $\alpha5$ helix of the α subunit and H3, H5 and H6 of the receptor, with receptor-

339   dependent contacts in H2, H7 and H8. The differences may arise partially from the subtle

340   difference in bending of the C-terminal part of the $\alpha5$ helix and the different positions of the

341     $\alpha5$ helix within the receptor, both presumably arising from the different amino acid

342   sequences of the respective receptors. The interactions observed here between A_{2A}R and the

343   β subunit are also observed in the Class B receptors, but are absent from the crystal structure

344   of the β_2AR-G_S structure, although a shift of the β subunit by only a few ångstroms would be

345   sufficient for interactions to occur.

346   The poor density of ECL2 in the cryo-EM map of A_{2A}R coupled to the heterotrimeric

347   G protein, suggests that this region is more dynamic than suggested from the X-ray

348   structures, probably due to a combination of pH effects and the lack of the salt bridge

349   between His264 and Glu169. This salt bridge has been suggested to be highly important in

350   modulating the kinetics of ligand binding[12]. Interestingly, a recent structure[13] of $A_{2A}R$ bound

351   to compound-1 was crystallised at pH 6.5, and no crystal contacts were formed by ECL2. In

352   this structure, the N-terminal section of ECL2 lacked density as we observed in the cryo-EM

353   map and, in the latter region, Phe168 adopts two conformations. In one conformation Phe168

354   stacks against the ligand and in the other conformation Phe168 points towards the

355   extracellular surface (Figure 5). The ionic bridge between Glu169 and His264 seems to be

356   present in this structure, so the two conformations of Phe168 may be a consequence of the

357   ligand. The cryo-EM structure thus adds support to the contention that ECL2 is flexible and

358   may be important in modulating the accessibility of the orthosteric binding site to ligands.

359   The cryo-EM structure presented here allows for the first time a direct comparison of

360   the structure of a GPCR bound to an identical ligand in the same conformation as determined

361   by cryo-EM and X-ray crystallography. This is highly interesting with respect to drug

362   discovery where tractability and speed of the structure determination are balanced by the

363   resolution required for a particular aspect of any given project. Cryo-EM offers a relatively

364   fast route to the structure of a GPCR in an active conformation coupled to the heterotrimeric

365   G protein G_S. The quality of the cryo-EM map was very similar to the electron density map

366   from the X-ray structure, despite the reported resolutions being 4.1 Å and 3.4 Å respectively.

367   In both cases, the ligand density was unambiguous, but adenosine is an asymmetric molecule

368   and difficulties would have been encountered if the ligand was more symmetrical, such as

369   caffeine. However, there is no doubt that cryo-EM is preferred in terms of overall speed;

370   extensive protein engineering is required to obtain crystals of GPCRs[32], through adding

371   fusion proteins, deletions of flexible regions, removal of post-translational modifications and

372   thermostabilisation. In theory, none of these modifications will be required for a cryo-EM

373   structure, particularly as mild detergents, amphipols and nanodiscs are all compatible with

374   structure determination of membrane proteins by cryo-EM and will maintain often quite

375   unstable membrane proteins in a functional state[33]. However, once a crystal structure has

376   been determined, they can often attain much higher resolution than structures of membrane

377   proteins obtained so far, although high resolution cryo-EM structures are possible from single

378   molecule imaging[34]. Another current advantage of X-ray crystallography is the possibility of

379   soaking crystals to get multiple structures of a receptor bound to different ligands through

380   molecular replacement[35]. Finally, there is still a size limitation of the molecule imaged by

381   cryo-EM for structure determination[36] and experimentally this is now at about 65 kDa[25].

382   However, given the continued drive towards improving the technology of cryo-EM, there is
383   no doubt that this technique will play a pivotal role in structure-based drug design in future
384   years[37].

385

386   **Materials and Methods**

387
388   **Expression and purification of the human adenosine A_{2A} receptor.** Construction of the
389   thioredoxin-A_{2A}R fusion protein and C-terminally truncated A_{2A}R (1-317), both containing
390   the N154A mutation, is described elsewhere[26]. The constructs were expressed using the
391   baculovirus expression system as described previously[17,38]. Cells were harvested by
392   centrifugation 72 hours post infection, resuspended in hypotonic buffer (20 mM HEPES pH
393   7.5, 1 mM EDTA, 1 mM PMSF, cOmplete[TM] (Roche) protease inhibitor cocktail), flash-
394   frozen in liquid nitrogen and stored at −80°C until use. The purification of the thioredoxin-
395   A_{2A}R fusion protein was performed in the detergent LMNG in the presence of 100 μM
396   NECA using Ni^{2+}-affinity chromatography followed by SEC as described previously[17,38].

397

398   **Preparation of mini-G_s heterotrimer.** The mini-G_S construct (399) used in single particle
399   cryo-EM reconstructions is based on the construct 393 that was used in the structure
400   determination of the A_{2A}R- mini-G_S crystal structure[17,19]. However, unlike construct 393,
401   mini-G_S399 binds $\beta\gamma$ [26]. The expression and purification of the respective components and
402   assembly to make the complex containing mini-G_S-$\beta_1\gamma_2$, and the preparation of nanobody
403   Nb35, were all performed following the protocols described previously[19,20,39].

404

405   **Preparation of the A_{2A}R-mini-$G_S\beta_1\gamma_2$-Nb35 complex**. Thioredoxin-A_{2A}R, mini-G_S-$\beta_1\gamma_2$
406   and Nb35 were mixed in a molar ratio of 1:2:4, to yield a final thioredoxin-A_{2A}R
407   concentration of 1 mg/ml. 0.1 U of apyrase was added and the mixture was incubated
408   overnight at 4°C. Excess G protein and nanobody were removed by SEC on a Superdex 200
409   Increase column (running buffer 20 mM HEPES pH 7.5, 100 mM NaCl, 0.1% LMNG, 100
410   μM NECA). Peak fractions with an absorbance value at 280 nm of 1.5-2 were used
411   immediately for grid preparation or flash frozen in liquid nitrogen and stored at −80°C until
412   use.

413

414   **Radioligand binding assays.** Insect cells expressing $A_{2A}R$ were resuspended in 1 ml of

415   assay buffer (25 mM HEPES pH 7.5, 100 mM KCl, 1 mM $MgCl_2$, protease inhibitor cocktail)

416   at a final concentration of 3×10^6 cells/ml. Cells were sheared by 10 passages through a bent

417   26G syringe needle. Cell membranes were diluted 50-fold to 100-fold in assay buffer and

418   aliquots prepared as appropriate. In saturation binding assays, cell membranes containing

419    $A_{2A}R$ were incubated with ^{3}H-ZM241385 (0.1 - 40 nM) for 2 h at 21°C. Non-specific binding

420   was determined in the presence of 10 μM unlabelled ZM241385. In competition binding

421   assays, cell membranes were incubated with NECA (1 nM - 1 μM) for 2 h at 21°C, in the

422   presence or absence of 25 μM mini-G_S393. 5 nM ^{3}H-ZM241385 was added followed by a 2 h

423   incubation. Assays were terminated by filtering through PEI-treated 96-well glass fibre GF/B

424   filter plates (Merck Millipore) and washing with ice-cold assay buffer. Filters were dried,

425   placed into scintillation vials and incubated overnight in 4 ml Ultima Gold scintillant (Perkin

426   Elmer). Radioactivity was quantified by scintillation counting using a Tri-Carb counter

427   (Perkin Elmer). Apparent K_D and apparent K_i values were determined using GraphPad Prism

428   version 6.0 (GraphPad Software, San Diego, CA).

429

430

431   **Cryo-EM grid preparation and data collection.** Cryo-EM grids were prepared by applying

432   3 μl of sample (total protein concentration 1 mg/ml) on glow discharged holey gold grids

433   (Quantifoil Au 1.2/1.3 300 mesh). Excess sample was removed by blotting with filter paper

434   for 4-5 seconds prior to plunge-freezing in liquid ethane using a FEI Vitrobot Mark IV at

435   100% humidity and 4°C. In all cases data was collected on a FEI Titan Krios microscope at

436   300kV. Data without VPP and initial VPP images were acquired using a Gatan K2-Summit

437   detector and a GIF-quantum energy filter (Gatan) with a 20 eV slit and zero loss mode to

438   remove inelastic scattering. For the initial non-VPP dataset, EPU automatic data collection

439   software (FEI) was used while the VPP date set of the K2-summit detector was collected

440   using SerialEM automatic data collection software[40].

441   The non-VPP data set contained a total of 2800 micrographs, collected as 40 movie

442   frames at a dose rate of 2 e⁻/pixel/sec (1.25 e⁻/Å^2 per frame) for 10 seconds, with a total

443   accumulated dose of 50 e⁻/Å^2. The magnification was 200,000x yielding 0.66 Å/pixel at the

444   specimen level.

445   The K2-VPP dataset was the result of merging three datasets with slightly different

446   collection parameters: (a) 213 micrographs collected as 40 movie frames at 5.2 e⁻/pixel/sec

447   over 10 seconds for a total dose of 40 e⁻/Å^2; (b) 232 micrographs collected as 23 frames at 9

448   e$^-$/pixel/sec over 4.6 seconds for a total accumulated dose of 30 e$^-$/Å^2; (c) 461 micrographs

449   collected as 30 movie frames at a dose rate of 6 e$^-$/pixel/sec over 6.5 seconds for a total dose

450   of 30 e$^-$/Å^2. In all cases the magnification was set to obtain a pixel size of 1.14 Å. The last

451   data set was acquired using a Falcon III detector in electron counting mode by recording 75

452   movie frames (0.8 seconds per frame) at a dose rate of 0.5 e$^-$/pixel/sec (0.4 e$^-$/Å^2 per frame)

453   for a total accumulated dose of 30 e$^-$/Å^2 acquired over a period of 60 seconds. Pixel size at

454   the specimen was calibrated to be 1.07 Å. A total of 827 images were incorporated into the

455   dataset.

456

Data processing and model building

457

458

459   All data processing was performed using RELION-2[41]. Good quality images were

460   selected manually and drift correction, beam induced motion and dose weighting was

461   performed for each of the datasets with MotionCor2[42], using 5 x 5 patches and the

462   corresponding dose per frame. CTF fitting and phase shift estimation were performed using

463   Gctf-v0.1.06[28]. In all cases, auto-picking[43] was performed with a Gaussian blob as a

464   template[27]. Elimination of false positives or "bad particles" was performed over two rounds

465   of reference-free 2D classification. 10,000 random particles were used for *ab initio* model

466   generation using the Stochastic Deepest Descent (SDG) algorithm incorporated in RELION-

467   2.1. The resulting model was used as input for the initial 3D classification. After a single

468   round of 3D classification, particles in quality models were pooled together for refinement.

469   The FalconIII-VPP data was divided into three classes, where two of them presented clear

470   structural features resembling a GPCR-G-protein heterotrimer complex. During refinement of

471   the Falcon III + VPP data, the low-pass filter effect of the Wiener filter in the regularised

472   likelihood optimisation algorithm was relaxed through the use of a regularisation parameter

473   (T=5). This allowed the refinement algorithm to consider higher spatial frequencies in the

474   alignment of the individual particles yielding a map of higher quality. Nevertheless, both

475   half-reconstructions were kept completely separately, and the final resolution estimate (at the

476   post-processing stage in RELION) was based on the standard FSC between the two unfiltered

477   half-reconstructions. Signal subtraction of the micelle was performed as described in the

478   results section and were used only in the last iteration of refinement. Application of 'particle

479   polishing' in RELION (corrects for beam induced motion and performs experimental dose-

480   weighting) did not improve the quality of the density.

481   Model building and refinement was carried out using the CCP-EM software suite[44].

482   The activated $A_{2A}R$ and mini-G_S coordinates were taken as starting models (PDB code 5g53)

483   together with the βγ coordinated from the $β_2AR$ complex structure[20]. Jelly-body refinement

484   was performed in Refmac5[45] followed by manual modification and real space refinement in

485   Coot[46]. Refinement with restraints (generated in ProSMART[47]) was performed in Refmac5 in

486   order to maintain the secondary structure in regions with poorer map quality.

487

Acknowledgements

Author Contributions

496   J.G-N. made cryo-EM grids, performed data collection and determined the structure. Y.L.

497   performed pharmacological assays, purified $A_{2A}R$ and βγ, purified receptor G protein

498   complexes, made cryo-EM grids, collected cryo-EM data, and performed processing of

499   images. B.C. purified Nb35 and mini-G_s. X.B. performed initial data collection and image

500   processing. C.G.T. managed the project, performed data interpretation and wrote the

501   manuscript. All authors contributed towards the final version of the manuscript.

Figure legends

Figure 1 Pharmacological analyses of $A_{2A}R$. a, Saturation binding of the inverse agonist ^{3}H-ZM241385 to $A_{2A}R$ constructs gave the following apparent K_{DS}: $A_{2A}R$ (circles), 0.5 ± 0.1 nM; TrxA-$A_{2A}R$ (squares), 0.8 ± 0.2 nM. **b**, Competition binding curves measuring the displacement of ^{3}H-ZM241385 with increasing concentrations of NECA gave the following K_is for NECA; $A_{2A}R$ (filled circles), 1.0 ± 0.5 μM; $A_{2A}R$ + mini-G_S (open circles, dashed line), 2.6 ± 1.8 nM; TrxA-$A_{2A}R$ (filled squares), 1.1 ± 0.4 μM; TrxA-$A_{2A}R$ + mini-G_S (open squares, dashed line), 1.8 ± 1.2 nM. Data are the average from two independent experiments performed in duplicate and errors represent the SEM.

Figure 2. Cryo-EM of the $A_{2A}R$ complex in the presence and absence of a VPP. a-c, Each panel contains three sections, with the left-hand section showing a representative micrograph obtained on a Titan Krios, the central section depicting 2D class averages and the right-hand section the refined 3D reconstruction obtained from the data collected. **a**, Data collected without using a VPP on a K2 Summit detector. **b**, Data collected using a VPP on a K2 Summit detector. **c**, Data collected using a VPP on a Falcon III detector in electron counting (EC) mode. **d**, Gold-standard FSC curves for the three 3D reconstructions with resolutions estimated at 0.143. **e**, Difference in B-factors between the three datasets.

Figure 3. Local resolution cryo-EM map. **a,** Local resolution map of the Falcon III + VPP model prior to refinement with signal subtracted particles as calculated with RELION. **b,** Local resolution of the same model after refinement of signal subtracted particles (also calculated with RELION) **c,** $A_{2A}R$ complex displayed as putty cartoons, where B-factor of the coordinates relates to the thickness of the tube.

Figure 4. Comparison of map densities from the cryo-EM data and X-ray diffraction data. The structure of the $A_{2A}R$–heterotrimeric G protein complex determined by cryo-EM is depicted as a cartoon. The four panels show regions of the structure and the associated density maps from the cryo-EM data and, where present, electron density (2Fo-Fc) from the X-ray structure of the $A_{2A}R$–mini-G_S (PDB code 5g53). Densities for the maps shown in the panels were sharpened using the following B factors (resolution of filtering in parentheses): β subunit and $A_{2A}R$, -170 Å^2 (3.7 Å); mini-G_S–$A_{2A}R$ interface, 130 Å^2 (3.7 Å); NECA, -130

545   Å^2 (4.1 Å).

546

547   **Figure 5. Structure of A$_{2A}$R–heterotrimeric G$_S$. a,** Superposition of A$_{2A}$R (pale green)

548   coupled to mini-Gs (pale blue) with A$_{2A}$R (dark green) coupled to mini-G$_S$ dark blue), βγ

549   (red) and Nb35 (yellow). **b,** Superposition of NECA bound to A$_{2A}$R in the cryo-EM and X-

550   ray structures after alignement of A$_{2A}$R (PyMol). **c,** The position of His264 in the cryo-EM

551   structure (dark green, density shown by black mesh), differs from its position in the X-ray

552   structure (light green). No density is observed for the side chain of Glu269 in the cryo-EM

553   structure, but when modelled it would be too far away to make a contact with His264. **d,** The

554   interface between ICL1 of A$_{2A}$R (dark green) and the β subunit (red) is depicted, with density

555   shown as a black mesh.

556

557   **Figure 6. Comparison of A$_{2A}$R and β$_2$AR coupled to heterotrimeric G$_S$. a**, A$_{2A}$R (dark

558   green) and β$_2$AR (dark grey) were aligned using regions of the receptors predicted to be

559   within the cytoplasmic leaflet of the lipid bilayer. The position of mini-G$_S$ (pale green)

560   coupled to A$_{2A}$R is compared to the position of the GTPase domain of the α subunit (pale

561   grey) coupled to β$_2$AR. The βγ subunits and Nb35 have been omitted for clarity. **b**,

562   Transmembrane region H1 and ECL1 in A$_{2A}$R (dark green) extends closer to the β subunit

563   (pale green) whereas β$_2$AR (dark grey) is too far away from the β subunit (pale grey) to make

564   extensive contacts.

Figure 3 - Figure supplement 1. Modelling quality of the A$_{2A}$R structure.
a, Amino acid sequence of A$_{2A}$R used in the cryo-EM structure determination. Residues are coloured according to how they have been modelled: black, good density allows the side chain to be modelled; red, limited density for the side chain present and therefore the side chain has been truncated to Cβ; blue, no density observed and therefore the residue was not modelled. Regions highlighted in grey represent the transmembrane α-helices and amphipathic helix 8 is highlighted in yellow. Cys residues involved in the formation of disulphide bonds are in bold. In the cryo-EM structure densities for the disulphide bonds Cys74-Cys146 and Cys77-Cys166 are observed. Densities corresponding to the disulphide bonds Cys71-Cys159 and Cys259-Cys262 are not observed in the cryo-EM data. The sequence of A$_{2A}$R is from residue 8-316, with the initial Ala residue at position 7 being part of the linker between the N-terminal thioredoxin fusion and A$_{2A}$R. **b**, Model of A$_{2A}$R showing the Cα positions of amino acid residues with poor density (spheres) and regions unmodelled (dotted lines).
