Abstract:
Here we introduce Protein-indexed Assay of Transposase Accessible Chromatin with sequencing (Pi-ATAC) that combines single-cell chromatin and proteomic profiling. In conjunction with DNA transposition, the levels of multiple cell surface or intracellular protein epitopes are recorded by index flow cytometry and positions in arrayed microwells, and then subject to molecular barcoding for subsequent pooled analysis. Pi-ATAC simultaneously identifies the epigenomic and proteomic heterogeneity in individual cells. Pi-ATAC reveals a casual link between transcription factor abundance and DNA motif access, and deconvolute cell types and states in the tumor microenvironment *in vivo*. We identify a dominant role for hypoxia, marked by HIF1A protein, in the tumor microvenvironment for shaping the regulome in a subset of epithelial tumor cells.

Introduction

Cell-to-cell variation is a universal feature that impacts normal development and human disease[1]. While recent advances in single cell research have improved our ability to document cellular phenotypic variation[1], the fundamental mechanisms that generate variability from identical DNA sequences remain elusive. Uncovering the molecular mechanism behind cellular heterogeneity would be helpful in clinical diagnosis, understanding the basic mechanism of developmental disorders, molecular basis of drug resistance in cancer and therapy of human diseases in the long term. In the last decades, studies revealed that chromatin structure is a main player regulating gene expression, and that it is tightly linked to heterogeneity in transcription and phenotype[2]. To fully understand the molecular mechanism determining cell-to-cell heterogeneity, it is essential to define the chromatin landscape in each individual cell.

Recent advances in single cell chromatin technologies, such as single cell ATAC-seq and single cell DNase-seq revealed the variation of chromatin organization across individual cells[3-5]. These technologies demonstrate that accessibility variance is associated with specific transcription factors and provide new insight into cellular variation of the "regulome"[3]. In these approaches, cells are randomly selected for next generation sequencing and the cellular variation is decoded using computational de-convolution. Thus, using available technologies, we only interpret the cellular variation and define subtypes indirect by clustering, dimensionality reduction such as principle component analysis method or projection onto a bulk scaffold. Therefore, until now, the cell-to-cell epigenetic variation cannot unambiguously be linked to the cellular phenotype or cell state. Staining of proteins for specific cell types and cell stages is helpful to indicate the cellular phenotype, for example phosphorylated Fokal Adehsion Kinase for a migratory cell state[6] or HIF1α staining for cells in a hypoxic environment. While an extensive effort was put on increasing throughput of these single cell technologies[2,4], the direct linkage of cellular phenotype to the chromatin variation of individual cells remains largely ignored.

Here, we describe a novel single-cell multiomic approach, Protein-index single cell ATAC-seq (Pi-ATAC), in which we index and quantify protein expression using index Fluorescence Activated Cell Sorting (FACS) and enumerate the accessible DNA elements of the same individual cell. The combination of protein and epigenetic profile allows us to directly link the cellular phenotype and environment to the chromatin variation of individual cells. We applied Pi-ATAC to primary, heterogeneous mouse breast tumors and

characterized cell states of tumor-infiltrating immune cells as well as tumor cells simultaneously. In addition, we link epigenetic variability of tumor cells to the hypoxic tumor microenvironment.

Results

Development of Pi-ATAC method

Protein-index single cell ATAC-seq (Pi-ATAC) directly links the cellular phenotype or microenvironment to the epigenetic profile, because it uses antibody staining and index FACS sorting to combine protein abundance information with the epigenetic profile of a cell. Cells or tissue are first fixed using paraformaldehyde (PFA), then gently dissociated and permeabilized using the standard ATAC-seq lysis buffer (see **Methods**), followed by antibody staining against protein epitopes of interest. As the cells are already fixed and permeabilized, intracellular as well as intra-nuclear staining are possible. Then, cells are transposed in bulk. The reaction is stopped by addition of EDTA, without any purification step. As single cells are sorted into individual wells containing the reverse crosslinking buffer (see **Methods**), fluorescence intensities of antibodies against protein epitopes of interest are recorded and assigned to the position of sorted cells. After reverse crosslinking, libraries are prepared by barcoding PCR (**Figure 1a**).

The reverse crosslinking buffer used in Pi-ATAC was specially developed to be compatible with the barcoding PCR step. In ATAC-see (a method for imaging and sequencing DNA accessibility), tagmentation is also performed on fixed cells, together with either intra-nuclear or cytoplasmic protein staining[7], and thus the ATAC-see protocol also contains a reverse crosslinking step prior to a DNA purification step. However, for single cell ATAC-seq, a DNA purification step is not practical because the limited material from one single cell library is likely lost during purification. Therefore, library preparation with single cell barcoding via PCR is performed directly in the reverse crosslinking buffer. However, DNA Taq polymerase is not compatible with sodium dodecyl sulfate (SDS) included in the traditional reverse crosslinking buffer[8]. Hence, we developed a reverse crosslinking buffer without SDS (see **Materials** and **Methods**), in which the DNA Taq polymerase is not inhibited.

First we confirmed the functionality of the new reverse crosslinking buffer followed directly by PCR without purification in bulk ATAC-seq libraries. Quality of the bulk ATAC-seq libraries prepared using the new reverse crosslinking either with or without DNA purification is comparable to the previous protocol of reverse

crosslinking buffer with purification, including (i) enrichment of fragments at transcription start sites, (ii) fragment amount observed in open chromatin peaks identified, and (iii) coverage on both gene promoters and distal elements (**Supplementary Fig. 1a-e**). Together, we conclude that the new reverse crosslinking buffer is compatible with the PCR reaction for library preparation in Pi-ATAC.

Validation of Pi-ATAC workflow in single cells

　　　　We next validated the workflow and accuracy of FACS based scATAC-seq. In order to evaluate the precision of FACS sorting, we used a mixture of two cell types of different sizes and species ("barnyard experiment"): GM12878 human lymphoblastoid cell line (LCL) and V6.5 mouse embryonic stem cells (ESC). Of note, the size difference between these two cell types is not a concern in the FACS based scATAC-seq method, whereas the C1 microfluidics system requires separation into two size-restricted integrated microfluidic chips (IFC). First, both mouse ESC (n=144) and human LCL (n=144) were fixed with 1% formaldehyde and mixed in a 1:1 ratio. Then ATAC was performed in bulk. Next, we sorted single cells from the mixture of cells by FACS without regard to cell type, and collected individual cells in 96-well plates containing the new reverse crosslinking buffer. After sorting, plates were incubated at 65 degrees over 8hs, followed by a Proteinase K inactivation step at 80 degrees. For library preparation, PCR master mix and barcoding primers were added directly to the individual wells. Finally, PCR products were pooled together; purified, and sequenced. All fragments were then aligned to mouse and human genomes. Indeed, we found that each individual well contained predominantly either human or mouse DNA sequences, using a 500 fragment cutoff and 96% species specificity (0 hybrid out of 288 cells,- **Figure 1b,** see **Methods**), confirming the precision of our index FACS sorting.

　　　　To assess the single cell Pi-ATAC library quality, we prepared libraries from 192 GM17878 cells and comprehensively compared those to bulk GM12878 ATAC-seq datasets (n=4). Single cells that produced low quality data were excluded from downstream analysis using nuclear fragment amount and fraction of reads in accessible chromatin peaks, as previously described [9]. Of the 192 GM12878 cells, 168 (87.5 %) passed filter (**Supplementary Fig. 2a,** see Method for details). Aggregation of these 168 single cells shows comparable accessibility patterns as bulk ATAC-seq (**Figure1c, Supplementary Fig. 2b** $R(77,855)=0.81$, $p<0.00001$). We then measured transcription factor (TF) variation scores in GM12878 Pi-ATAC data, using the computational tool ChromVar [9] (**Methods**). The most significant variable TF motif was NF-κB family (**Figure 1d**), which

agrees with the previous report from the same cell line by scATAC-seq approach[3].

Next, we compared Pi-ATAC data to publically available scATAC-seq data[3]. GM12878 Pi-ATAC and GM12878 scATAC-seq data yielded similar profiles of genome wide accessibility (R(77,855)=0.8, p<0.00001. **Supplementary Fig. 2c)** as well as overall transcription factor motif variability **(R (384)** = 0.7, p<0.00001. **Supplementary Fig. 2d**). To ensure that antibody staining of extra- or intracellular proteins does not interfere with the quality of Pi-ATAC, 384 GM12878 cells were stained against the B-cell surface marker CD19 and intracellular phosphorylated NF-κB (**Supplementary Fig. 2e**). The antibody staining did not substantially affect the quality of Pi-ATAC, with 298 (77.6%) passing filter (**Supplementary Fig. 2f**). The stained GM12878 Pi-ATAC data share concordance with previously published GM12878 scATAC-seq data in accessibility of peaks (R(77,855) = 0.72, p<0.00001. **Supplementary Fig. 2g**), in the genomic annotation of peak distribution (**Supplementary Fig. 2h**) and in transcription factor motif accessibility at NF-κB and Jun motifs (**Supplementary Fig. 2i**). We next compared our GM12878 Pi-ATAC data to available scATAC-seq data across multiple cell types[3]. Two-dimensional t-distributed stochastic neighbor embedding (t-SNE) projection based on TF motif accessibility revealed clustering of single cells largely according to cell type, demonstrating Pi-ATAC GM12878 clusters together with the published scATAC-seq GM12878 data and distinct from other cell types (**Figure 1e**).

We next quantified the information content provided by single cells in Pi-ATAC. Sparse DNA accessibility data from an individual cell suffice to infer TF motif activity, based on the summed accessibility of DNA elements containing the TF motif vs. background elements, as previously reported for scATAC-seq[9] (**Figure 1d, e**). For individual DNA elements, we find that data aggregation from 50 or more single cells by Pi-ATAC correlated significantly with bulk ATAC-seq on peak accessibility quantifications (Pearson correlation R=0.615 for 77,857 peaks in 50 cells, R=0.694 in 100 cells, p<0.0001, FDR<0.01, **Figure 1f,** see **Methods**). This observation is controlled for cell-to-cell variance and sequencing depth artifacts, as determined by 1,000 simulation runs of subsampling equalized contribution of 500 fragments in peaks per single cell from a randomly selected 50 cells subset. The same analysis produced similar results in protein epitope-stained Pi-ATAC data vs. published GM12878 scATAC-seq data[3]. Similar results are obtained by down-sampling to 500 fragments in peaks from bulk ATAC-seq data to mimic single cell data ("mimic from bulk" in **Figure 1f, see Methods**).

Together, these results indicate that Pi-ATAC-seq captures cell-cell variation in active regulatory DNA as well as previous published scATAC-seq protocols while providing protein epitope measurements. With appropriate cell lineage and cell state characterization, Pi-ATAC data from appropriate single cells can be aggregated to reproduce a "pseudo-bulk" genomic DNA accessibility profile.

Pi-ATAC probes transcription factor protein abundance versus DNA motif access

The K562 chronic myeloid leukemia (CML) cell line is a heterogeneous cell mixture containing both precursor and differentiated cells[10]. Several key transcription factors such as GATA1, GATA2 or TAL1 regulate hematopoietic precursor status[11,12]. We, and others demonstrated that the self-renewal and multipotency of K562 cells is correlated with high expression level of GATA2[13,14]. It is unclear whether GATA2 is a pioneer factor in this context, i.e. creating the first DNA access at its cognate motif, or follows other TFs by accessing DNA elements occupied by other TFs. Therefore, we applied Pi-ATAC to K562 cells using GATA2 staining to measure the epigenetic status and heterogeneity of the precursor cells within the K562 population (see **Methods**). To focus only on the nuclear presence of GATA2, we isolated the K562 nuclei to exclude cytoplasmic GATA2 as well as mitochondria contamination.

As expected, GATA2 staining intensity in K562 nuclei is variable, ranging from 1 to 8400 RFU, clearly clustering into three groups, which we categorized as high, medium and low (**Supplementary Fig. 3a**). Of the 288 nuclei sorted, 223 (77.4%) passed the filter (**Supplementary Fig. 3b**). In line with previous scATAC-seq results[3], our Pi-ATAC results display highest variability in the motif accessibility of the GATA and Jun/FOS family (**Supplementary Fig. 3c**). Within the significant variable TF motifs, we observed two main sub-groups by TF motif accessibility, one group enriched with Jun/Fos, and the other dominated by GATA family motifs (**Supplementary Fig. 3d,** see **Methods**). We then asked whether the GATA2 protein staining intensity correlates with the accessibility of individual TF motifs, particularly the GATA2 motif itself. Surprisingly, we did not find a significant correlation between accessibility of GATA2 motif itself with GATA2 staining (**Supplementary Fig. 3e**), but we observed significant positive correlations of GATA2 protein level with accessibility of other transcription factor motifs, including TAL1::TCF3 (R=0.21), MTF1 (R=0.19), CEBPA (R=0.12), GSC (R=0.15), SRF(R=0.16), and DUX(R=0.26, all with p < 0.05 and FDR<5%), which are involved in maintaining hematopoietic cells in a de-differentiated cell state[11,12,15-17] and determining hematopoietic cell fate in multipotential progenitor cells[18] (**Supplementary Fig. 3e**). TAL1, TCF3 and MTF1 have been reported to

be potential binding partners in larger protein complexes with GATA2[19,20]. At the same time, we also observed that the accessibility of TFAP motif is significantly anti-correlated with GATA2 stain (R= -0.2, p < 0.05) (**Supplementary Fig. 3e)**. TFAP was previously reported to drive hematopoietic differentiation[21], the opposite role of GATA2 in CML cells. Based on direct quantification of nuclear GATA2 protein and chromatin access from the same cell, our results suggest that GATA2 is not a pioneer factor in K562 cells, but rather cooperates with other TFs such as TAL1 and MTF1 to promote CML cell self renewal.

Our findings suggest the feasibility to use Pi-ATAC to directly probe TF mechanisms linking protein abundance, and DNA accessibility.

Simultaneous Pi-ATAC of tumor cells and immune cells

We next aimed to apply Pi-ATAC to primary tumor samples. Tumor tissue is comprised of different cell types, including tumor, stromal and tumor-infiltrating immune cells, each with heterogeneous cell sizes and cell surface markers. Therefore we first tested whether Pi-ATAC will work on an artificial mixture of mouse breast tumor cell line 4T1 and mouse splenocytes. This mixture allows us to test (i) the sort efficiency of cells with comparable size differences as occurring in the primary tumors, (ii) lineage-specific antibodies, such as the mutually exclusive expression of EpCAM in the breast cancer cells and CD45 in splenocytes and tumor-infiltrating immune cells. As expected, the mixture of breast cancer cells and splenocytes are clearly distinguished and sorted using EpCAM and CD45 antibodies (**Figure 2a, Supplementary Fig. 4a**). We sorted 192 cells and performed Pi-ATAC, of which 190 (99.0%) cells passed the filter (**Supplementary Fig. 4b**). Importantly, aggregated single cells from EpCAM+ 4T1 and CD45+ splenocytes show cell type-specific open chromatin at *Epcam* and *Cd45* loci respectively (**Figure 2b**), confirming the specificity of the antibodies and sorting. Within the top 30 out of 278 significant variable TF motifs, we observed two clusters of chromatin accessibility profiles demonstrating 4T1 and mouse splenocytes respectively. Addition of the protein staining information confirms the chromatin accessibility clustering and also reveals that three spenocytes (1.5%) cluster with 4T1 cells (**Figure 2c, d**). At the same time, we detect unique features of the chromatin landscape of both cell types: previously reported Spic and Irf motifs in immune cells and Nfi family motifs in 4T1 tumor cells (**Figure 2d**). Together, these results demonstrate the specificity and precision of Pi-ATAC approach to deconvolute cell communities.

Pi-ATAC of breast tumor ecosystem

Cancer heterogeneity is a major driver of tumor evolution, progression, and emergence of drug resistance. Although cancer heterogeneity can be

assessed with recent advances in single cell technologies, the focus lies mainly on cell-to-cell transcriptional or mutational differences. The heterogeneity of epigenetic information within a tumor, particularly in solid tumors, is largely unexplored.

As a case study, we applied Pi-ATAC to the fast growing and highly invasive *MMTV-PyMT* genetically engineered mouse breast tumor model[22] to simultaneously dissect EpCAM+ tumor cells and tumor-infiltrating immune cells (CD45+) from the same mouse breast tumor (**Figure 3a**, **Methods**). We stained a single cell suspension of the dissected tumor with anti-EpCAM and anti-CD45 as above and performed Pi-ATAC on 384 cells (**Supplementary Fig. 5a**). We did not exclude any tumor regions or cells, obtaining an unbiased view of the composition of the tumor. Of all stained cells 4% were immune cells (CD45+), 28% were epithelial tumor cells (EpCAM+) (**Supplementary Fig. 5a**). The quality of Pi-ATAC in these primary tumor cells isolated from a solid tumor was equivalent to Pi-ATAC performed of any cell line with 369 (96.1%) cells passing the filter (**Supplementary Fig. 5b**). Aggregated single cells from EpCAM+ and CD45+ cells show cell type-specific open chromatin at *Epcam* and *Cd45* loci respectively (**Supplementary Fig. 5c**).

Surprisingly, although the distinction of the protein staining is pronounced, the t-SNE projection of EpCAM+ cells and CD45+ cells of bias-corrected deviations for motifs did not form two distinct clusters (**Figure 3b**). However, the protein information aids visualization of a polarity of the distribution of the EpCAM+ cells and tumor-infiltrating immune cells and reveals mixing of the two cell types. The previous observed clear separation of 4T1 and mouse splenocyte epigenetic profiles excludes the possibility of antibody cross-contamination.

We next calculated the variability of TF motifs across all cells, resulting in 84 significant variable motifs (P < 0.05 after Benjamini-Hochberg correction on multiple tests, **Supplementary Table 1**). Unsupervised hierarchical clustering of the chromatin accessibility of the 84 TF motifs across 369 cells revealed three modules of TF motif accessibilities (28 motifs in m1, 14 in m2 and 42 in m3) and seven subgroups of single cells (s1-s7 with cluster size range from 27 to 68 cells) (**Figure 3c, d(I), Supplementary Fig. 5d, e**). TF motifs of m1 consisting of immune cell specific motif families (Spic, Runx, Ets, et. al) show uniform specific accessibility among cells in s1 and s2 (**Figure 3c, d(II)**). M2 motifs, including chromatin remodeling relevant TF motifs such as Smarcc1, Jun and Fos family are consistently accessible in cells of s1 and s4 (**Figure 3c, d(III)**). M3 comprises TF motif families Hmga, Hif, Nfi, Tead, p53, Grhl1 and Fox. We observed heterogeneity across all cellular subgroups for TF motif accessibility in m3, however highest mean motif accessibility in s3, s4 and s6 (**Figure 3c, d(IV),**

Supplementary Figure 6). Collectively, the seven different cellular subgroups might reflect the heterogeneity of the composition of EpCAM+ tumor cells and CD45+ tumor infiltrating immune cells.

Next, we aligned the FACS protein staining information to the seven cellular subgroups (**Figure 3c, d(V)**). As expected, s1 and s2, the cellular clusters exhibiting high chromatin accessibility of motifs associated with the immune cell lineage, are significantly enriched with CD45+ cells (92.4% of 66 cells in s1 and 94.1% of 68 cells in s2, Chi-square test p<0.0001 for others, after Benjamini-Hochberg correction of multiple tests, **Supplementary Table 2**). The majority (102 out of 177 (57.6%)) of EpCAM+ cells fall into s3, s4 and s7 (76.7% of 30 cells in s3, 88.2% of 68 cells in s4 and 90.7% of 43 cells in s7, enriched with EpCAM+ cells, Chi-square test p<0.0001 for others, after Benjamini-Hochberg correction of multiple tests, **Supplementary Table 2**). The remaining 75 of 177 EpCAM+ cells are in s5 and s6 mixed together with CD45+ cells. EpCAM+ subgroups are characterized by accessibility of TF motifs in m3, a module characterized by heterogeneous accessibility in various TF motifs such as p53-, Tead-, Nfi- and Hif- families. This heterogeneous TF motif accessibility in m3 prevents clear categorization of some cells, especially cells in s3, s5, s6 and s7; only the protein information guides the classification into immune and tumor cells. Interestingly, m2 motifs associated with chromatin remodeling TFs such as Smarcc and Fos show specific accessible in subgroups of both EPCAM+ (s1) and CD45+ (s4) cells (**Figure 3d(III)**), suggesting variable regulation on different subgroups within each cell type. Our result demonstrates the Pi-ATAC dissects chromatin profile of different cell types simultaneously from the primary tumor, and the staining information is necessary to unambiguously define the cell type from such complex system.

Assuming the previous analyzed artificial mixture of immune and tumor cells defines TF motif accessibility characteristic for these cell types, we compared TF motif variability of 4T1 to splenocytes, and of CD45+ tumor infiltrating immune cells to EpCAM+ primary tumor cells (**Figure 3e**). Of the 84 significant variable TF motifs across the primary cells 49 are shared between the two datasets. Of note, while the top ten most variable motifs from the tumor-immune cell mixture experiment are all m2 motifs shared with the primary cells, most of the heterogeneous TF motif accessibility in m1 and m3 was not observed as significantly variable in the cell line mixture. Thus, we next asked which TF motifs are the main contributors to the heterogeneity in m3 and m1 assuming that contributing TFs are unique features of *in vivo* tumors. Motifs along the y-axes stand out as having additional variability of accessibility in tumor cells and infiltrating immune cells compared to the artificial mixture (**Figure 3e**). Of these

motifs, the most variable ones are defining m1 of the hierarchical clustering (**Figure 3e, lavender dots**). These results demonstrate that motifs accessible in m1 are unique to the tumor infiltrating immune cells, because of their absence in the splenocytes. While m1 motifs are accessible specifically in CD45+ cells, m3 accessibility is biased towards EpCAM+ cells (**Supplementary Figure6**). Interestingly, the predominant TF motif specific to primary tumor cells enriched in m3 is Hif (**Figure 3e pink dots**). We found the Hif motif to be the most significant unique variable motif of the heterogeneous m3 module (**Figure 3d(IV)**). HIF protein stability is tightly linked to the hypoxic environment[23], thus we hypothesize that the hypoxic microenvironment in a solid tumor may modulate the chromatin structure and contribute to the heterogeneity of chromatin accessibility observed in the primary tumor.

Hypoxia drives single cell epigenetic variability in tumor microenvironment

To directly demonstrate that the hypoxic microenvironment influences the tumor epigenetic landscape *in vivo*, we applied Pi-ATAC to EpCAM and HIF1α stained cells in the *MMTV-PyMT* breast tumor model. We isolated 956 EpCAM+ cells and observed 762 negative, 139 low and 55 high HIF1α protein-positive cells from the tumor (**Figure 4a**). Among these 956 cells analyzed by Pi-ATAC, 839 passed the filter (**Supplementary Fig. 7a**). The different groups of HIF1α level might reflect the distance of the cell from the hypoxic center in the tumor or the time a cell was exposed to hypoxia. The variability of transcription factor motif accessibility profiles across the three HIF staining groups is substantially different (**Figure 4b, Supplementary Table 3**). This difference is not due to the variable sample size of the HIF staining groups as demonstrated by downsampling simulations (**Supplementary Fig. 7b, Supplementary Table 3**)**.** Interestingly, transcription factor motif accessibility varies most among the negative hypoxic cells (**Figure 4b, Supplementary Fig. 7b**). Among the strongest variable motifs in the negative HIF1α group are Fos, Smarcc1 and Batf, which were observed to be accessible in a subgroup of EpCAM+ cells all previous experiments. The variability of low and high HIF1α stained cells is similar; they are dominated by p53 TF family motifs. Hypoxia is known to induce p53-mediated apoptosis [24], which may be reflected in the TF motif activity. Additional TF motifs that are highly variable in hypoxic cells include Grainyhead and Snail, TFs involved in epithelial-mesenchymal transition and known mediator of breast cancer metastasis [25,26]. These TF motifs as well as the more uniform distribution of accessibility across all cells are in line with the previous observed heterogeneous TF motif accessibility.

Fox and E2f3 were previously reported to be regulating transcription of HIF target genes[27,28]. Indeed, the tumor Pi-ATAC data demonstrate a significant increase of DNA accessibility of motifs for Fox family and E2f3 in the cells with high HIF1α protein ($P < 0.05$, **Figure 4c**) in a more detailed comparison of transcription factor motif accessibility across the three groups. At the same time, we observed TF motifs of Pit1 and Atoh8 lost significant DNA accessibility ($P < 0.05$) in cells with high HIF1α protein (**Supplementary Fig. 8**). Atoh8 expression was reported to be reduced in hypoxic conditions[29]. Pit1 is an important developmental factor[30] associated with cancer but not previously associated to be regulated by the HIF network.

Surprisingly, we found on average decreased accessibility at HIF motifs in HIF1α high cells compared to negative and low (**Figure 4c,** p<0.05). However, we also observe a bimodal distribution of HIF motif accessibility within this HIF1α high group (**Figure 4c, p<0.05 for Hartigans' dip statistic**). This feature is not due to variable sample size across the three staining groups, as shown by down-sampling simulation in negative and low HIF1α clusters to the same number of cells as found in the HIF1α high group (*n*=42) (**Supplementary Fig. 9**). This bimodality shows heterogeneity in HIF motif accessibility, which might reflect distance to the hypoxic center or time of hypoxia exposure.

By organizing single cells based on HIF1α protein levels, we now can interpret a subset of DNA accessibility dynamics that likely reflect the hypoxic microenvironment modulating cooperating transcription factors acting on target gene promoters and enhancers.

To confirm if the DNA accessibilities of tumor cells, particularly HIF, Fox, E2f3, Atoh, Pit1 motifs, are indeed modulated by hypoxia and no other tumor microenvironmental stimuli, we used an *in vitro* cell line culture system to simulate the *in vivo* hypoxia microenvironment. We incubated the mouse breast tumor cell line 4T1 in 1% O_2 for various time points (6hs, 12hs, 24hs, 36hs, 48hs and 72hs). To avoid the degradation of HIF proteins under normoxia, we fixed and collected cells in 1% O_2 followed by HIF1α protein staining and standard bulk ATAC-seq at the indicated time points. Increased HIF protein stability was then measured by flow cytometric analysis. We observe an immediate increase in HIF1α protein abundance followed by a stronger increase and saturation at about 48hs – 72hs in low O_2 (**Figure 4d**). That observation confirms that the 4T1 cells experienced bona fide hypoxia.

All bulk ATAC-seq libraries have good reproducibility at all the time points (**Supplementary Fig. 10a-c**). We hypothesized that we might observe dynamic chromatin changes due to low oxygen and stabilized HIF, some of which might involve direct targets of HIF or co-factors or factors inducing HIF. We indeed

observe changes in the chromatin accessibility across time in low oxygen, with 635 at 6h to over 1000 sites opening at 72hs compared to normoxic cells. Interestingly, only a small number of DNA elements (~20-70) lose DNA access during this treatment (**Figure 4e**). These differential accessible chromatin sites were annotated to 755 significantly differential accessible transcription factor motifs, using the Cis-BP database (**Supplementary Fig. 10d, Supplementary Table4,** see **Methods**).

This reference time course allowed us to next focus on the dynamic changes of transcription factor motifs, which we assume to be involved in hypoxic responses of tumor cells, because they are enriched in HIF1α high group in the Pi-ATAC tumor experiment (**Figure 4c**). Indeed, we found that the chromatin accessibilities are affected at HIF, Fox, E2f3, Ptx1 and Atoh8 motifs during the different time points of hypoxia incubation (**Figure 4f, Supplementary Fig. 11**). Also *in vitro* HIF motif accessibility undergoes dynamic changes, showing both decrease and then increase at different time points of hypoxia treatment confirming the slight decrease and variability observed *in vivo*. Foxp1 and E2f3 motif gain DNA accessibility with increasing duration of hypoxia incubation (**Figure 4f**). At the same time, accessibility of Pit1 and Atoh8 motifs decrease with longer hypoxia incubation, both results confirming the accessibility differences observed in HIF1α high vs. negative group *in vivo* (**Supplementary Fig. 11**).

In summary, Pi-ATAC is the first technique that allows directly linking the microenvironment to epigenetic heterogeneity in a tumor.

Discussion

Here, we develop a novel single-cell multiomic technology, Pi-ATAC, that simultaneously measures protein epitopes and active DNA regulatory elements of the same individual cell. Pi-ATAC enables investigation of the basic molecular mechanism of cellular heterogeneity from multiple angles. We demonstrate, that Pi-ATAC is applicable to both fixed cells from cultured cells and solid tumors *in vivo*, without any cell size restrictions. Pi-ATAC is easily scalable, fast and economical (~$0.15/cell – $1.50/cell, cost calculation in **Methods**). Pi-ATAC is high throughput and easily scalable; with sorting into 384 well plates and use of 96x90 adapter combinations to index 8640 single cells in one experiment. Importantly, Pi-ATAC can be performed without any specialized instrument or reagents, allowing ready access to the broad community. In our experiments we sort and ATAC up to 1000 cells for a tumor experiment, demonstrating scalability and throughput.

In Pi-ATAC, choice of antibodies allows to combine phenotypic characterization of cells with their epigenetic profile. Investigators can prospectively focus their sequencing power on rare but interesting cells. Another advantage of Pi-ATAC is that fixed cells can be stored prior to tagmentation, allowing collection of rare cells and pooling across multiple experiments. Moreover, Pi-ATAC can directly link protein abundance or modifications with chromatin landscape to address mechanisms of gene regulation. For example, staining of pathways including hyperactive kinases in tumors, or micro-environmental conditions such as stabilized HIF protein in hypoxia. Using hypoxia and HIF staining as an example, we demonstrate that Pi-ATAC allows the direct link of the microenvironment to the epigenetic landscape of single cells. In the future, Pi-ATAC may be combined with single cell RNA-seq from the same cell to understand gene regulation and cell identity of the exact same cell. The biological insight of this new technique will be of great value for single cell research in future.

The tumor microenvironment has been recognized as an integral component of malignancies in mammary and other carcinomas, contributing in confounding ways to tumor progression, metastasis, therapy resistance, and disease recurrence[31]. In the tumor microenvironment immune cells change from an immune-active to an immune-suppressive state, stromal cells turn into tumor-promoting tissue. The altered phenotype of these cells is proposed to be mainly due to epigenetic deregulation of gene expression[32]; however until now, a direct measurement linking the microenvironment with epigenetic changes does not exist. These epigenetic changes are highly dynamic, causing heterogeneity of cell states within a tumor, which contributes to drug resistance, and tumor recurrence[33]. By directly linking the environment with HIF1α protein accumulation and the chromatin profiles of single cells, we show that tumor hypoxia dominantly shapes the regulome profiles of both parenchymal tumor cells and infiltrating immune cells, becoming the dominant epigenomic signature for a minority of cells in the tumor. Moreover, different levels or durations of hypoxia can induce distinct TF activity states that expand tumor heterogeneity. Pi-ATAC may be useful to address potential prognostic and therapeutic opportunities revealed by these insights in future studies.

Methods:

Cell culture: GM12878 were purchased from Coriell Institute and grown in RPMI 1640 (11875-093, Gibco), 2 mM L-glutamine (25030-081, Gibco), 15% fetal bovine serum (07905, Gibco) and 1% Pen/Strep (15140-122, Gibco). 4T1 mouse breast cancer cells were purchased by ATCC (CRL-2539) and cultured in RPMI 1640 supplemented with 10% fetal bovine serum (07905, Gibco) and 1% Pen/Strep (15140-122, Gibco). K562 human chronic myeloid leukemia cells were purchased from ATCC (CCL-243) and cultured in IMDM supplemented with 10% fetal bovine serum (07905, Gibco) and 1% Pen/Strep. V6.5 Mouse embryonic stem cells (mESCs, Novus Biologicals) were cultured in DMEM/F12 supplemented with N2, 10 ng/ml bFGF (R&D Systems), and 1,000 U/ml of LIF. For the 4T1 in vitro hypoxia experiments, cell lines were cultured in a Ruskinn Invivo2 workstation maintained at 1% O_2 and 5% CO_2, and cells were collected with trypsin digestion in the Ruskinn Invivo2 workstation and fixed immediately after 6hs, 12hs, 24hs, 36hs, 48hs and 72hs incubation.

Mice: MMTV-PyMT mice were ordered from The Jackson Laboratory and bred and housed in the Stanford University Research Animal Facility in accordance with the guidelines (APLAC #14046).

Splenocyte isolation: A spleen was dissected from a MMTV-PyMT mouse which did not have a tumor at the time of euthanization. Then the spleen was sliced into small pieces. Single cells were isolated from these pieces by placing them onto a 70 μm cell strainer and mechanically pushing the cells with a plunger through the strainer. Red blood cells were permeabilized using ACK buffer (Thermo Fisher, A1049201). After washing cells twice with RPMI 1640 medium, cells were counted and used in the 4T1–splenocyte mixture Pi-ATAC experiment.

Mouse breast tumor dissection and dissociation: Tumor growth has been monitored and mice were sacrificed at 3 month of age, when tumors reached a 1 cm^3 size. The mouse was immediately perfused using 4% Paraformaldehyde, which was subsequently quenched with 0.125 M glycine. The tumor was dissected and first cut into small pieces on ice, followed by enzymatic digestion using 200 U CollagenaseV in HBSS + 0.1% FBS for 1 h at 37 degrees rotating. After centrifugation cells were resuspended in PBS and this suspension was filtered through a 70 μm cell strainer to remove any remaining clumps. Cells can be stored in PBS for at least 1 week at 4 degrees.

Bulk ATAC-Seq: Fixed ATAC-seq was performed as previous described[7]. GM12878 cells were fixed with 1% formaldehyde (Sigma, USA) for 10 min and

quenched with 0.125 M glycine for 5 min at room temperature. After the fixation, cells were counted and 50,000 cells were used per ATAC-seq reaction. The transposition reaction follows the normal ATAC-seq protocol. After the transposition, a reverse crosslink solution (final concentration of 50 mM Tris-Cl, 1mM EDTA, 1% SDS, 0.2M NaCl, 5 ng/ml proteinase K) was added up to 200 μl. The mixture was incubated at 65 °C with 1200 rpm shaking in a heat block overnight, then purified with Qiagen Mini-purification kit and eluted in 10 μl Qiagen EB elution buffer. Sequencing libraries were prepared following the original ATAC-seq protocol[34]. The sequencing was performed on Illumina Hi-Seq at the Stanford Functional Genomics Facility.

Bulk Pi-ATAC-seq without elution: GM12878 cells were fixed with 1% formaldehyde (Sigma, USA) for 10 min and quenched with 0.125 M glycine for 5 min at room temperature. After the fixation, cells were counted and 50,000 cells were used per ATAC-seq reaction. For bulk Pi-ATAC of 4T1 cells, cells were first fixed in hypoxia, then counted and permeabilized, followed by transposition. The transposition reaction is the same as for standard ATAC-seq except with 0.05% Igepal CA-630 in the lysis buffer. After 30 min transposition, at 37 degrees, the reaction was quenched using 40 mM EDTA, then cells were centrifuged and supernatant was discarded. 20 μl of reverse crosslinking solution was added to the cell pellet. Reverse crosslinking was performed 65 degree overnight and inactivated by a 10 min incubation at 80 degrees the next day. The 25 μl PCR master mix (NEB, M0541S) and 5 μl of two unique primer combinations were directly added to the reverse crosslinking mixture and PCR was performed as previous described[35]. The PCR product was purified with Qiagen MinElute purification kit and eluted in 20 μl Qiagen EB elution buffer. The 75x2 paired end sequencing was performed on Illumina HiSeq4000 at the Stanford Functional Genomics Facility.

Pi-ATAC of mixture of GM12878 and mES cells:
50,000 GM12878 and 50,000 mouse ESCs were mixed 1:1. The mixture was fixed with 1 % formaldehyde (Sigma, USA) for 10 min and quenched with 0.125 M glycine for 5 min at room temperature. Then, cells were permeabilized using standard ATAC lysis buffer (10 mM Tris ph7.5, 10 mM NaCl, 3 mM MgCl2, fresh 0.1% NP40) and immediately spun down. Cells were then transposed in bulk; for 100,000 cells 2x ATAC reactions were calculated. After 30 min tagmentation, reaction was quenched by addition of 40 mM EDTA. Cells were centrifuged, supernatant discarded and pellet resuspended in PBS for single cell index sorting. In the analysis, all alignments below 500 fragments were disregarded.

Pi-ATAC of mixture of 4T1 cells and splenocytes:

50,000 4T1 and 50,000 splenocytes were mixed 1:1. The mixture was fixed with 1 % formaldehyde (Sigma, USA) for 10 min and quenched with 0.125 M glycine for 5 min at room temperature. Then, cells were permeabilized using standard ATAC lysis buffer (10 mM Tris ph7.5, 10 mM NaCl, 3 mM MgCl2, fresh 0.1% NP40) and immediately spun down. Cells were then transposed in bulk; for 100,000 cells 2x ATAC reactions were calculated. After 30 min tagmentation, reaction was quenched by addition of 40 mM EDTA. After that, cells were stained at room temperature with anti mouse EpCAM-BV421 (BD Horizon, #563214) CD45-Alexa488 (BioLegend #103122, clone 30-F11) for 30 min. Cells were then washed twice, the final pellet resuspended in PBS for single cell index sorting.

Pi-ATAC of GM12878 cells: GM12878 cells were counted and 100 000 cells were fixed with 1 % formaldehyde (Sigma, USA) for 10 min and quenched with 0.125 M glycine for 5 min at room temperature. Then, cells were permeabilized using standard ATAC lysis buffer (10 mM Tris ph7.5, 10 mM NaCl, 3 mM MgCl2, fresh 0.1% NP40) and immediately spun down. For indicated experiments 100,000 cells were then stained at room temperature with anti human CD19-PE Clone H1B19 (BioLegend 302207) and rabbit anti human Phospho-NF-kB p65 (Ser536, CellSignaling) followed by donkey anti rabbit 488 secondary antibody. After staining (30 min each antibody), cells were transposed in bulk; for 100,000 cells 2x ATAC reactions were calculated. After 30 min tagmentation, reaction was quenched by addition of 40 mM EDTA. Cells were centrifuged, supernatant discarded and pellet resuspended in PBS for single cell index sorting.

Index sorting and library preparation for Pi-ATAC
Single cells were index-sorted into 96-well plates without any specific staining selection using the FACS AriaII (BD Biosciences). The plates were pre-filled with 20 µl reverse crosslinking buffer (see above) per well. For each experiment, index sort files (fcs) were exported using BD FACS Software and then further analyzed by FlowJo and R.
For reverse crosslinking all 96-well plates were incubated over night at 65 degrees, then proteinase K was inactivated by 10 min incubation at 80 degrees.
Single cell libraries were prepared by adding 25 µl 2 x PCR Master Mix (NEBNext High fidelity, NEB) and 2.5 µl 25 mM barcoding primer to each well[3]. PCR Cycling conditions: 72°C for 5min; 98°C for 30 s; 20 cycles at 98°C for 10 s, 63°C for 30 s, and 72°C for 1 min. After that, all wells were pooled, purified using the MinElute kit from Qiagen and eluted in 20 µl Qiagen EB elution buffer.

Pi-ATAC of K562 cells: First, we isolated the K562 nuclei by following the protocol as reported[36]. For the Pi-ATAC, 200,000 Nuclei were transposed; for

100,000 nuclei 2x ATAC reactions were calculated. After 30 min tagmentation, reaction was quenched by addition of 40 mM EDTA. After that, cells were stained at room temperature with mouse anti human GATA2 (Abnova, 1-102) 30 min at room temperature, followed by donkey anti mouse 488 secondary antibody. Cells were then washed twice, the final pellet resuspended in PBS for single cell index sorting.

Pi-ATAC of tumor cells: $1*10^6$ Cells isolated from a PyMT mouse breast tumor (see above) were stained for 30 min at room temperature for rat anti mouse EpCAM-BV421 (BD Horizon, #563214), HIF1a-PE (R&D, #IC1935P), CD45-Alexa488 (BioLegend #103122, clone 30-F11), followed by donkey anti rabbit 488 secondary antibody. After staining cells were transposed in bulk. Here, for 4000 final cells we tagmented 400,000 cells, meaning 8x ATAC reactions were calculated. After 30 min tagmentation, reaction was quenched by addition of 40 mM EDTA. Cells were centrifuged, supernatant discarded and pellet resuspended in PBS for single cell index sorting.

Single cells were index-sorted into 96-well plates without any specific staining selection using the FACS AriaII (BD Biosciences). The plates were pre-filled with 20 µl reverse crosslinking buffer (see above) per well. For each experiment, index sort files (fcs) were exported using BD FACS Software and then further analyzed by FlowJo and R.

For reverse crosslinking all 96-well plates were incubated over night at 65 degrees, then proteinase K was inactivated by 10 min incubation at 80 degrees. Single cell libraries were prepared by adding 25 µl 2 x PCR Master Mix (NEBNext High fidelity, NEB) and 5 µl of two unique primer combinations, the PCR Cycling conditions: 72°C for 5min; 98°C for 30 s; 20 cycles at 98°C for 10 s, 63°C for 30 s, and 72°C for 1 min. After that, all wells were pooled, purified using the MinElute kit from Qiagen and eluted in 20 µl Qiagen EB elution buffer.

Pi-ATAC library purification, quantification and sequencing: The pooled single cell Pi-ATAC library were loaded on 6% PAGE, run at 160 V for approximately 10 minutes purification, stain the gel with SYBR Gold. One 0.5ml tube was prepared for one sample, and a hole was made in the bottom of 0.5ml tube with 20 gauge needle. The gel slice with range of above 150bp DNA were cut and put in the 0.5ml (with a hole in the bottom). Next, the 0.5ml tube is put in the 2ml tube and centrifuged with max speed for 3 minutes at room temp. After removing the 0.5ml tubes, and 300ul Buffer (500 mM NaCl, 1 mM EDTA, 0.5% SDS) was added in the gel. The gel is incubated at 55 degree overnight with 1400 rpm shaking. Next day, the gel is centrifuged with max speed for 3 minutes

at room temp, and the supernatant is recovered for DNA purification with ChIP DNA Clean & Concentrator Kits (ZYMO RESEARCH, D5205). The recovered DNA is quantified with Agilent High Sensitivity DNA ChIP and sequenced on Illumina Hi-Seq at Stanford Functional Genomics Facility.

Pi-ATAC cost per cell: For Pi-ATAC, reagent costs is largely driven by the PCR master mix. Cost estimate per cell: Tn5 enzyme (Illumina, $0.00049 per cell, assuming 2.5 μl Tn5 per 50,000 cells), NEBNext® High-Fidelity 2X PCR Master Mix,(NEB, M0541) and primers (~$1.30 per cell) and negligible costs for antibodies per cell (about $3 per protein per 10^6 cells). In summary, it costs about $1.50 per cell with 50 microliter PCR reaction system. In addition, we had succeeded with low scale volume PCR reaction system at 5 microliter per well of a 96-well plate, where the cost is ~$0.15 per cell.

Bulk Pi-ATAC data preprocessing: Paired-end reads were trimmed for Illumina adapter sequences and transposase sequences using custom-written script and mapped to hg19 or mm9 respectively using Bowtie2[37] v2.1.0 with parameters – "very sensitive". Reads were subsequently filtered for alignment quality of > Q30 and were required to be properly paired. Duplicate reads were removed with Picard (http://picard.sourceforge.net) v1.79. Reads mapping to the mitochondria were removed and not considered. The uniquely mapped reads are merged before peak calling if bulk samples origin from the same cell/tissue/condition. Peak calling was performed by MACS2[38] narrow peak mode with parameters –q 0.01 –nomodel –shift 0. Peaks were filtered for following categories: (1) mitochondrial fragments inserted in nuclear genomic sequences, by Nuclear MiTochondrial Sequences (NumtS) (http://hgdownload.cse.ucsc.edu/goldenPath/hg19/database/ or http://hgdownload.cse.ucsc.edu/goldenPath/mm9/database/).
 and (2) the consensus excludable ENCODE blacklist genomic regions (http://mitra.stanford.edu/kundaje/akundaje/release/blacklists/hg19-human/hg19-blacklist.xls or http://mitra.stanford.edu/kundaje/akundaje/release/blacklists/mm9-mouse/mm9-blacklist.bed.gz).
To process comparison among bulk samples from multiple cell/tissue/conditions, peak sets from all conditions were merged by bedtools merge to a consensus peak list. Number of raw reads mapped to each peak in each sample was quantified using multicov in Beltools. Peak raw counts were normalized using DESeq2.

Pi-ATAC data processing: All single cell Pi-ATAC data were preprocessed with custom-written script as previous described[3] and bulk preprocessed. Briefly, pair-ended reads were trimmed with adapter sequences, were mapped to hg19 or

mm9 with Bowtie2 v2.1.0 with parameter-X2000. Uniquely mapped reads were filtered for low-quality reads, duplicates, and reads mapped to mitochondrial genome. Peak summit calling was processed with aggregated single cells of one cell/tissue condition, by MACS2 narrow peak mode with parameters –q 0.05 – nomodel –shift 0 –call summits. We annotated peaks as the summit-centered 500 base pair long genomic region. The top 50,000 peaks with least q value reported by MACS2 were included for downstream analysis in most datasets; whereas top 30,000 peaks were included for K562 dataset. Single cell libraries were further filtered with requirement of at least 500 fragments mapped to genome and at least 0.5 times the median proportion of fragments in peaks reached by aggregated single-cells of the same cell/tissue condition (chromVAR)[9].

Pi-ATAC data information content analysis:
The quantification of fragments mapped to each peak for the genomic DNA accessibility was compared between bulk GM12878 Pi-ATAC samples and single cell Pi-ATAC. Peak quantification of bulk data was calculated as mean value of the four samples. Peak quantification of Pi-ATAC was calculated for single cell as well as for single cells aggregation in group-size five, ten, 20, 50, 100 and 150. To adjust cell-cell variance, 1,000 times of simulation was processed to randomly select cells from the 192 GM cells into the group. To adjust sequencing depth artifact, 500 of fragments passing the final filter were randomly subsampled from the bam file for each cell in each time of simulation. The same process was conducted for public scATAC-seq GM12878 data[3]. We also generated 50 'mimic' single cell data through down-sampling 500 fragments passing the final filter directly from each of the four bulk samples. Pearson correlation coefficient with significance was calculated between peak quantification of bulk and single cell data from each approach.

TF deviation and variability analysis: Single-cell Pi-ATAC data processing and calculation of TF deviation was performed using the R package chromVAR as reported[9]. TF motifs were derived from the JASPAR dataset for human data, while Homer and Cis-BP databases were used for mouse data, with R package motifmatchr. Briefly, for each TF, the accessibility in each cell was calculated by subtracting the number of Pi-ATAC reads in peaks covering the corresponding motif in the cell, and was normalized by the total TF accessibility in the cell. The accessibility deviation value for the TF in each cell is subtracted by the mean accessibility calculated for sets of background peaks with similar accessibility and GC content to obtain a bias-correction, and further divided by standard deviation of the deviations calculated for the background peak sets.

The Z-score of deviations for each TF is used for visualized in both t-SNE projection plots and heatmaps of unsupervised hierarchical clustering based on correlation metric, by R packages Rtsne and pheatmap.

The variability of the TF motif across single cells in the sample set was determined by the standard deviation of the TF deviations across the cells. The metrics is close to 1 if the motif is not significantly more variable compared to the background peak list of that motif. To remove artifact of cell amount difference among the three groups of mouse breast tumor assembled by HIF1α staining, 100 times of simulation was processed through downsampling 42 cells from HIF1α low and HIF1α median group to re-calculate TF variabilities.

c, UCSC genome browser track comparison of aggregated 168 single cell Pi-ATAC to bulk ATAC-seq (both GM12878).
d, Ranking of transcription factor (TF) motif variability plot of unstained Pi-ATAC data (GM12878).
e, t-SNE projection generated from TF deviation z-scores. Pi-ATAC data of GM12878 cells (violet) were projected together with scATAC-seq of GM12878 cell on Fluidigm platform(orange), and distinct from other cell types[3].
f, Pearson correlation of fragment counts in ATAC-seq peaks in bulk GM12878 ATAC-seq data compared to aggregated single cells from indicated single cell ATAC-seq approaches and mimic single cells from bulk (shown are distribution of 1,000 times simulation on down sampling 500 fragments from each randomly selected single cell or bulk sample).

Figure 2: **Pi-ATAC precisely dissects the cell types based on epigenetic profile**.
a, FACS sorting gating strategy and data of EpCAM+ and CD45+ cells from mixture of 4T1 cells and mouse splenocytes; the histogram of protein staining is presented in Supplementary Fig. 4a.
b, Genome browser tracks of aggregated Pi-ATAC 4T1 (EpCAM+) (n=95) and splenocytes (CD45+) (n=95) at the *Epcam* and *Cd45* loci.
c, t-SNE projection generated from TF deviation z-scores showing the projection of chromatin accessibility from Pi-ATAC 4T1 (EpCAM+) (*n*=95) and splenocytes (CD45+) (*n*=95).
d, Heatmap of unsupervised hierarchical clustering of the 30 top variable TF deviations from 4T1 (EpCAM+) (*n*=95) and splenocytes (CD45+) (*n*=95) Pi-ATAC. Each column represents a cell and each row a transcription motif. The staining cluster information from FACS was assigned to each individual cell (top color bar).

Figure 3: **Pi-ATAC dissects EpCAM positive tumor cells and Tumor-infiltrating immune cells from the same mouse breast tumor**
a, schematic illustrating the different cell types in the mouse breast tumor.
b, t-SNE projection of TF deviation z-scores of Pi-ATAC EpCAM+ (*n*=177) and CD45+ (*n*=192) cells from the same mouse breast tumor.
c, Unsupervised hierarchical clustering of the TF deviation z-scores of all 84 significant variable TFs (p < 0.05 after Benjamini-Hochberg correction on multiple tests) across EpCAM+ (*n*=177) and CD45+ (*n*=192) cells from the same mouse breast tumor. Each column represents one cell and each row a transcription factor motif. Motif modules (m1-3) and cell subgroups (s1-7) are marked with distinguished colors. In addition, the staining cluster information from FACS was assigned to each individual cell (top color bar).
d, t-SNE projection of TF deviations of 84 significant variable TF motifs of EpCAM+ and CD45+ cells isolated from a tumor. **I,** color coded by cellular subgroup information; **II-IV**, color coded by the accessibility of the TF motif with most significant variability in each module (see Figure 3d): Ets2 in m3 (**II**), Smarcc1 in m2 (**III**) and Hif in m1 (**IV**). Red is highly accessible, blue is low accessible; **V**, color coded by immune-phenotype.
 e, Scatter plot of TF motif variability across 4T1-Splenocyte mixture to TF variability across EpCAM+ - CD45+ primary tumor cells. Colors indicate TF motif modules as in (c). Arrow points to Hif.

Figure 4: **Epigenetic variability is modulated by the hypoxic microenvironment**
a, FACS sorted EpCAM+ and HIF1α+ double positive cells from the same mouse breast tumor; three groups of HIF1 α staining were assigned, HIF1α negative (*n*=762), HIF1α low (*n*=139), HIF1α high (*n*=55) (right plot).
b, Ranking of transcription factor motif variability of different HIF1α staining groups, HIF1α negative (*n*=702), HIF1α low (*n*=95), HIF1α high (*n*=42).
c, Examples of TF motif deviations which significantly change in HIF1α high group compared to the others. In each comparison, HIF1α negative (*n*=702), HIF1α low (*n*=95), HIF1α high (*n*=42).
d, Flow cytometry analysis of HIF1α protein abundance in 4T1 breast cancer cells cultured in 5% oxygen (Ctrl, gray) or 1% oxygen for indicated time points.
e, Chromatin accessibility changes of hypoxic conditions compared to control. Red indicates higher, blue lower accessibility.
f, TF deviation examples of motifs whose accessibility increases in hypoxia over time in 4T1 breast cancer cells**.**

Chang_Figure 3

Supplementary information

Supplementary Figure 1: Development of bulk Pi-ATAC. **a,** Left: Correlation of reads in peaks (log2) of ATAC-seq library replicates of fixed GM12878 cells, which were reverse-crosslinked using the old buffer [1] and then purified. Middle: Correlation of reads in peaks (log2) of ATAC-seq library replicates of fixed GM12878, which were reverse-crosslinked using a new buffer and then purified. Right: Correlation of reads in peaks (log2) of ATAC-seq library replicates of fixed GM12878, which were reverse-crosslinked using the new buffer and then not purified but directly barcoded by PCR, representing the bulk Pi-ATAC workflow; **b,** Comparison across fixed ATAC-seq methods. Left: Scatter plot of fragment quantification in peaks (log2) of fixed GM12878 using the old reverse crosslink buffer vs. new buffer. Middle: Scatter plot of fragment quantification in peaks (log2) of fixed GM12878 using the old reverse crosslink buffer vs. new buffer. Right: Scatter plot of fragment quantification in peaks (log2) of GM12878 using the new reverse crosslink buffer with cleanup vs. new buffer without any cleanup (Pi-ATAC); **c**, UCSC genome browser tracks of ATAC-seq peaks of fixed GM12878 (green), fixed GM12878 with new reverse crosslink buffer (red) and Pi-ATAC GM12878 peaks (blue); **d**, TSS enrichment of fixed ATAC-seq libraries prepared with old reverse crosslink buffer (green), new reverse crosslink buffer (red) and Pi-ATAC (blue) (all GM12878); **e,** ChromHMM profile of the ATAC-seq peak distribution across the genome. Left two columns show old reverse crosslink buffer, middle the new reverse crosslink buffer, right two columns bulk Pi-ATAC data of GM12878 cells (all replicates).

Supplementary Figure 2: Single cell Pi-ATAC of GM12878 cells. **a,** QC of unstained Pi-ATAC GM12878 data: each dot represents a cell, gray cells did not pass the filter of enough fragments and enough proportion of fragments in peaks. 168 of 192 sorted cells (87.5 %) passed the filter and were used for downstream analysis; **b**, Scatter plot of fragment quantification in peaks (log2) of published GM12878 ATAC-seq data to unstained Pi-ATAC GM12878. Correlation was calculated using Pearson correlation coefficient; **c**, Scatter plot of fragment quantification in peaks (log2) of published scATAC-seq GM12878 data to unstained Pi-ATAC GM12878, Pearson correlation coefficient shown; **d,** Scatter plot of transcription factor (TF) accessibility variability of published scATAC-seq GM12878 data to motif variability of unstained Pi-ATAC GM12878 (Pearson correlation coefficient); **e,** FACS density plot of GM12878 cells fixed and stained with CD19 and pNFkB; **f**, QC of stained Pi-ATAC GM12878 data: each dot represents a cell, gray cells did not pass the filter of enough fragments and enough proportion of fragments in peaks. 298 of 384 sorted cells (77.6 %) passed the filter and were used for downstream analysis; **g,** Scatter plot of fragment quantification in peaks (log2) of published scATAC-seq GM12878 data compared to stained Pi-ATAC GM12878, Pearson correlation coefficient shown; **h**, Profile of scATAC-seq peak distribution across the genome. Left: published data, Middle: unstained Pi-ATAC data, Right: stained Pi-ATAC data. All libraries were prepared from GM12878 cells; **i**, Unsupervised hierarchical clustering of the transcription factor accessibility deviations (rows) across stained GM12878 cells (columns). Staining intensity of pNF-kB of each cell is shown by the bargraph above the heatmap.

Supplementary Figure 3: Single cell Pi-ATAC of stained K562 nuclei. **a,** Dot plot and histogram of the index sorted 288 K562 nuclei stained for GATA2. Gates indicate low (15.4%), medium (76.8%) and high (7.49%) staining groups; **b**, QC of stained Pi-ATAC K562 nuclei: each dot represents a cell, gray cells did not pass the filter of enough fragments and enough proportion of fragments in peaks. 223 of 288 sorted cells (77.4%) passed the filter and were used for downstream analysis; **c**, Ranking of TF motif variability of K562 Pi-ATAC data; **d**, Unsupervised hierarchical clustering of the transcription factor accessibility deviations (rows) across stained K562 nuclei (columns). Staining intensity of GATA2 of each cell is shown by the color bar above the heat map; **e**, Pearson correlation coefficients of staining intensity with selected transcription factor accessibility deviations (red dots). Left to right: GATA2, TAL::TCF3, MTF1, TFAP2A. The correlation coefficients corresponding to p-value 0.05 are shown by dotted line (red). 500 times of permutation was processed on cell labels with distribution of correlation coefficient shown as density plot (grey curve), and FDR 5% shown by dotted line (blue).

Supplementary Figure 4: Pi-ATAC of a mixture of 4T1 and Splenocytes. **a,** The histogram represents the protein staining of CD45+ cells (upper panel) and EpCAM+ cells (lower panel) from the 4T1-Splenocytes mixture; **b**, QC of Pi-ATAC of stained 4T1- Splenocytes mixture. 190 of 192 sorted cells (98.95%) passed the filter and were used for downstream analysis.

Supplementary Figure 5: Pi-ATAC of tumor and immune cells isolated from a mouse breast tumor. **a,** FACS gating strategy to collect EpCAM+ and CD45+ cells from the same mouse breast tumor (left two plots) and resulting sorted cells (right plot) **b,**QC of Pi-ATAC of EpCAM - and CD45 positive cells isolated from a tumor. 369 of 384 sorted cells (96.09%) passed the filter and were used for downstream analysis; **c,** UCSC genome browser tracks of Pi-ATAC peaks of CD45+ immune cells (green), and EpCAM+ tumor cells (red) at the *Epcam* (top) and *Cd45* locus (bottom). **d-e**, The number of clusters was determined by average silhouette width with R package "factoextra". The best number of clusters is three for transcription factor motif accessibility (**d**) and seven for cell subgroups (**e**).

Supplementary Figure 6: Mean of the TF motif deviation within the modules and subcellular clusters indicated (see Figure 3d).

Supplementary Figure 7: Pi-ATAC of EpCAM and HIF1α positive tumor cells isolated from a mouse breast tumor. **a**, QC of Pi-ATAC of EpCAM and HIF1α double positive cells isolated from a tumor. 839 of 956 sorted cells (87.76%) passed the filter and were used for downstream analysis; **b**, transcription factor motif ranking variability plot of Pi-ATAC-seq in different staining groups of HIF1α after downsampling to equal cell numbers (100 times of simulation), mean value and standard deviation shown by error bars.

Supplementary Figure 8: Pit1 TF motif deviation across HIF1α staining groups (left) and Atoh8 TF motif deviation across HIF1α staining groups (right). In each comparison, HIF1α negative (*n*=702), HIF1α low (*n*=95), HIF1α high (*n*=42).

Supplementary Figure 9: Standard deviation of HIF motif accessibility deviation in high HIF1α cluster (yellow dot). 10,000 times of down-sampling simulation in low and median HIF1α clusters to the same number of cells as found in the high HIF1α cluster (*n*=42). Density plot of standard deviation distributions of HIF motif deviation re-calculated in simulation is plotted (green and grey curves) to confirm the slight but significant (FDR < 0.04) higher heterogeneity of HIF motif in high HIF1α cluster compared to median and low HIF1α clusters.

Supplementary Figure 10: The summary of the hypoxia time course ATAC-seq from 4T1. **a**, Reproducibility of ATAC-seq from different time points under hypoxic conditions; **b**, Correlation matrix of all ATAC-seq samples across different time points under hypoxia; **c**, PCA plot shows clustering of chromatin accessibility from different time points under hypoxia condition; **d**, transcription factor motif accessibility across different time points under hypoxic conditions analyzed using chromVAR using the CIS-BP motif database (see **Methods**).

Supplementary Figure 11: Pit1 TF motif accessibility deviation across HIF1α staining groups (left) and Atoh8 TF motif accessibility deviation across HIF1α staining groups (right) in 4T1 cells.

Supplementary Tables:

Supplementary Table 1: List of the TF motif variability of the EpCAM+ and CD45+ cells isolated from a mouse tumor calculated by chromVAR.

Supplementary Table 2: List of the significant variable motifs and their module assignment from the EpCAM+ and CD45+ cells isolated from a mouse tumor.

Supplementary Table 3: List of the 755 significant (p-value < 0.05, B.H.) TF motif variability of the 4T1 cells across a hypoxia time course (calculated by chromVAR).

Supplementary Table 4: List of the TF motif variability of EpCAM+ and HIF1α+ cells isolated from a mouse tumor, calculated by chromVAR.
