Abstract

Understanding the movement patterns of animals across different spatio-temporal scales, conditions, habitats and contexts is becoming increasingly important for addressing a series of questions in animal behaviour studies, such as mapping of migration routes, evaluating resource use, modelling epidemic spreading in a population, developing strategies for animal conservation as well as understanding several emerging patterns related to feeding, growth and reproduction. In recent times, information theory has been successfully applied in several fields of science, in particular for understanding the dynamics of complex systems and characterizing adaptive social systems, such as dynamics of entities as individuals and as part of groups.

In this paper, we describe a series of non-parametric information-theoretic measures that can be used to derive new insights about animal behaviour with a specific focus on movement patterns. We show how these measures can be used to characterize the movement patterns of several animals across different habitats and scales. Specifically, we show the effectiveness in using Shannon entropy to characterize the movement of sheep with Batten disease, mutual information to measure association in pigeons, Kullback Leibler divergence to study the flights of Turkey vulture and, Kolmogorov complexity to find similarities in the movement patterns of animals across different scales and habitats. Finally, we discuss the limitations of these methods and we outline the challenges in this research area.

Introduction

Information theory has always played an important role in biology [23] [53]. It is a field that is devoted to studying the storage, communication and quantification of information founded by Claude E. Shannon in his influential paper [52] and lies at the interface of mathematics, statistics, computer science and electrical engineering. While initial research in this field was mainly theoretical, we have witnessed a plethora of practical applications in the past decades. For example, concepts and techniques from this field have been used in several fields such as neurobiology [48], pattern recognition [15], cryptology [58], bioinformatics [43], quantum computing [38], complex systems [36] [40] with significant success.

Recently, due to technological advances, low cost miniaturized sensors have been increasingly adopted for tracking the behaviour of animals across different scales and habitats. These sensors include but not limited to Global Positioning System (GPS) technology, accelerometers and radio-frequency identification (RFID) tags. This has led to the explosion in the deployment of these sensors in different habitats across scales

by animal behaviour researchers. A natural consequence of this development is that it is now possible to try to quantify and understand a variety of aspects related to animal behaviour such as migration patterns and routes, feeding, reproduction and mating patterns, conservation, monitoring of endangered species, epidemic spreading, resource use, social behaviour and association. In the field of animal behaviour, GPS, accelerometers and cameras are the predominant sensors deployed to measure several behavioural properties of animals. We limit our discussion here to GPS sensors due to their ability to be deployed in the wild as well as their popularity relative to other sensors. Previously, GPS sensors have been used to study selfish herd behaviour of sheep under threat [32], the hierarchical structures of group dynamics in flocks of pigeons [41], migration patterns in vultures [39], productivity in cows [10], and social relationships in birds [45] just to name a few.

We believe that information-theoretic approaches can provide *complementary* insights in the study of animal behaviour. In other words, these approaches do not replace the existing ones, but they are able to provide additional information about animal behaviour patterns, especially in terms of movement, which are not apparent using other types of analysis. Probabilistic approaches are also usually more robust in presence of noise, a common feature of sensor data. The number of applications of concepts and techniques from information theory to analysis of animal movement in the literature is limited. However, information-theoretic metrics have been used in the past for example to study information flow in animal-robot interactions [12] as well as predator-prey relationships [42] [28] in animals.

In this paper, we discuss how four information theoretic metrics, namely entropy, mutual information, Kullback-Leibler divergence and Kolmogorov complexity (normalized compression distance) can be effectively applied to the study of animal movement. In other words, we explore how they can be used as tools for studying animal movement data. Indeed, the goal of this work is not to introduce new metrics, but to demonstrate the potential in using information theoretic concepts to understand animal behaviour. We introduce each metric separately and then we discuss how each metric can be applied to a practical problem, by discussing a case study in details. More specifically, we demonstrate how these metrics can be used to characterize the movement patterns of animals across different scales and habitats. It is worth noting that these methods do not provide new ground-truth information, but they allow for identifying emergent patterns and formulating hypotheses that can be verified for example by means of further experimental observations in the field. The case studies are mostly based on datasets from the Movebank database [63].

The rest of the paper is organized as follows. In Section 1, we describe the Shannon entropy and demonstrate how it can be used to characterize the movement patterns of sheep with neurodegenerative disease. In Section 2, we describe the notion of mutual information and show how it can be used to measure association as well as reconstruct the flight dynamics in pigeons. We describe the Kullback-Leibler divergence in Section 3 and show how it can be used to characterize the annual movement patterns of the Turkey Vulture. In Section 4, we describe the Kolmogorov Complexity (normalized compression distance) and demonstrate how it can be used to find relationships in animal movement patterns across scales and habitats. We conclude our work by highlighting the challenges and a summary of the methods described in this work.

1 Shannon Entropy

1.1 Overview

The information content of a random variable is defined by the Shannon entropy as a measure that quantifies the level of uncertainty embedded in such variable. In the case of animal movement, Shannon entropy provides a useful quantification of the level of regularity and predictability of the movement of an animal.

More formally, it can be defined as the uncertainty associated with a random variable X with realization x, which can be described by the following equation:

$$H(x) = -\sum_x p(x) \ log \ p(x) \tag{1}$$

where $p(x)$ is the probability density function and the summation is taken over all possible realizations of X. The base of the logarithm is not important and can take any value, provided the same base is used throughout the analysis.

Most of the information theoretic measures that exist today, some of which we will discuss below, are derived from Shannon entropy. However, there are other several definitions of entropy such as Renyi entropy [46] and Tsallis entropy [57]. The discussion of these metrics is outside the scope of the present article.

Due to the noisy nature of most datasets, probabilistic metrics are becoming increasingly useful for modelling not only animal movement data but in general real world datasets to account for any form of uncertainty inherent in datasets of this nature such as missing data. Therefore, entropy can be used for assessing the overall welfare and well-being of animals instead of a metric like distance travelled. Most animals are known to have an activity-rest pattern except under highly unfavourable conditions or when they have some sort of impairment in their general well-being. This implies that animals are supposed to have a relatively high entropy except for the period of harsh conditions when they are either aestivating or hibernating. In this light therefore, entropy can be used to characterize the movement patterns of animals so as to assess the state of their health. In addition, it can also be used in lieu of tortuosity to describe how tortuous an animal's path is using the turn angle as the input. The conditional entropy is an important element of the conditional mutual information and can be used for example in understanding swarm behaviour [37].

In the following subsection, we will consider a case study illustrating a possible application of Shannon entropy to the study of animal behaviour and, more specifically, to the characterization of the movement patterns of sheep with neurodegenerative diseases.

1.2 Case study: Shannon entropy as a tool for characterizing movement patterns of sheep with neurodegenerative disease

Investigating for abnormal locomotion patterns is essential towards early diagnosis of a number of neurodegenerative diseases such as Batten disease in animals. Sheep with neurodegenerative diseases such as Batten disease are known to get stuck in a behaviour (movement inclusive) over time due to gradual loss of motor skills [47] and social awareness [34]. Here, we use Shannon entropy to characterize the movement patterns of a flock of sheep comprising sheep with a natural mutation for Batten disease and their age matched control (mean age of 2 years) group using the dataset of [22]. We use the trajectory of each sheep sampled every second and compute the distance covered every ten minutes over eleven hours (20:00-7:00) each day for a total period of six days. The choice of time window is to minimize the influence of external environmental noise in the dataset while ten minutes was chosen as it is a long period enough to

observe the behaviour of these sheep. We further bin the resulting distance calculated so as to assign the symbols. To bin the data, we use the head/tail classification rule by [29] resulting in 12 bins, considering we are working with a skewed distribution. We compute the entropy for each sheep (see Table 1 in supplementary material) as well as the mean entropy (Figure 1a) for the two groups of sheep. Our results show that the Batten sheep on the average have a lower entropy than the normal sheep with p-values (0.0076, 0.1042, 0.2628, 0.0065, 0.0234, 0.0205) across the six days respectively. The potential impact of uncontrollable environmental variables such as unfavourable weather conditions is significant and may influence the behaviour of the sheep especially because the experiment was carried out in an open field. Therefore, the result should be interpreted with caution. We compare the entropy of the two groups of sheep with their respective average distance covered in (Figure 1b) and its mean variance (Figure 1c). The Batten sheep can be seen to have covered, on average, a longer distance over the period of observation.

2 Mutual Information

2.1 Overview

We now describe another information theoretic measure intimately linked to entropy, called mutual information [51]. The mutual information of two random variables X and Y defines the mutual influence one variable has over the other. Specifically, it quantifies the amount of information in one variable embedded in the other. For this reason, mutual information can be used as a measure of association or social-grouping, for example in the characterization of leader-follower relationship, group coordination and, more generally, collective behaviour [56].This can be further used to build a social network [33] as opposed to the gambit of the group approach widely used in the animal behaviour modeling community.

Mutual information is similar to the correlation coefficient. However, mutual information also captures non-linear relationships between two variables. More formally, the mutual information of two discrete random variables X and Y, with realizations x and y respectively, is given by:

$$I(X;Y) = \sum_y \sum_x p(x,y) \, log \, \frac{p(x,y)}{p(x)p(y)} \tag{2}$$

In this, $p(x)$ and $p(y)$ are the marginal probability distribution functions of X and Y respectively and $p(x,y)$ is the joint probability distribution function of X and Y.

In the case of continuous random variables we have:

$$I(X;Y) = \int_Y \int_X p(x,y) \, log \, \frac{p(x,y)}{p(x)p(y)} \tag{3}$$

Here the summation for the case of discrete distribution functions has been replaced by a double integral. Mutual information is non-negative, i.e., $I(X;Y) \geq 0$ and only zero only when X and Y are completely independent, making $p(x,y) = p(x)p(y)$ and thus $log \dfrac{p(x,y)}{p(x)p(y)} = log(1) = 0$. It is also symmetric: $I(X;Y) = I(Y;X)$. As mentioned earlier, other information theoretic measures are derived from entropy. The mutual information can be written as a function of entropy as follows:

$$\begin{aligned} I(X;Y) &\equiv H(X) - H(X|Y) \\ &\equiv H(Y) - H(Y|X) \end{aligned} \tag{4}$$

$H(X|Y)$ and $H(Y|X)$ represent conditional entropies and $H(X)$ and $H(Y)$ the marginal entropies.

We now consider a potential application of mutual information, in its application to the study of association in pigeons.

2.2 Case study: Mutual information for measuring association and leadership in pigeons

As mentioned earlier, the de-facto method used in the animal behaviour community for measuring association is the gambit of the group otherwise known as co-location [21]. To detect significant association and weed out any form of co-location by chance, a permutation test is carried out [20]. However, there is no well defined method for choosing the appropriate radius to define co-location. Also, the directional correlation delay time method used by [41] in reconstructing pigeon flight network structure can only detect linear relationships leaving the non-linear relationships undetected. Previously, [13] used transfer entropy to infer leadership in Zebrafish, we state here that its our aim to detect association using a bidirected graph and not a directed graph where information flow and its direction is of utmost importance. In addition, transfer entropy may not be exceptionally better than mutual information in instances where the agents are constantly changing positions relative to one another [50].

We demonstrate how Mutual Information can be used to overcome the limitations associated with the methods above by using it to measure association between pigeons in flight. We use the dataset of [50] [59] and picked flight 8 as the result was discussed in the literature in detail. We compute, the time-series of the turn angle of each bird followed by the pairwise mutual information of these time series of the nine birds involved in the flight to obtain a distance matrix (see Table 2 in supplementary material). As expected, there will always be some measure of association between all the birds in the flight, we use a randomization test to determine a threshold for significant pairwise mutual information (see supplementary material). We further build a social network (Figure 2a) to visualize the flight formation. Our result is consistent with two previous studies on pigeon flight. First, we observe that pigeons do have a hierarchical formation when in flight as seen in (Figure 2a). This is a result consistent with the observations in [41]. Also, we were also able to detect the leader as node M during the flight which is the node M with one edge. This result is also consistent with the ground truth in the literature [50]. In addition, while it is obvious from the flight network there is only one leader, who is followed directly by only one bird node S, it is not clear from our analysis whom the other seven birds are following. Since bird S appears to be connected to all birds in the network including the leader and the remaining seven birds seems to have at least 5 other connections, we are of the opinion others may be adopting a nearest neighbor approach in deciding whom to follow or just simply following bird S. We compare this approach with three other methods: correlation coefficient, transfer entropy and Granger causality (Figure 2). While it is not straightforward to compare the performance of the four methods, one basis for comparison is concerns leadership. mutual information is able to identify the leader from the flock better than other methods and is followed by the correlation coefficient. With transfer entropy and Granger causality, its not clear exactly which of the birds is the leader. We attribute the poor performance of the transfer entropy and Granger causality to the continuous change in positions of the birds when flying.

3 Kullback-Leibler divergence

3.1 Overview

Kullback-Leibler divergence (KLD) also known as relative entropy measures the distance between two probability distributions. Essentially, it measures the information loss while substituting a probability distribution for another giving a lower score to two distributions with the same behaviour and a higher score if they have an extremely different behaviour.

In animal movement modelling, KLD can be used to quantify changes in behaviour of an individual animal or discrepancies in behaviour in a group. For discrete probability distributions P and Q, KLD is defined as follows:

$$
\begin{aligned}
D_{Kullback-Leibler}(P||Q) &= \sum P(x) \ log \ \frac{P(x)}{Q(x)} \\
&= \sum P(x) \ log \ P(x) - \sum P(x) \ log \ Q(x) \\
&= H(P) - H(P,Q)
\end{aligned}
\tag{5}
$$

where $H(P,Q)$ is the joint entropy between P and Q and $H(P)$ the entropy of P. For continuous probability distributions P and Q, KLD is given by:

$$
D_{Kullback-Leibler}(P||Q) = \int_{-\infty}^{+\infty} P(x) \ log \ \frac{P(x)}{Q(x)} dx
\tag{6}
$$

KLD is asymmetric, i.e.:

$$
D_{Kullback-Leibler}(P||Q) \neq D_{Kullback-Leibler}(Q||P)
\tag{7}
$$

However, there is a symmetric version which is given by:

$$
D_{Kullback-Leibler}(P||Q) + D_{Kullback-Leibler}(Q||P)
\tag{8}
$$

There are many applications of KLD can be many. For example, it can be used for detecting behavioural change points and modes such as foraging, resting and travelling in animals by constructing a sliding window that moves across a time series while computing the KLD of the probability distributions of contiguous windows. This has implications for example in determining regime shifts, most especially for animals who move in non-homogeneous ways. In addition, it can also be used in identifying points of change in landscape for animals who travel long distances over a heterogeneous landscape that affects their behavioural states. KLD also has applications in determining activity-rest patterns in animals. The KLD can also be used to evaluate the impact of environmental variables on the behaviour of animals by comparing the changes observed using only behavioural data together with the joint density function of behavioural data and environmental data.

Another potential application is the use of Kullback-Leibler divergence for monitoring of the health of animals that co-exist in groups. This can be achieved by computing the pairwise Kullback-Leibler divergence between the probability distribution of movement data of all animals in the group while seeking animals with a significant divergence from the remaining members of the group. This approach, when integrated with appropriate machine learning tools such as hierarchical clustering, can be used to classify animals into healthy and non-healthy or automatic classification of animals into species.

3.2 Case study: Kullback-Leibler divergence reveals Turkey Vulture has predictable annual movement patterns

Previously, KLD has been used by [30] to measure the divergence from the equilibrium behaviour of the blue tuna fish after a telemetry device was attached to it. In our own case, we use KLD to describe the movement patterns of the Turkey Vulture. The Turkey Vulture, according to [18], is the world's most abundant and widely distributed avian scavenger with a population in excess of five million individuals. We characterize the movement patterns of the Turkey Vulture (*Cathartes aura*) [18] [8] across several years by comparing how the movement patterns at the beginning of the year (January) vary relative to the remaining months of the year across the next three years. The bird by name Leo was chosen as it possesses a movement dataset that spans several years. We compute the Kullback-Leibler divergence (symmetric version) across several years and our results (Figure 3) show that the movement strategy of this bird is highly predictable. We observe from Figure 3 that the Kullback-Leibler divergence across three years is full of peaks and troughs (migratory season). The peaks represent the movement back to the breeding sites as well as the breeding season when there are little movement activities in the temperate regions of America while the troughs represent the migrating period when the birds migrate to tropical regions in search of food. It is a known fact that these specie of birds start breeding in the temperate regions such as North and South America where they have abundance of food during the spring and this breeding continue until the onset of fall. Once fall starts and winter starts to set in, these birds migrate to tropical regions where it is warmer and there is abundance of rain and food all throughout the year. However, at the onset of spring around march, these birds migrate back to the temperate regions of America where they are guaranteed abundant food and resources although some do stay back in the tropics. We compare the KL divergence with the mean difference as well as the Earth Mover's Distance (EMD) of the monthly movement data of interest. The EMD appears to do as much as the same job KL divergence is doing even though the peaks are sharper. We also compare how the movement patterns in other months of the year (February to December) vary relative to the remainder of the dataset over three years. Results, (Figure 4) show the bird have different movement patterns in the months between June and September relative to other months of the year, which is essentially its breeding season [1]. Overall, from the analysis above, it can be seen that the bird have three different annual movement patterns spread between (a) October to March when it is searching for food away from its breeding ground (troughs in Figure 3) (b) April to June when its flying back to its breeding ground (first half of the peaks in Figure 3) and (c) June to September when it is actually breeding (second half of the peaks Figure 3).

4 Kolmogorov Complexity

4.1 Overview

As a last measure we describe a similarity metric influenced by Kolmogorov complexity (KC), a metric with foundations in the field of algorithmic information theory. The Kolmogorov complexity of an object represents the shortest computer program that produces the object as output. More formally, the KC of a string x with respect to a reference machine U is defined by [25] as:

$$\min_{z}\{\{l(z) : U(z) = x, z \in \{0,1\}^*\}\tag{9}$$

---

[1] http://eol.org/pages/1049010/details.

Where z is a program that prints string x and then halts and l is the length. The concept of Kolmogorov complexity can be used as an inference tool to find the shortest description of behavioural data. The smaller the KC of a sequence the regular or simple it is and vice-versa. To find similarities in a heterogeneous dataset, we describe the Normalized Information Distance (NID) [61], a similarity measure influenced by Kolmogorov complexity and defined as:

$$NID(x,y) = \frac{max \; \{K(x|y), K(y|x)\}}{max \; \{K(x), K(y)\}} \tag{10}$$

Due to the non-computability of the NID, the NID has been re-written [16] as the normalized compression distance (NCD) by simply approximating the Kolmogorov complexity K, using a compressor Z. The NCD between two strings x and y can be defined as:

$$NCD(x,y) = \frac{Z(xy) - min \; \{Z(x), Z(y)\}}{max \; \{Z(x), Z(y)\}} \tag{11}$$

Here xy is the concatenated together. These strings can be documents, software, genomes or even images. The NCD takes on non-negative values in the range $0 \leq r \leq 1 + \epsilon$ with ϵ defined to account for imperfections in the compression methods see [16] for more details.

The NCD has been used in a variety of disciplines for different purposes such as anomaly detection [31], gene expression dynamics [43], classification of music [14], classifying computer worms and viruses and detecting the origin of new ones [62]. Since the NCD has been shown to work well with sequences and strings, it can be used, for example, in monitoring the behaviour of animals to know when they deviate from a previously or commonly known sequence of states for example by virtue of climate change [27]. It can also be used to find similarity in movement patterns of conspecifics across different habitats.

4.2 Case study: Kolmogorov complexity as tool for classifying animal movement patterns across scales

Animals across different habitats, scales, and species are known to have different movement patterns. However, little or no study has been carried out to find out which groups of animals possess similar movement strategies across different habitats and scales. Recently, [2] attempted to classify several animals across different species into similar groups using principal component analysis on some movement metrics with hierarchical clustering. Their result suggests that all animals organize into four distinct groups of movement syndromes namely migratory, central place, nomadic and territorial. In this study, we observe the movement patterns of eleven animals (Table 1) across different spatio-temporal scales and habitats. For our study, we obtain the datasets of the Galapagos tortoise (*Geochelone nigra*) [9] [1], Springbok (*Antidorcas marsupialis*) [3] [1], African buffalo (*Syncerus caffer*) [4] [17] [24] [1], African elephant (*Loxodonta africana*)(original unpublished data contributed by Miriam Tsalyuk and Wayne M Getz) [1], Black-backed jackal (*Canis mesomelas*) [7] [1], California sea lion (*Zalophus californianus*) (original unpublished data contributed by Dan Costa) [2] [1], Galapagos albatross (*Phoebastria irrorata*) [19], Sheep and Sheepdog (*Ovies aries*) [60] [59], Northern elephant seal (*Mirounga angustirostris*) [49] [1], White-backed vulture (*Gyps africanus*) [54] [55] [1] and Burchell's Zebra (*Equus burchellii*) [5] [6]. All these datasets use the same 1 hour sampling period [2]. First we compare the monthly movement patterns of all the 85 animals to find similarities by computing their pairwise NCD with the gzip compressor followed by hierarchical clustering of the resulting distance matrix (see supplementary

material for details). The only metric used here is distance covered every hour, which we further processed to its binary equivalent (strings of zeroes and ones). We refrained from using the turn-angle here as it is an unreliable metric considering the noisy nature of most sensors. Our results (Figure 5) show that animals organize into three groups of those that live on land (zebra, elephant, springbok, jackal, sheep and buffalo), those that live in water (tortoise, sea lion and elephant seal) and those that fly (albatross and vulture). Amongst the animals that live on land, we notice there appears to be some similarity between the movement patterns of the elephant and zebra while others seem to organize into distinct groups of conspecifics. Therefore, we hypothesize that there might be a correlation between the feeding and movement patterns of animals. We observe a small number of unexpected classifications: for example, Vulture V_1 was classified among the animals that live in water. This might be due to noisy data, or possibly, limitations of the proposed approach. To find long-term similarities among animals movement patterns we compare approximately one year movement data of 16 animals (Table 1) across six different species being the only long-term animal movement datasets we could obtain. Results (Figure 6) show that there might be some similarities in the long-term movement patterns of vultures and jackals which are both scavengers. This supports a hypothesis that there might be a correlation in the movement patterns of animals with similar feeding habits. The rest of the animals organize into groups of tortoises and those that live on the land (zebra, elephant and springbok). We compare this approach with the pairwise mutual information of the distance covered with respect to the two instances discussed above (see Figures 1 and 2 in supplementary material). The classification produced by the NCD can be seen to be more meaningful relative to the mutual information.

5   Challenges And Limitations

While we have highlighted the potential use of information theoretic metrics in obtaining insights about animal movement and also show the applications of these metrics to real animal movement data, we would like to underline that these methods should be applied with caution given their inherent limitations. First, the issue of missing data remains a challenging problem due to logger failure thereby hindering researchers from obtaining maximum insight from the dataset they study using these tools. For this reason, when using the methods described above, it is worthwhile to make provision for the presence of missing data during the analysis process. In addition, it suffices to state here that care must be taken while choosing the appropriate amount of data from which inference can be made. For example, let us consider the analysis of the similarities of the complexities of animals across different taxa and spatio-temporal scales. We saw a similarity only in the long-term movement patterns of jackals and vultures. This phenomenon might not have been observed if datasets of shorter length had been used.

We issue a caveat on estimating probability density functions (PDF) of continuous movement data. At the moment, most of the methods and tools available are based on the assumption of underlying normal distributions. Considering that continuous animal movement data often follows skewed (e.g., power-law or truncated power-law) distributions [26] [11], researchers employing some of the methods described here, for example the Kullback-Leibler divergence, should exercise appropriate caution while estimating the PDF of very skewed distributions. In our case, we took special precaution while computing the probability distribution for entropy by binning the data around several mean values of the data in the direction of skewness. In other cases, we did not take any special precautions: for example, the distribution for the turn angle of the pigeons is Gaussian. For simplicity, we approximate the Turkey Vulture movement data distribution as Gaussian as the volume of the monthly data is small. There are however

estimators that makes use of k-nearest-neighbour density estimation [44] methods to compute some of the metrics we have discussed here such as KL divergence and also, one potential approach to solving this problem could be to model these skewed distributions as a mixture of Gaussians.

Furthermore, appropriate methods for permutation and randomization must be used while determining a threshold, for example for the calculation of the pairwise mutual information between animals in a group. Finally, we cannot stress enough the importance of using the appropriate volume of data as most information-theoretic measures involve estimation which is essentially a data hungry process.

6 Conclusion

We have demonstrated the use of a class of non-parametric information theoretic tools for studying movement patterns of animals and have showed how they can be used with several animal movement datasets. First, we demonstrate how Shannon entropy can be used to characterize the movement patterns of sheep with Batten disease where the distance covered every ten minutes was used as the basis for generating symbols to compute the entropy. The result shows that the Batten sheep have a lower entropy than their control counterparts. Also, we describe the use of mutual information for detecting associations in animals using pigeons as an example. Our findings show that this method can be very useful in lieu of the widely used gambit of the group approach as we were able to implicitly detect the leader from the flight data. We have showed how the Kullback-Leibler divergence can be used to characterize the movement patterns of the Turkey Vulture. From our results we were able to see that the movement patterns of this bird is highly predictable over several years. Lastly, we describe a metric with foundations in the field of algorithmic information theory known as Kolmogorov complexity (normalized compression distance). We used this metric to characterize the movement patterns of animals across different taxa and spatio-temporal scales with results suggesting there might be a correlation between the feeding and movement patterns of animals. These methods provide *complementary* insights in the study of animal behaviour. In other words, they provide additional information about animal movement that are not apparent using other types of analysis. This class of probabilistic methods are also usually more robust in presence of noise, which is inherent in location data.

As part of our future research agenda, we plan to explore more movement datasets as they become publicly available and possibly other types of behavioural datasets, for example from accelerometers, in order to show further how these information theoretic metrics can be used to obtain novel insights about the behaviour of animals in their natural habitats.

Author Contributions

All the authors designed the study, performed the analysis of the data, and wrote the manuscript. KA carried out the experiments.

Tables & Figures

Species	No of individuals	Habitat	Feeding strategy
African buffalo (B)	5	Land	Herbivore
African elephant (E)	5(3)	Land	Herbivore
Black-backed jackal (J)	11	Land	Scavengers
Burchell's zebra (Z)	2(2)	Land	Herbivore
California sea lion (sl)	15	Water	Piscivore
Galapagos albatross (A)	8	Land/Air	Piscivore
Galapagos tortoise (T)	7(4)	Land/Water	Piscivore/Herbivore
N. elephant seal (SE)	14	Water	Piscivore
Sheep & Sheep-dog (SD)	5	Land	Herbivore
Springbok (Sp)	9(1)	Land	Herbivore
White-blacked vulture (V)	4(2)	Land/Air	Scavengers

Table 1. Summary of 85 individuals within 11 species. The code in front of the species represents the label codes used for each animals in the hierarchical clustering while the number in the bracket under the no of individuals represents the number of animals with up to one year of observational data.
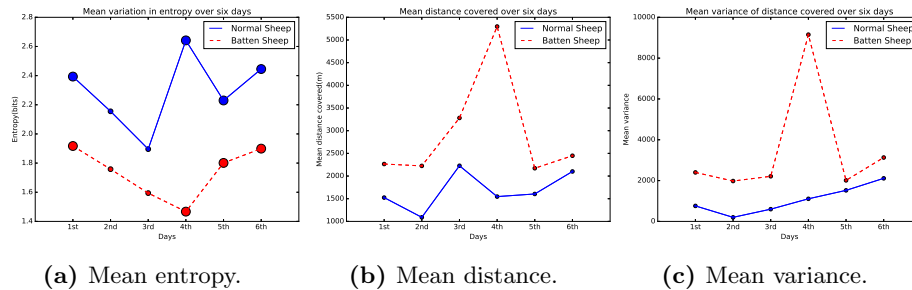

(a) Mean entropy.   **(b)** Mean distance.   **(c)** Mean variance.

Figure 1. (a) Mean entropy of the two groups of sheep across 6 days where the larger circles represent days when the mean difference in entropy are statistically significant. The sheep affected by Batten disease can be seen to have a lower entropy due to the tendency to repeat the same behaviour over a long period of time (b) Mean distance covered by the two groups of sheep (c) Corresponding variance of the mean distance covered.

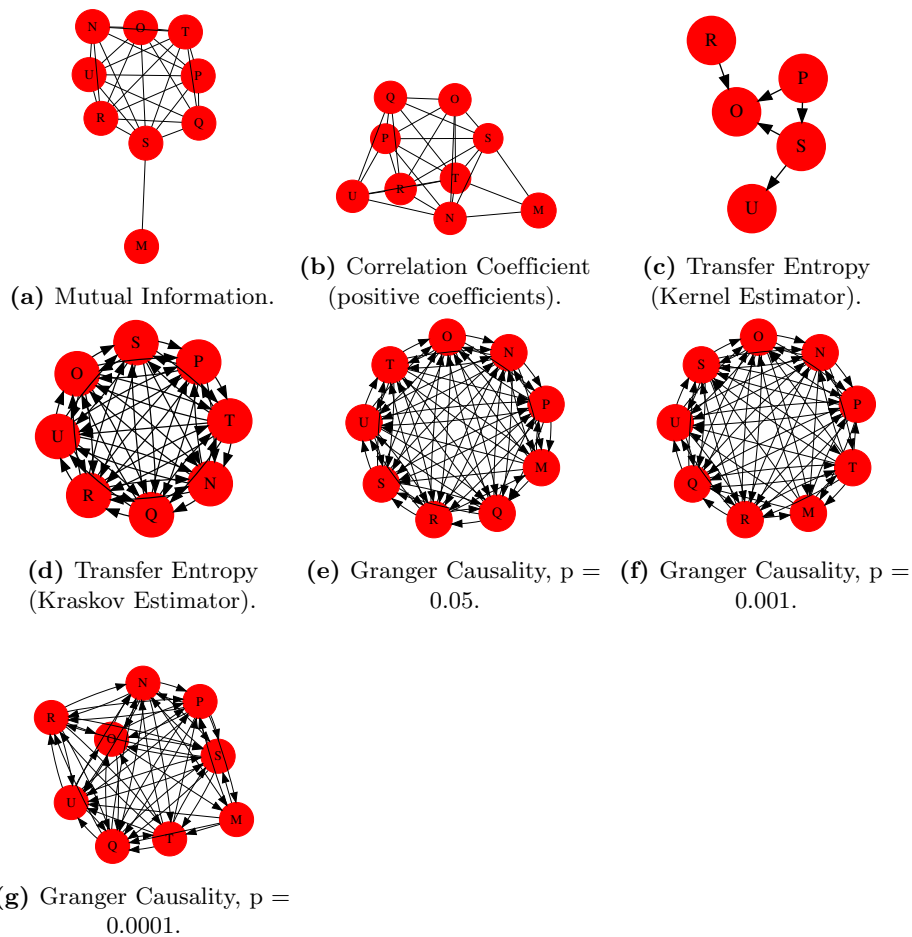

(a) Mutual Information.

(b) Correlation Coefficient (positive coefficients).

(c) Transfer Entropy (Kernel Estimator).

(d) Transfer Entropy (Kraskov Estimator).

(e) Granger Causality, p = 0.05.

(f) Granger Causality, p = 0.001.

(g) Granger Causality, p = 0.0001.

Figure 2. Flight dynamics of homing pigeons characterized by (a) Mutual Information (b) Correlation Coefficient (c) Transfer entropy (Kernel estimator) [35] (d) Transfer entropy (Kraskov estimator) [35] (e) Granger Causality (p-value = 0.05) (f) Granger Causality (p-value = 0.001) (g) Granger Causality (p-value = 0.0001). The tables presenting the pair-wise values can be found in the supplementary material.
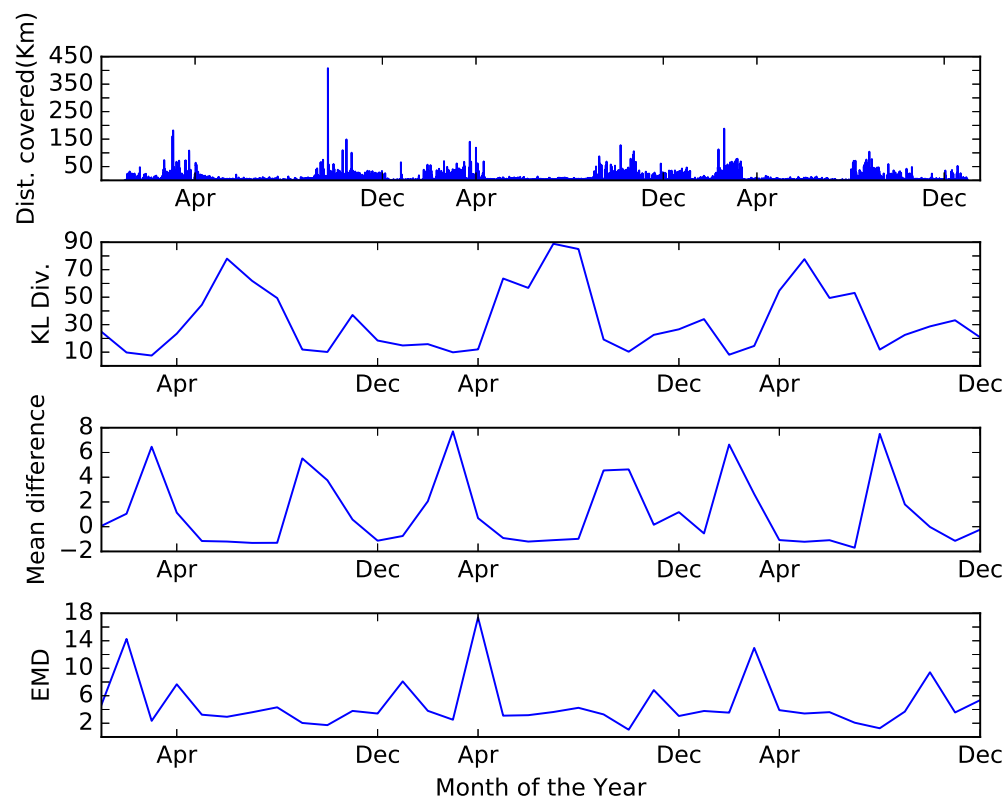

Figure 3. Kullback-Leibler divergence of the monthly movement pattern over a period of 3 years. The peaks represent the annual period of breeding as well as the flight back home after winter and the troughs, migratory period during which the bird travels in search of food. We compare the KL divergence with the mean difference and the Earth Movers Distance (EMD).
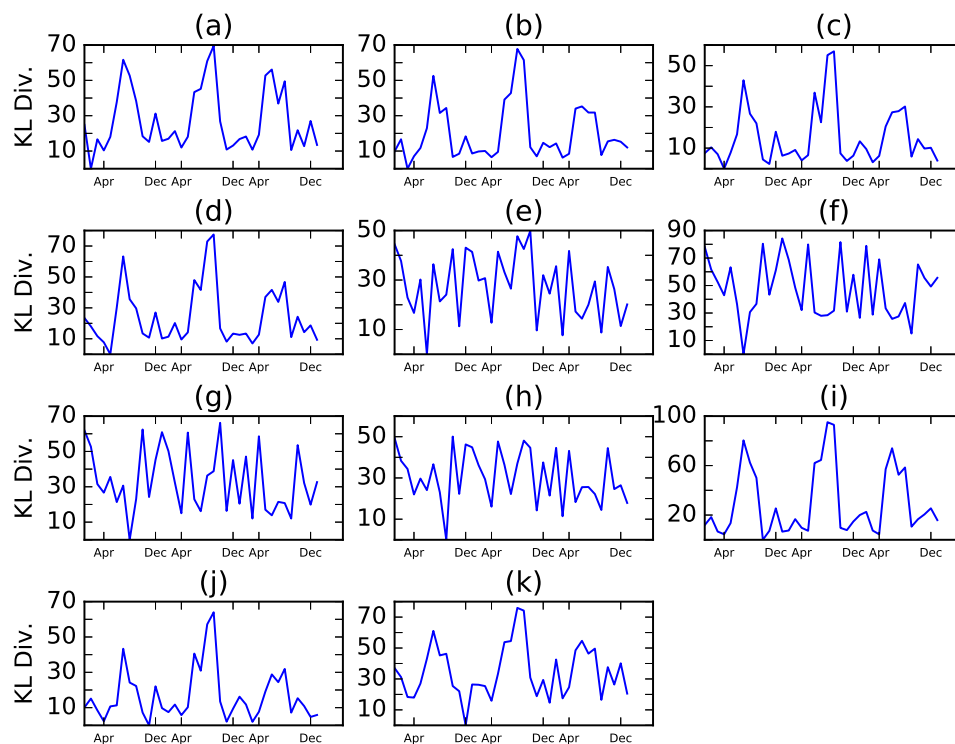

Figure 4. Kullback-Leibler divergence of the monthly movement pattern over a period of 3 years where the reference month is (a) February (b) March (c) April (d) May (e) June (f) July (g) August (h) September (i) October (j) November (k) December. From the result, it can be seen that the movement pattern during January, February, March, April, May, October, November and December are the same while the bird exhibits a different pattern in June, July, August and September. This suggests that the breeding season of this bird is between June and September. The result is consistent with the information about Turkey Vulture in North America as they lay their eggs between May and June, incubate them for between 38 and 41 days and when the eggs hatch. The hatchlings are further brooded for a period between 70 and 80 days resulting in between 108 and 121 days of breeding, which is equivalent to four months of breeding.
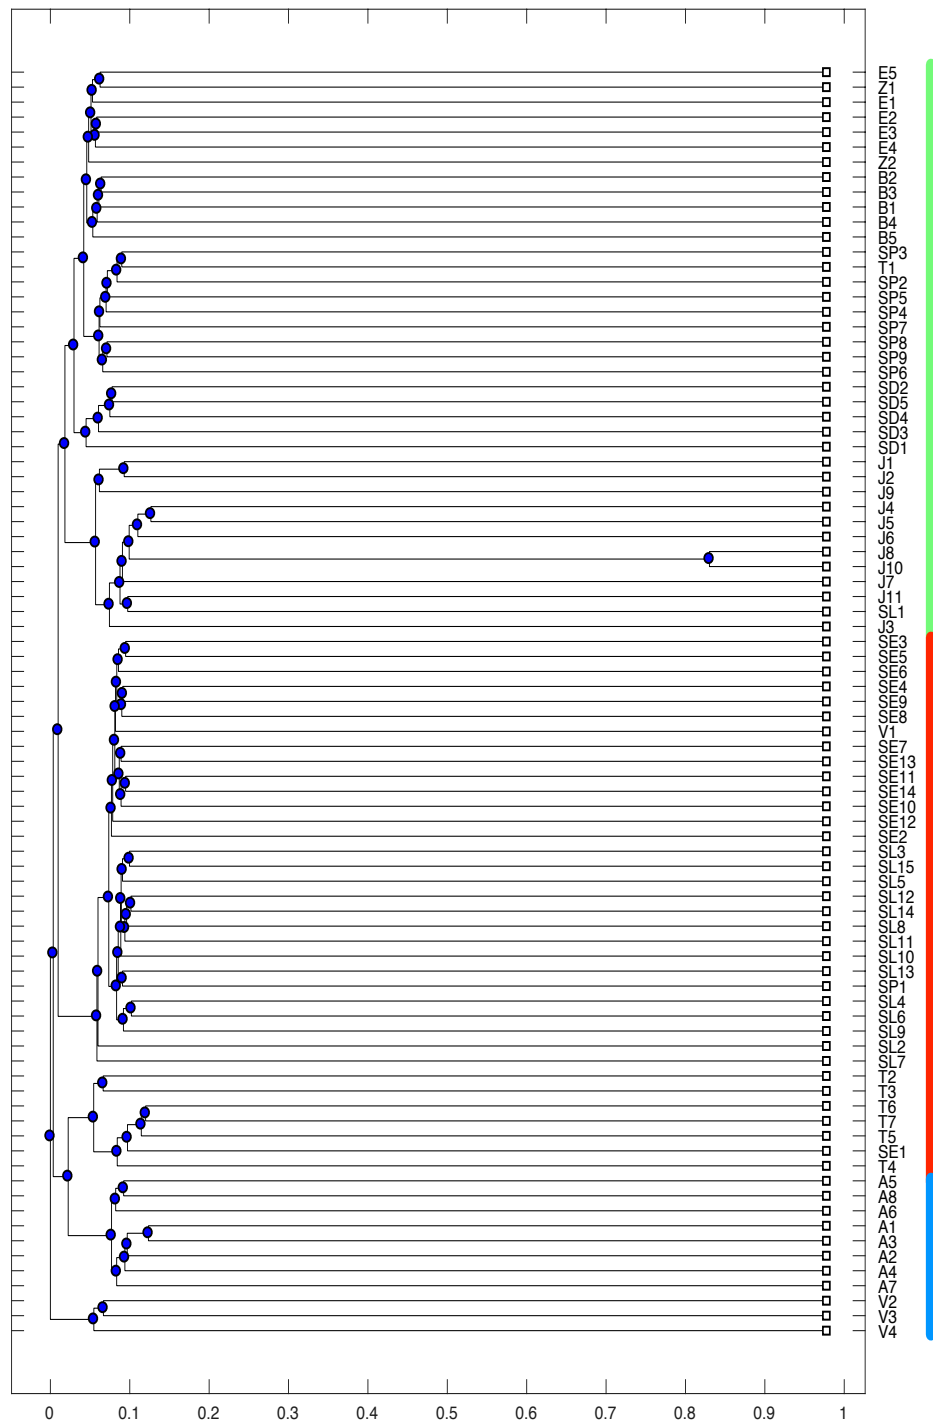

Figure 5. Hierarchical clustering of the pairwise NCD of 85 animals spread across 11 species. All the animals on the average organizes into three groups of those that live on land (green), those that live in water (red) as well as those who fly (blue).
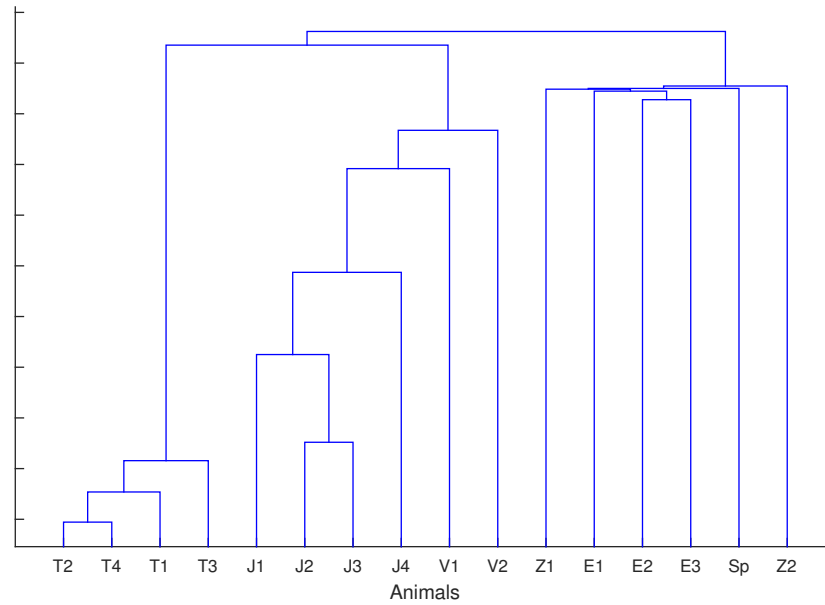

Figure 6. Hierarchical clustering of the pairwise NCD of 16 animals spread across 6 species representing the movement patterns over a period of one year. The animals organize into three distinct groups that are correlated with their feeding patterns.
